It may be said, in the first place, that the question was not discussed solely on its own merits. We have alluded to the introduction of a disturbing element; and this took the shape of a counter proposal to devote the unexpected subsidy to furthering the schemes which the County Council has in hand for the housing of the working classes, the purchase of open spaces, and similar efforts to ameliorate the condition of the London poor. This, it must be admitted, was a highly-flavoured red-herring to trail across the path of the technical educationists; and it does not surprise us that in an assembly of barely one hundred representatives of metropolitan populations, fifty darted hotly on the opposite scent. The more influential, and certainly the ablest of the members present, voted in the minority of 45, and they may hope to muster a majority on their side very soon if they are really in earnest. So far as the two proposals are concerned, there is a good deal to be said for both, and for one perhaps as much as for the other. Both objects are most desirable in themselves; both are attainable by the expenditure of money, and from both may beneficial results be confidently predicted. But, whereas the prospective results of technical education have to be argued, and to some extent conjectured, those from the improved habitations and general condition of the poor are demonstrable certainties which nobody ventures to dispute. This fact was betrayed in the conduct of last week's discussion at the London County Council, where not a word was spoken either in support or in opposition to the amendment, its merits being accepted as beyond cavil, the only question open being whether its claims to attention were superior to or more urgent than those of the technical education of our artisans. The minority thought, perhaps, that as the poor are always with us, there is no fear of them slipping out of the sphere of benevolent activity; whilst in respect to the technics of manufacture and commerce, the object to be attained by their cultivation may slip from our reach beyond recall if not seized betimes and securely held. Perhaps, too, the urgency for technical education is not so deeply felt in the metropolis as it is in the great industrial centres of the provinces, where local prosperity depends upon the pre-eminence of the English operative, and where the opposing claims of industrial dwellings, if quite as deserving, are not so attractive as in London. Be this as it may, however, the friends of the London working classes have scored a point against the friends of national industry, without any argument at all.

But having thus satisfied their consciences, it is not improbable that when the question of disposing of the money has to be seriously considered, the problem of investing it to secure the best results will prove as hard of solution and as uncertain in its operations as any investment in technical education would have been. From the general tone of the debate, indeed, we may augur that money will be forthcoming in due course for both these commendable objects. For although, as we have observed, nothing was said against ameliorating the condition of the working classes, neither was anything said against technical instruction. The Vice-Chairman, Sir T. FARRER, did indeed minimise the value of polytechnics by describing them as mere experiments which were on their trial, and of by no means paramount importance; but the judgement of the Vice-chairman is somewhat discounted by his further argument for diverting the money to other purposes than those recommended in the Report, because, if it were adopted, the drinking interests would be henceforward bound up with the cause of education. In this line of reasoning he had been preceded by other speakers of the temperance persuasion, who seemed to think that somehow or other people would be induced to drink more beer and spirits in order to encourage technology. It is difficult to treat such scruples seriously, especially as they were not followed up by a blunt refusal of the unholy thing. Mr. CHARRINGTON and his followers voted no doubt with Mr. BENN, with the result, if the decision stands good, that the working classes, who are the chief consumers of beer and spirits, will drink more of these beverages in order to swell the fund for improving their dwelling houses. We know perfectly well they will do no such thing; and we know, too, that the drink bill rises invariably with increased prosperity. That it has risen quite remarkably of late may perhaps be accepted as evidence that the money already expended on the extension and improvement of our technical training, amounting to a vast sum, is beginning to bear good fruit. This reflection may at all events console us for a temporary defeat of the cause in the London County Council.

## STANDARDS OF LIGHT.

For all who have to do with electric lighting, the ultimate standard with which incandescent lamps are to be compared is of direct and considerable interest. It is, therefore, with some regret that we chronicle the general tendency of a recent Paper read by Mr. W. C. Young before the London Section of the Society of Chemical Industry on "Standard Sperm Candles." Naturally, the first and ostensible object of the communication was the discussion of the question as to the reliability of the sperm candle for determining the candle-power of the gas supplied to London and other large towns by the stereotyped system commonly in use, but as any decision come to with regard to the most extensive and uniform series of tests carried out anywhere on the photometric value of an illuminant cannot but influence photometry generally, it is in our opinion expedient to discount the conclusions arrived at by Mr. Young lest their application to the measurement of the candle-power of incandescent lamps lead to undesirable results. Mr. Young is a staunch upholder of the standard sperm candle for the gas photometrist's purpose, and with that belief we are not disposed to quarrel, the matter not concerning us. But he appears scarcely sufficiently alive to the urgent necessity of sweeping away the anomalous archaic and inaccurate "standard" afforded by the sperm candle and replacing it by one or other of the several very practicable devices (which it would be invidious to particularise) in which a substance of known composition is consumed under constant conditions. When once a reasonably accurate standard had been thus secured it would be extremely simple to make a candle which should be as approximately equal to it, or a multiple or sub-multiple of it, as its uncertain nature will allow. This would satisfy the contention of those who declaim against anything more accurate than the standard candle on the ground that the former is cheap, simple, and portable, forgetting that more important qualities may be sacrificed to gain cheapness, simplicity, and portability. As a matter of fact this is practically what has been done for standards of light; standards other than the candle are based not on the real but on the ideal sperm candle, its illuminating power being arrived at from the average of numerous observations of that of candles possessed of an objec-

Digitized by Google

tive existence. But the retention of a standard incapable of reproduction at any time with reasonable accuracy is indefensible, and any decision in favour of the sperm candle for special purposes might be mischievous if unaccompanied by a rider exposing its inefficiency on general and broader grounds.

## THE ATLAS ACCUMULATOR.

At a recent meeting of the Société Internationale des Electriciens, M. R. V. Picou read a Paper on the "Atlas" accumulator, the outcome of the joint labours of Mr. Carl Hering and MM. Abdank-Abakanowicz, d'Arsonval and Picou. Each element, as shown in Fig. 1, consists of a pile of positive and negative plates separated by thin sheets of perforated indiarubber, thin sheets of lead being "sandwiched" in at intervals. The positives are of peroxide of lead, and the negatives of spongy lead, both being pierced with numerous holes. The pile of plates is kept in position, and electric connection is effected, by means of nuts and bolts of an alloy of lead, as shown, which are arranged to permit of expansion in every direction.

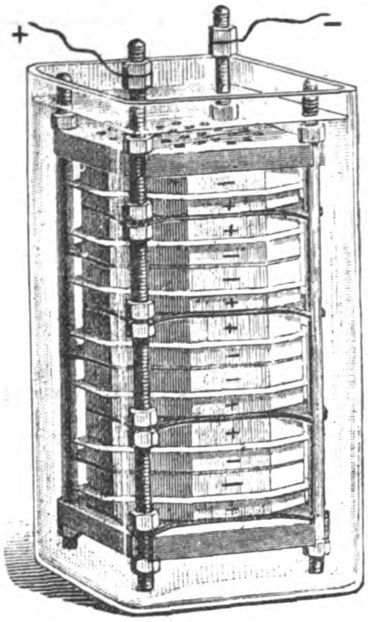

Fig. 1.—Atlas Accumulator.

The following are some of the data given by M. Picou :—

| | | |
|---|---|---|
| Porosity of Plates ... ... | = | 50 per cent. |
| Density of Plates ... ... | = | 4 |
| Capacity per lb. of plate ... | = | 9 amp. hours. |
| Discharging current ... ... | = | ·7 to 9 ·amp. per lb. of plate. |
| Dimensions of a 150-ampere hour cell ... ... ... | = | $6\frac{1}{2} \times 7\frac{1}{3} \times 13$ inches |

In the course of his remarks M. Picou stated that he had found out experimentally that accumulators ought preferably to be charged at a constant E.M.F. of about 2·3 volts per cell. M. Hospitalier then showed some curves illustrating this point. A Gadot accumulator (type 2ter.), with plates weighing 9·35 kilogramme (20·61b.), was charged with a constant current of about 1 ampere per kilogramme of plate (·45 ampere per lb.) and discharged through a constant resistance at the rate of 1·5 ampere per kilogramme of plate (·67 ampere per lb.). The charges and discharges were repeated a number of times until concordant results were obtained. A quantity efficiency of 80 per cent., and an energy efficiency of 70 per cent., was attained. (See curves, Fig. 2.) This same accumulator was then charged at a constant E.M.F. of 2·3 volts and discharged as before until the E.M.F. fell to 1·7 volts. The efficiencies were about the same as before. It is, however, to be observed that the strength of the current was at first very great, being nearly 50 amperes, or more than five times the normal. In spite of this current the accumulator did not gas. The curves (Fig. 3) give the data connected with this experiment. From the diagram we can see that at the end of the first hour the charge had nearly attained 50 per cent. of its maximum value, 75 per cent. being reached after two hours, and 83 per cent. after three hours, the maximum being reached after six hours' charging. From a practical point of view this is of some importance, since it means that we may charge a cell in this way to within 17 per cent. of maximum in three hours without injury, while to reach

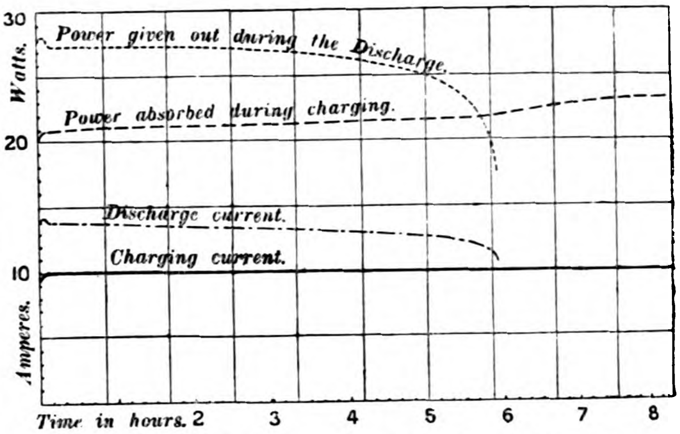

Fig. 2.—Gadot Accumulator (11 plates of 850 grms.)

Ampere hours supplied 83 } Efficiency 83·2.

this state with a constant current would have taken $6\frac{1}{2}$ hours. Moreover, the E.M.F. required to charge a 52 cell battery is only 120 volts with the constant-potential method but 135 volts when a constant current is employed.

These experiments were carried out in M. Hospitalier's laboratory at the Ecole de Physique et de Chimie, by MM. Chevalot and Delarivière, under the direction of M. Gaston Roux.

## THE THUNDERSTORMS OF SIXTY-SIX SUMMERS.

Not a little obscurity still hangs about the nature of thunderstorms, and the subject has of late engaged the thoughts of many scientific men, in this country, and on the Continent, and elsewhere. A thunderstorm committee was appointed by the Royal Meteorological Society a short time ago, and is now at work. In its second report (*Quart. Jour.*, January, 1890) are given two diagrams, showing, by means of curves, for eleven different districts of England, the monthly averages of days of thunderstorm and lightning, also the yearly values in the years 1871-87. While these are no doubt instructive, it has been thought a drawback that cases of sheet lightning were included in the comparison. For sheet lightning is often the indication of a thunderstorm a long way off. One case is recorded—*e.g.*, in which the reflected lightning of a thunderstorm near the Northern French coast was seen as far as our northern midland counties.

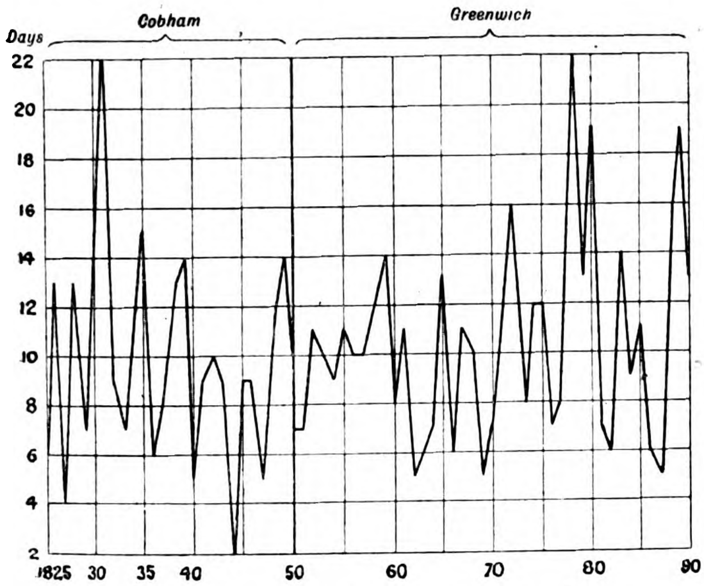

Fig. 1.—Days on which Thunder was heard.

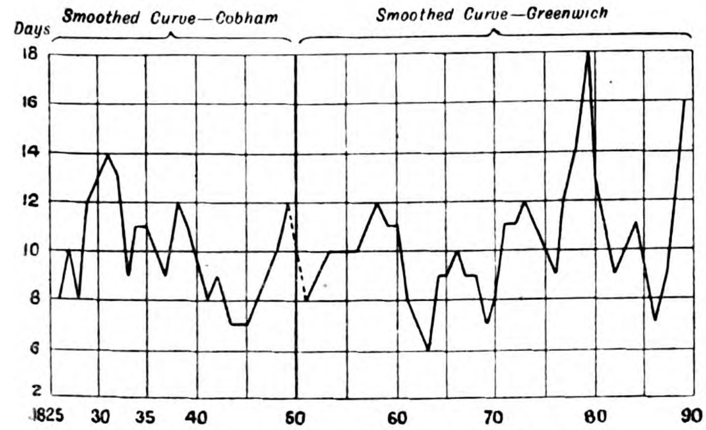

Fig. 2.—Days on which Thunder was heard.

At present, putting sheet lightning aside, the number of days, in May to September of each year since 1825, on which thunder was heard at Cobham (to 1850) and Greenwich (1850 to 1890) are shown in the diagrams. The Cobham is shown as far as it goes; and the Greenwich one as given in the *Weekly Return*. (It will be seen that in 1850 the Cobham observer records 10 days, and the Greenwich seven. The two records do not fully agree. But the data are probably sufficient for the purpose).

Looking at the curve (Fig. 1), then, one sees, first of all, that its highest points are in 1831 and 1878. In each year there were 22 days, in May to September, on which thunder was heard. The range extends down to 2 in 1844. A singular feature of the Greenwich curve at once strikes the eye. It is the succession of similar double-crested waves (five of them completed since the first decade), the second crest always lower than the first. What is the cause of this phenomenon? It seems difficult to suppose it purely accidental. We appear to be now in the hollow of a crest, and should almost expect to have rather more thunderstorms this year than we had in 1890, but not so many as in 1889.

The curve (Fig. 2) has been smoothed somewhat by the well-known method of making three years' averages, and the result appears in the upper part of the diagram, which perhaps gives a clearer idea of how thunderstorms have been distributed in this period of sixty-six years. It may be noted that, taking the intervals between the tops of the waves here given, from 1838, the numbers run as follows:—11, 9, 8, 7, 6, 5, 5 years. Also the gradual rise of the curve from 1863 to 1879 may be remarked.

No very obvious relation subsists between the numbers of days of thunder and the mean temperature of the summer and autumn months; though, doubtless, a detailed study of temperature would show variations in that to be related to the numbers of days of thunder, as here indicated. As regards rainfall, some of the highest years in this curve (*e.g.*, 1887 to 1889) are years of excessive rainfall; but it is not always so.

## THE TELEPHONIC REPRODUCTION OF SPEECH.*

BY E. MERCARDIER.

The principal object of the telephone is the reproduction of speech at a distance with all its component elements; the articulations with their inflections, the vowels and diphthongs with their characteristic accents, timbre with all its delicacy, and the whole reproduction with sufficient intensity. But the transformations of energy, which go to make up telephonic effects, tend to injuriously affect the human voice.

*Alteration of Timbre.*—This consists in the production of a disagreeable snuffling, which often distorts words. I pointed out in a previous communication† that this impairing of the timbre was due to the fact that frequently the movements due to the production of the fundamental note, and the harmonics of the telephone diaphragm were superimposed on those due to the voice, without, however, becoming confounded with them. Hence a more or less great disturbance of the electric waves, which reach the telephone receiver, of the movements of the molecules of the diaphragm, and finally of the sound waves which result from these movements, and which reach the ear of the listener. If my theory be correct, it was not necessary in order to correct this alteration of timbre to take a diaphragm the fundamental note of which is superior to the limit of the sounds emitted in articulate speech, that is to say, one whose fundamental note is somewhere about $ut_4$ for men and $ut_5$ for women. Then the human voice would not tend to produce the fundamental note and harmonics of the diaphragm, which would no longer coincide with the tones of the human voice. Moreover, in order to produce them it would be necessary (owing to the stiffness of the diaphragm) to employ a mechanical force greater than that which the human voice is capable of exerting when speaking. This has been verified by experiment. I will only cite two extreme cases. A diaphragm of 100mm. diameter and 1mm. thick, or one 30mm. diameter and ·1mm. thick. Both satisfy the condition mentioned above, and fixed to appropriate telephones neither of them produces a sensible alteration in the timbre of the voice.

*Alteration of Articulations and Vowels.*—This consists on the one hand of the exaggerated predominance of certain consonants, vowels and syllables, *p*, *b*, *r*, *k*, *a*, *o*, *an*, *on*, *ent*, and in the marked weakening of *l*, *s*, *c*, *z*, *i*, *e*, and *u*. The consequence is, that it is frequently very difficult to understand the meaning of a sentence and to decipher the words distorted in this way. Hence a constant source of error. The alteration is due in large measure to the shape and aperture of the buccal cavity, which are different in the pronunciation of the various articulations and vowels mentioned above, and to the resulting energy of the sound waves being much weaker in the second case than in the first. From this point of view this distortion would seem inevitable, but it is also due in some degree to the correlative production of the harmonics of the diaphragm. In fact, while seeking to remedy this defect, I found that it was markedly diminished by precisely the same method as indicated above, employed to suppress the alteration of timbre,

* *Comptes Rendus*, Vol. CXII., No. 3.
† *Comptes Rendus* November, 1885.

Digitized by Google

that is to say by suitably proportioning the thickness and diameter of the diaphragm so that its fundamental note shall be very sharp. The line joining the transmitter to the receiver also plays a certain part in this connection, which I hope to examine later on.

*Various Effects.*—The third difficulty which is present in a large number of telephones is the production of two parasitic resonances. One of these is not very inconvenient, since it is weak, and only noticeable by trained ears. It consists in metallic crackling, which seems to me to be due to a kind of friction along the radii of the diaphragms, caused by a change in the direction of the lines of force. This effect disappears in a diaphragm with a high fundamental note, either because it is then too shrill to affect the ear, or because it is not produced at all, owing to the mechanical force necessary for its production being greater than that which the human voice can exert. The other effect is more intense and of greater tonality: it is the resonance due to the mass of air enclosed in the telephone box itself. To cause this vague effect (composed to some extent of the various inflections of the timbre of the voice) to disappear, it is only necessary to take the precaution to leave a very small air space underneath the diaphragm, which can be attained by filling the interior of the boxes with felt. We thus see that apart from this last effect, which is easily eliminated, the distortions suffered by articulate speech when reproduced telephonically can be considerably diminished, if not entirely obviated, and this by a simple means, the same for all, consisting merely in the employment of diaphragms having a high fundamental note, whether they have considerable thickness and considerable diameter, or are thin and are of small diameter. At the same time that we obtain clearness in the reproduction of speech, we satisfy the conditions necessary to obtain sufficient loudness,* a very fortunate circumstance since the two desiderata of clearness and loudness are equally indispensable. This fact thus permits us to approximate perfection in an instrument as delicate as it is marvellous.

## ON THE INFLUENCE OF THE STRENGTH OF THE MAGNET IN A MAGNETO TELEPHONE RECEIVER.†

BY C. R. CROSS AND H. E. HAYES.

The following investigations of Messrs. C. R. Cross and H. E. Hayes, carried out in October last in the Physical Laboratory of the Massachusetts Institute of Technology, are of interest in view of their connection with recent work by M. Mercadier (*The Electrician*, January 23rd, p. 368, and present issue):—

The present investigation is a continuation of the research described in a previously-published Paper by Messrs. Cross and Williams. With a magneto telephone transmitter it was found that, as the strength of the magnet was increased, the induced current produced by a definite motion of the diaphragm increased quite rapidly to a maximum, and then gradually decreased. With diaphragms of different thickness it was found that, as the field necessary to saturate the diaphragm increased in strength, the maximum value of the induced current occurred with a greater strength of field, and also that the value of this maximum current increased with the thickness of the diaphragm, other things remaining the same.

The diaphragms used were of iron, and of the same thickness as in the previous experiments, viz., Nos. 21, 22, and 23 B.W.G., corresponding to a thickness of 0·032in., 0·023in., and 0·024in., respectively.

A series of observations gave the results shown in the curves shown in Fig. 1. The induced currents are represented by abscissæ, the strengths of the field by ordinates. The numbers 21, 22, and 23, affixed to the curves, indicate the thickness of the corresponding diaphragms by their gauge number. The curves show that with the diaphragms numbers 21, 22, 23, the maximum induced currents were 124, 93, 91, respectively, corresponding to relative strength of field 61, 56, 49. The results prove that, within the limits of the experiments, the maximum current is greater, and is reached with a stronger field, as the diaphragm is thicker. An examination of the curves (Fig. 1) shows that the point of maximum current is less distinctly marked with the thinner diaphragms than with the thickest. We are inclined to believe this to be an accidental peculiarity, due to a slight yielding of the diaphragm, which was fastened at its edges and which when thin would tend to bulge towards the magnet, thus causing its whole motion to be performed in a stronger field, and so giving rise to a stronger induced current than would otherwise be the case. An extremely slight displacement of this kind will produce a noticeable difference in the resulting induced current. This effect may also have acted to diminish somewhat the difference between the maximum current obtained with the two thinnest diaphrams, which difference is much less than the difference between the maximum current with the two thickest ones. Care was taken in all the experiments that the magnet of the apparatus should be far below saturation, even with the strongest magnetising currents which were used.

Our experiments were next directed to a study of the conditions operative in the magneto receiver, and particularly to ascertain the effect of a varying degree of magnetisation in the magnet of the receiver upon the change in its strength when subjected to the action of a slight current of the same order of magnitude as that used in telephony. The apparatus employed consisted of a core of soft Norway iron, 6in. long and a quarter of an inch in diameter, and provided with a suitable magnetising coil. A diaphragm was placed opposite one end of the core, as in the usual magneto receiver. This end of the core also carried two coils of fine wire, like the ordinary telephone magnet coil, one having a resistance of about 130 ohms, the other of about 190 ohms. The former of these coils was connected with a storage cell, a fixed resistance, and a key. By means of this apparatus a current of suitable magnitude could be caused to traverse the coil, which evidently corresponds to the coil of the ordinary receiver, and which we have called the "line coil." The effect of this current will be slightly to increase or decrease the magnetisation of the bar magnet, as in the receiver itself. The second fine wire coil is a "measuring coil," and is connected in

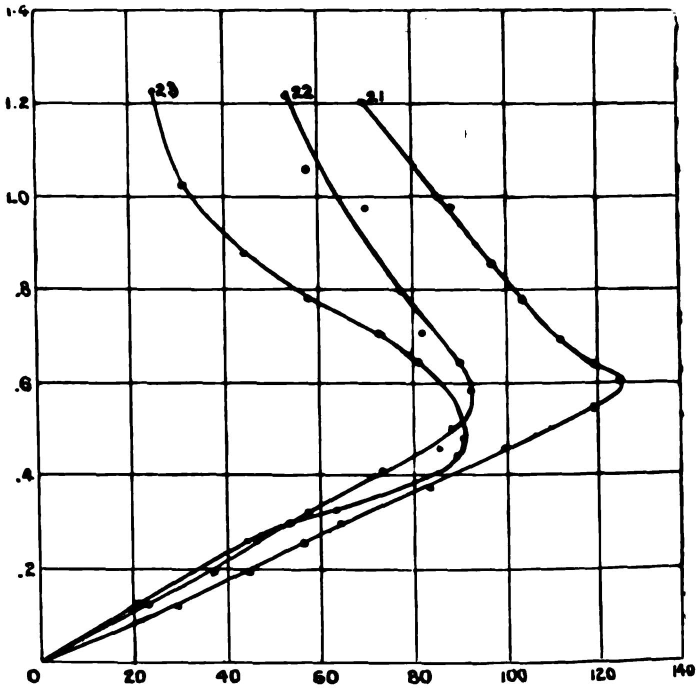

Fig. 1.—Curves showing the relation between the induced currents and the Strength of the Magnetic Field.
Induced Currents, Ordinates, ·2, ·4, ·6, &c.
Strength of Field, Abscissæ, 20, 40, 60, &c.

circuit with a ballistic galvanometer, from whose deflection when a current was sent through the first fine-wire coil the effect of this current on the magnet of the receiver could be determined. A magnetometer arranged in the usual manner showed the relative strength of the field of the receiver magnet under differing conditions of magnetisation. The observations consisted in adjusting the magnitude of the current through the magnetising coil so as to give a certain deflection of the magnetometer needle. The magnetising circuit included a suitable resistance coil, by the use of which any desired current could readily be secured. The key was then pressed, so that a certain current flowed through the line coil. The proper value was given to this current by means of a rheostat. The induction occurring in the measuring coil gave rise to a transient current through this circuit, the value of which was known from the deflection of the needle of the ballistic galvanometer included in it. Of course the key had to be kept down until the observation was completed, and it was also necessary, on account of the self-induction of the measuring circuit, always to read either on opening or on closing the key. In our experiments the latter alternative was chosen.

The results were plotted as previously by using the relative strength of the field as expressed by tangents of the magnetometer deflections as ordinates, and the induced currents in terms of an arbitrary unit as abscissæ. The deflection of the ballistic galvanometer used was proportional to the strength of the transient current passing through its coils.

A series of observations was first made with the diaphragm removed, in order to study the deportment of the core alone under varying degrees of magnetisation. The results are shown graphically in Curve 1, Fig. 2. It appears from these, that with increasing magnetisation of the core the induced current remains nearly constant for a time, and then diminishes rapidly and at an increasing rate, which afterwards becomes nearly constant, a result which would be anticipated from the corresponding diminution in the magnetic change which a small current in the line coil would produce. The current which traversed the line coil was six milliamperes, a value which was used in most of the measurements, it having been found by trial that the general character of the results was the same as when a smaller line current was used, while the greater magnitude of the deflection of the current induced in the secondary measuring circuit allowed more satisfactory readings to be made than if the line current were smaller. A corresponding series of measurements with a diaphragm of ferrotype iron, No. 31 B.W.G., 0·010in. in thickness, gave the results shown in Curve 31, Fig. 2. Curve 2, Fig, 2, is constructed with abscissæ equal to the difference of the corresponding abscissæ of curves 31 and 1, and shows for various strengths of field the increase of the induced current due to the presence of the diaphragm, an interesting illustration of the action to which Du Moncel ascribed the chief efficacy of the diaphragm.

In order to study the effect of the thickness of the diaphragm further measurements were made, using sheet-iron diaphragms, Nos. 21, 22, 23, 26 B.W.G., whose thickness was 0·032in., 0·027in., 0·24in., and 0·018in. respectively.

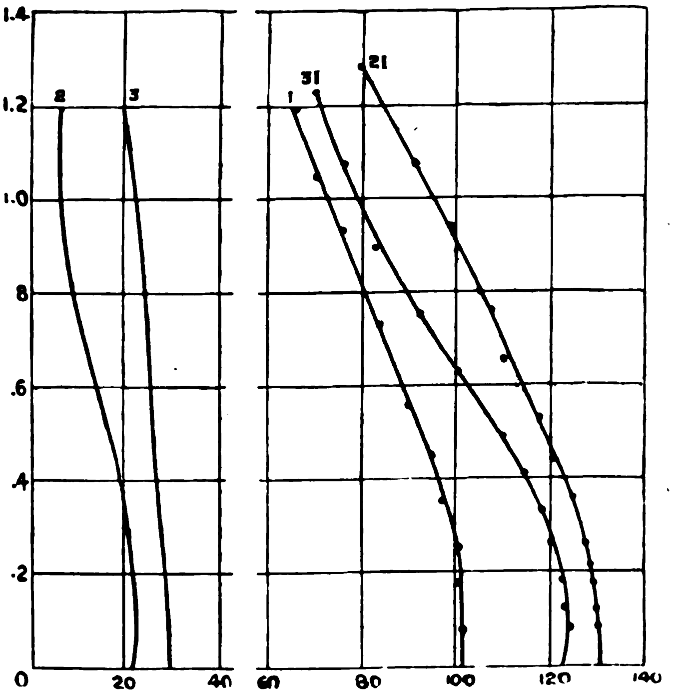

Fig. 2.—Curves showing Relation between Induced Currents and Strength of Field.
Induced Current, ordinates.
Strength of Field abscissæ.

Several series of measurements were made with currents of widely different strengths, and with the thinnest and the thickest of the diaphragms used in these experiments, in order to ascertain whether the induced current in the measuring coil was proportional to the inducing line current, and since this was found to be sensibly the case, the strength of six milliamperes was adopted, as already stated.

Considerable trouble was experienced in obtaining satisfactory consecutive readings of the deflections, on account of the close proximity of the laboratory to the streets, rendered especially disturbing by the presence of the electric railway. The difficulty was avoided as far as possible by working at night.

It will be seen from inspection of any one of the various curves last referred to, that as the strength of the field increases, the induced current increases, and then gradually diminishes. This would of course be anticipated, as the increased magnetisation of both the core and the diaphragm increases the strength of field in which the latter moves, and at the same time diminishes the susceptibility of both masses of metal to magnetisation. The effect of the former predominates slightly at first, but is overpowered by the latter cause when the magnetisation is increased. It would seem that above No. 22 an increased thickness of diaphragm causes little effect. A comparison of the curves will show that, with the exception of Curve 31, for which the diaphragm was of ferrotype iron, the value of the maximum induced current is greater according as the diaphragm is thinner; and also that the strength of field corresponding to this maximum current is likewise greater the thinner the diaphragm. The following approximate values were found from constructions of the curves on a large scale.

| | | | | |
|---|---|---|---|---|
| For No. 26, | Maximum Current = | 142, | Field = | ·18 |
| " " 23, | " " | 137 | " | ·13 |
| " " 22, | " " | 132 | " | ·10 |
| " " 21, | " " | 131 | " | ·06 |

It also appears that with the thinner diaphragms the decrease of the induced current with increase of field, after the maximum value of the current is reached, is more rapid than with the thicker ones. Moreover, the deviation of the latter portion of the curve from a straight line is greater in the case of the thinner diaphragms. The great value of the maximum induced current with the thin than with the thick diaphragm would naturally be ascribed to the less stiffness of the former, and its consequent greater motion when a current passes through the line, although its smaller mass and greater ease of saturation must in a measure counterbalance this effect. The quicker approach of the thin diaphragm towards saturation will explain the more rapid falling of the current with it, and also the ess uniform rate of this change as the field increases. Curve 3, showing the effect of the diaphragm, still further illustrates this.

It should be observed that the results which we have described do not necessarily show the varying accoustic effect of the receiver, since the amplitude of the motion of the diaphragm rather than the simple amount of the change of strength of the magnet determines the magnitude of the resulting air-waves—at least, according to the view commonly held. We hope to return to the study of this part of the problem, which is rendered somewhat difficult on account of the very small motion of the diaphragm.

## ON THE PHYSICAL PROPERTIES OF HARD-RUBBER, OR VULCANITE.*

BY ALFRED M. MAYER.

The discovery of the large coefficient of expansion of hard-rubber by Kohlrausch,† in 1873, and of its remarkable diathermancy by Bell,‡ in 1880, attracted the attention of physicists to this substance. In this paper I give additional and more minute experiments on the above-mentioned and other properties of this substance.

Hard-rubber, vulcanite, or ebonite, as it is variously called, is formed of rubber and sulphur. These are combined in proportions of about two parts of rubber to one of sulphur. These ingredients, intimately mixed, are by the action of a temperature of 300° F., lasting three hours, converted into a black compound. The sun, viewed through thin plates of this substance, appears of a deep red colour. The hard-rubber used in our experiments was formed of 64 parts of rubber of Para and 34 parts of sulphur.

*The coefficient of linear expansion* was obtained with the apparatus devised by me for this purpose and shown in the accompanying figure. A plate of steel one metre long and 6cm. broad had a lug of steel 15mm. broad screwed on to its end to act as an abutting piece against which the end of the bar of vulcanite, 96cm. long, 6cm. broad, and 1·3cm. thick was pressed by means of springs. A block of steel, carrying a tracer, while bearing against the end of the bar of vulcanite was slid along the end of the bar and traced on the surface of the steel bar a very fine line. The bars are in a closed case in which they have remained for 24 hours. The temperature is taken from thermometers lying on the vulcanite bar. After having traced the line the apparatus is placed in a metal case surrounded by ice, and after the temperature has become stationary another line is cut by the tracer. The bar in falling through the observed temperature has shortened by the distance between the lines less the shrinkage of the steel bar. The distance between the lines is measured by a micrometer microscope. As the tracer is of steel its contraction is the same as that of the steel bar on which it rests, so that we have only to consider the length of the steel plate equal to that of the vulcanite bar in computing the coefficient of expansion of the vulcanite. Calling this length $l$, the distance between the lines $d$, the coefficient of expansion of the steel $k$, and the coefficient of expansion of the vulcanite $e$, we have in the range of temperature $t$,

$$e = \frac{d \div l}{t} + k$$

The mean of twelve determinations thus made between 0°C. and 18°C. gave ·0000636 as the mean coefficient in the above range of temperature.

*The formula of the cubical expansion of ebonite* was determined by a mercurial thermometer made of a bulb of ebonite to which was

* From the *American Journal of Science.*

Digitized by Google

attached a glass capillary tube of cylindrical bore, the tube of vulcanite was placed in a metal shield to protect it from moisture, and it and the glass tube surrounded with ice. The distance of the mercury from a fine line engraved on the glass tube was read with a cathetometer when the level of the mercury had become stationary, and the lengths between the line and the level of the mercury at different temperatures, obtained by heating the apparatus in a hot air chamber furnished with a thermostat, was measured. Knowing the capacity of the ebonite bulb and of a millimetre in length of the glass tube we obtained the rate of the apparent expansion, or rather, contraction of the mercury, from which, after having allowed for the expansion of the glass tube and the mercury in it, we deduced the absolute expansion of the vulcanite. The results of these experiments may be closely expressed in the following formula.

$$V_t = V_0 + \cdot000182t + \cdot00000025t^2.$$

The formula of the cubical expansion of mercury as given by Mendeleeff* is

$$V = V_0 + \cdot0001801t + \cdot00000002t^2$$

It is thus seen that the cubical expansion of vulcanite exceeds that of mercury so that the apparatus we have described may be used as a thermometer in which, as Kohlrausch observed, the scale will be inverted; when the temperature *rises*, the mercury in the stem *falls*.

The following table gives the volumes of vulcanite and of mercury at temperatures from 0 deg. to 100 deg., as computed from the above formulæ. The difference (in the fourth column) which are all negative, show the increasing rate of expansion of the vulcanite over the mercury.

| Temp. | Vol. of Mercury. | Vol. of Vulcanite. | Differences. |
|---|---|---|---|
| 0° | 1·000000 | 1·000000 | ·000000 |
| 10 | 1·001803 | 1·001845 | ·000042 |
| 20 | 1·003610 | 1·003740 | ·000130 |
| 30 | 1·005421 | 1·005685 | ·000264 |
| 40 | 1·007236 | 1·007680 | ·000444 |
| 50 | 1·009055 | 1·009725 | ·000670 |
| 60 | 1·010878 | 1·011820 | ·000942 |
| 70 | 1·012705 | 1·013965 | ·001260 |
| 80 | 1·014536 | 1·016160 | ·001624 |
| 90 | 1·016371 | 1·018405 | ·002034 |
| 100 | 1·018210 | 1·020700 | ·002490 |

As the apparent expansion of mercury in glass of a Fahr. thermometer is ·0000869 of its volume for 1deg., and as the apparent contraction of mercury in a vulcanite thermometer is ·00249 from 32deg. to 212deg., it follows that the length of scale from 32deg. to 212deg. on a vulcanite thermometer $= \frac{\cdot00249}{\cdot0000869} =$ 28deg. ·6 of length of scale on a similar mercurial thermometer of glass.

Kohlrausch states in his Paper, cited above, that "the increase of the coefficient of expansion of ebonite with the temperature is very considerable. The linear expansion for the temperature $t$ can be put

$$\cdot000061 + \cdot0000076\,t."$$

This formula agrees well with that which we determined for the cubical expansion. Further on he says:—"The solid expansion of ebonite is, from the above numbers, at 0deg. equal to that of mercury; at higher temperatures it is still greater. It is possible that other kinds expand still more, so that as a curiosity a mercurial thermometer might be constructed whose readings sink on being heated. The great expansion may possibly be connected with the proportion of sulphur which ebonite contains: Kopp (Pogg. Ann., vol. lxxxvi, p. 156) found for the coefficient of sulphur ·000061 at 30deg. On the other hand, the contrast to soft caoutchouc is very remarkable. I will mention one fact which was observed in the observation of expansion. The bar of ebonite, which was about one centimeter in thickness, after being heated, required a considerable time before it assumed a constant length. Although the bad conductivity is doubtless the principal cause of this, I imagine that another phenomenon is also at work. Like the elastic change of form, the expansion by heat may also not take place instantaneously, but continue itself after the change of temperature, gradually becoming weaker. A few observations of Matthiessen's with glass (Pogg. Ann., cxxviii, p. 521), seem to point in this direction; probably this thermal after action, like the elastic, occurs in an eminent degree in organic substances."

*The specific heat of vulcanite* was determined by the method of mixtures. Small fragments of vulcanite were heated to near the temperature of boiling water in Regnault's apparatus and dropped into a water calorimeter. After corrections for equivalents in water of calorimeter and thermometer and for radiation and evaporation, three experiments gave these results:—

1) ·33124  2) ·33077  3) ·33225  Mean = ·33125

*On the diathermancy of vulcanite* and similar substances, numerous careful experiments were made by observing with a thermopile the percentages of heat rays transmitted by plates of different thicknesses.

The result of these measurements is to show that the rays transmitted by vulcanite and obsidian are of long wave-length; these are in greater percentage in the rays from the Locatelli lamp than in those from the sun. A plate of vulcanite one-half millimeter in thickness transmits 32 per cent. of these rays, while of the sun's rays 24 per cent. are transmitted. A plate of obsidian of 8mm. thickness acts in like manner, but it screens even a greater proportion of the sun's rays than it does those from the Locatelli lamp, for it transmits 16·5 per cent. of the former rays, and 32 per cent. of the latter.

In making the experiments on the transmission of the sun's rays I used a revolving diaphragm pierced with holes of various diameters. The face of this diaphragm was exposed to the solar beam, sections of which, equal to the area of the different holes, were transmitted to the thermopile, which was placed at such distances from the diaphragm that the whole of the rays transmitted were included in the area of the face of the pile. The deflections of galvanometer produced by beams going through holes of different diameters are given below:—

| Diameter of hole. | Deflection. | Diameter of hole. | Deflection. |
|---|---|---|---|
| 1) 1·25mm. | 8·5 | 3) 4·9mm. | 131·5 |
| 2) 3.4 | 63·0 | 4) 6·1 | 204·0 |

If the heat given to pile is as the area of the aperture, then the squares of the diameter of aperture divided by the deflections should equal a constant, as follows:—

$$1)\ \frac{1\cdot5625}{8\cdot5} = \cdot1838 \qquad 3)\ \frac{24\cdot01}{131\cdot5} = \cdot1826$$

$$2)\ \frac{11\cdot56}{63} = \cdot1835 \qquad 4)\ \frac{37\cdot21}{20\cdot4} = \cdot1824$$

Mean = ·18305.

I mention these experiments, because they show that such a diaphragm may be of service to those who wish to obtain in succession definite amounts of heat from a solar beam.

*The index of refraction of vulcanite* was measured by ascertaining, in a spectrometer, the angle of maximum polarisation of a polished surface of vulcanite. The mean of fourteen measures gave for this angle 57° 29′, and the tan. 57° 29′ = 1·568 for the index of refraction; a number nearly as great as the index of refraction of flint glass.

Thin lenses of vulcanite and of obsidian were made for me by Mr. John A. Brashear, and with them I concentrated the rays of long wave-length to invisible foci on the face of the thermopile.

## NEW TESLA ALTERNATING MOTOR.

We have already, says the *Electrical Engineer* of New York, described a number of different forms of alternating current motors designed by Mr. Nikola Tesla, depending upon a variety of phenomena met with in the employment of alternating currents. One general type of these consists of a machine with, say, four poles, between which is mounted an armature, generally wound with closed coils. On two opposite poles of the field are primary coils connected up in the main circuit. On the same cores are also wound secondary coils on the other pair of poles. When an alternating current is caused to pass through the primary coils, it energises directly one set of poles, and induces currents in the secondary coils, which in turn energise the poles; but the phases of the current in the secondary coils may differ in time from those of the primary current, and hence a shifting of the poles is effected that imparts a rotation to the motor.

In the new motor designed by Mr. Tesla, however, two energising circuits are brought into inductive relation in the motor itself, and the employment of an external induction device is thus avoided. The operation is dependent upon the existence of a certain difference of phase between the currents of the primary and secondary coils, and will be readily understood by reference to the accompanying diagram. Here A represents the field magnet of a motor, which is built up of sections or plates. B and C are polar projections upon which the coils are wound. Upon one pair of these poles, as C, are wound the primary coils D, which are directly connected to the circuit of an alternating-current generator G. The secondary coils, F, are wound on the same

Digitized by Google

poles with the primary, and connected with other coils, E, which surround the poles B. The current in both the primary and secondary coils will lag behind the impressed electromotive force, but to secure the proper difference in phase between the primary and secondary currents themselves, the resistance of the circuit of the secondary is increased, so as to reduce as much as possible its self induction. This is accomplished by makiog the coils E of comparatively small wire, having but few turns around the cores, or by inserting in the secondary circuit an artifical resistance, R. In practice, it has been found desirable to wind the armature with closed coils, in which currents are induced by the action of the primaries.

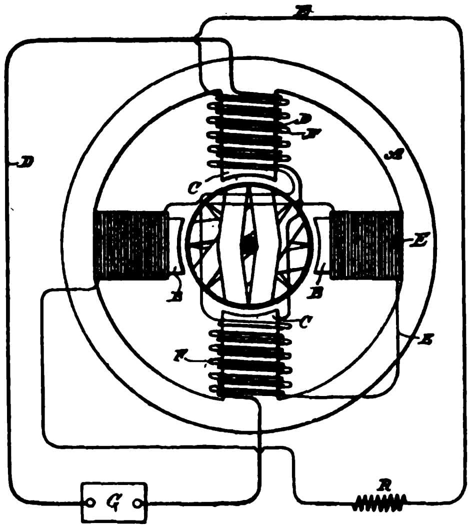

Diagram of Tesla Alternating Motor.

## ELECTRICITY AND ITS TACTICAL VALUE FOR MILITARY OPERATIONS.*

BY MAJOR R. L. HIPPISLEY, R.E.

I propose to confine myself in this lecture to the consideration of only one of the uses to which the electric light can be put for war purposes, namely, portable lights for field operations. A highly specialised equipment is necessary for this purpose—one which cannot be satisfactorily extemporised on the eve of war, and several units of which ought to be kept in store ready for an emergency. But it will be labour wasted and money ill-spent if this equipment is designed and brought out, and if no one will use it. Now, an electric light apparatus, portable enough to follow an army in the field, could be made use of for a variety of purposes.

Taking first its most obvious use—viz., in sieges—we may take for granted that every first-class fortress will soon have its first-class search-lights. In England preparations are being made on a large scale for the introduction of the most brilliant search-lights for our southern defences, both sea and land, to be at the disposal of the artillery for defensive purposes. We may, therefore, take for granted that a besieging army will find any permanent fortress, against which it may be engaged, in possession of electric lights with which to search out the night operations conducted against it. The siege of a fortified place would, therefore, no longer be the comparatively simple operation of constructing works at night and firing from them during the day. The construction of the ordinary siege works in the method hitherto adopted would not be possible except at an enormous sacrifice of life. But this advantage on the part of the attack can be greatly obviated by the employment by them of electric search-lights; for it has been shown from the Milford Haven experiments in 1886 that, when the atmosphere is at all heavily laden with smoke or with mist, the penetrating power of the lights from a fortress can be diminished to a large extent by the employment on the part of the attack of another beam, crossing the former at an angle. At Milford Haven it was found that the penetrative effect of the electric lights of the defence was very feeble when the beams were crossed by those of the attack, as the illuminated spaces at their intersection presented a screen, more or less opaque, according to the amount of smoke or mist with which the atmosphere was charged. An electric beam can therefore be used as a screen, behind which operations can be conducted in secret. The applicability of this use of the light in the attack of a fortress is obvious. In order to produce this screening effect, it is only necessary that a powerful search light should be placed in front of the flank of the ground to be hidden, so that its beam may be projected in front of it. It is better to throw the beam diagonally across the front, rather than to make it traverse straight across, because its obscuring power is much greater when so disposed, and also because it contributes to disconcert the enemy's fire by its dazzling effect upon those having to aim the guns. The projector used should be capable of throwing a very condensed beam, and care should be taken to avoid any stray rays illum'nating the ground which is intended to be hidden.

Not only will the electric light produce cover behind which parallels or siege batteries can be commenced, if the nature of the ground and the shape of the fortress admit of it, but it can also be used with great effect for the direction of the guns subsequently placed in such works. The firing can then be carried on at night with almost as great accuracy as during the day. Guns were laid by night at Lydd in 1886, on a work illuminated by a beam from a flanking position 1,200 yards distant from it. The outline of the work was shown up very distinctly, and the gun laid with perfect accuracy. The apparatus for use in sieges must be as powerful as it is possible to get. This applies, of course, to all the purposes to which the light can be put. The only limit is arrived at when the apparatus becomes so ponderous as to be unmovable. But as an army cannot set down in front of a fortress without bringing up its armament of heavy guns, one can afford to construct the apparatus for this purpose more heavily, and, therefore, more powerfully than for other things.

*Attack and Reconnoitring.*—A recent writer, who has collected into one book all the possible uses to which electric lights can be put for war purposes, has, it seems to me, been injudicious in puffing it beyond its merits. He has stated that it can be used in the attack of a position as distinguished from that of a fortress, and also in a reconnaissance in force by night. The employment of search-lights for such purposes will, no doubt, be considered a somewhat hazardous proceeding. Indeed, I should not have mentioned the employment of electric lights for such purposes as reconnoitring and attacking if it had not been that the writer just mentioned had enumerated such employments amongst its possible uses. Many great and radical improvements and changes would have to be introduced into the apparatus before any attempt could be made to carry out such undertakings, even if they could be defended on tactical grounds.

*Defence.*—It is quite another matter when we come to speak of the use of the electric light in the defence of a position against an expected night attack. Here we are on certain ground again. There is nothing to lose by the search-light and everything to gain. For it has been conclusively shown that the light can be placed so as not only to reveal nothing of the defenders' position and movements, but so that it actually affords additional security to them by the depth of the obscurity which it casts over objects in its immediate vicinity, which are out of the reach of the beam. It has been already mentioned that the apparatus is extremely difficult to hit. This is on account of, firstly, the difficulty of estimating the range, even with tolerable accuracy; and secondly, because without special appliances it is almost impossible to aim at the light. As an instance of the deceptive effects of distance, it may be remarked that if the beam be directed on to the ground so as to illuminate a patch of ground between the defenders and the enemy, but sufficiently far from the latter, it appears to anyone looking at the projector from a distance as if the light were situated immediately over the patch of illuminated ground; and if the projector be elevated or depressed slightly, so as to cause the illuminated patch to advance or retire, it seems as if the projector itself were advancing or retiring. Owing to this illusion it is almost an impossibility, without cross bearings, to determine the range of the light if it is kept constantly on the move, as it would have to be when searching for an enemy in front; and even if kept steadily fixed his difficulty in estimating the range is very great.

At Okehampton, in 1888, 32 rounds of shrapnel shell were fired from an unknown range, which was estimated at 1,680 yards by officers with range-finders and pickets with lanterns attached to them. In the morning they found the estimated range was 100 yards too great. Seven bullets passed through the mirror without doing any damage to the light. With regard to the difficulty of aiming, it is of course impossible to look at the direct light on account of its blinding effect, and, therefore, it is impossible to aim at in the ordinary way. Extraordinary methods of aiming, such as that by the shadows of the sights, or by using oiled black paper, are hardly likely to be resorted to by the troops engaged in the attack, even if the men could be taught how to do so. The experiments at Shoeburyness in 1883, at Lydd in 1887, and at Okehampton in 1888, have given remarkable evidence upon this point. At Shoeburyness 124 rounds were fired in one night from Martini-Henry rifles at the electric light apparatus, at ranges varying from 950 yards to 400 yards, and only one hit was made. On the following night 120 more rounds were fired, and five hits scored;

* From a Lecture delivered before the Aldershot Military Society.

Digitized by Google

and at the same time 75 rounds were fired rom a Gardner gun, and only one hit scored. Later on in the same year 400 rounds were fired from a Gatling gun, with the result that 19 bullets hit the apparatus, but this was largely due to the fact that the telephone was used to inform the officer at the firing-point of the results of his firing. It should also be remembered that the ranges were accurately known to a yard. At Lydd similar experiments were made. Ten marksmen fired 200 rounds at ranges of from 1,000 to 600 yards, without effecting any hits; 500 rounds were then fired from a Gardner gun at 1,000 yards, with the result of one hit; and 250 rounds at 600 yards from the Gardner gun, with three hits. The guns were aimed by the shadows of the sights on a piece of white paper held behind the backsight. In these experiments the light from the projector was thrown upon a plane mirror mounted on a pole The mirror could be traversed or elevated from a safe position behind a parapet where the projector was placed. The mirror was a thin sheet of silvered copper stretched on a frame, and though pierced occasionally with bullets, the reflected light from it was as strong as ever.

If opportunity offers in the defence of a position, the arrangements for displaying the light should be the same as those at Shoeburyness, Lydd, and Okehampton, the invulnerability of which has been so conclusively proved. It will be very seldom that an extemporised shelter cannot be made for the projector. The light is thus worked under cover, all that is exposed being the thin stretched metal mirror mounted on a pole, duplicates of which could be easily and cheaply provided in case of accidents, and could be substituted for the broken one in about a minute.

Perhaps you will permit me to make a few remarks upon the necessity for caution in drawing conclusions with reference to points which present themselves as unfavourable to the employment of the light in defence operations. When a demonstration has to be made, and experiments are being tried with the search-light apparatus, under novel circumstances, and in the presence of critical witnesses, it is almost impossible to get people to appreciate the difference between defects which are inherent and defects which are due to remedial causes. For instance, if anybody feels inclined to combat my assertion that the electric light can be so placed as to reveal nothing of the defenders' position, and yet afford him a clear view of the enemy, and if he has before his mind the results of the trials made at the North Camp Redoubt during the manœuvres of the Second Field Column last July, and to prove his point intends to call witnesses to say that the light did on the contrary reveal the outlines of the redoubt at certain times, I can reply that if properly manœuvred it would not have done so, and that all that occasion proves is the necessity for more care on the part of those who were directing the light. On the occasion referred to, the light was traversed through too wide an angle, and, before the advance on the redoubt had been begun, it was actually at one time pointing with its back to the enemy, and, therefore possibly, did reveal the some portions of the redoubt; while, however, the advance was being made, I think everybody agreed that the redoubt was quite invisible.

With respect to the limit of visibility of objects illuminated by the electric search-light, different observers have maintained discordant opinions. So much depends upon the state of the atmosphere, as regards clearness and dryness, that it is almost impossible to secure the same limits on any two separate occasions. The background and colour of the object also makes a great difference. Moonlight assists the light very materially. Under favourable conditions I think small bodies of infantry may be detected with ease at 2,000 yards, but more generally the useful limit is reached at 1,500 yards. In a climate like that of England we have the worst possible conditions of visibility, not only on account of the fog, which is almost invariably present to a greater or less degree, but also on account of the variability of the amount of invisible moisture in the atmosphere at different parts of the range. Where this invisible moisture in the air varies at different spots, as it would do if a stream traversed the path of the beam, the light is more intercepted than it would be if the air throughout were homogeneous. On the Continent and in dry climates the nights are generally much clearer, and the usefulness of the search-light correspondingly greater.

As regards our own preparations in this respect, I do not think we are yet fully alive to the advantages and importance of possessing portable search lights for field operations; and it has been my principal object on this occasion to try and show, not only that it is important that we should be so equipped, but also to show that, in some respects, foreign countries are ahead of us. Many experiments have been tried in England with search-lights of various degrees of portability, but as yet there has been only a part of one equipment recognised for field operations, and that is the steam traction-engine and dynamo exhibited at the manœuvres last year. There is yet no special vehicle for carrying the projector. I maintain that, valuable as the traction-engine is, it is not enough, and that we must also have a lighter apparatus for horse transport. We cannot do better than adopt one of the two Continental types, at any rate till a better one is produced, because they have thrashed out the subject in a most thorough manner, and their productions are the result of years of trial and error, and are likely to be the best and most complete that can be obtained.

DISCUSSION.

Lieut.-General Sir EVELYN WOOD said he had found the electric light of inestimable value in Egypt, and never went to sleep at night without throwing the light in the direction of the enemy to see if he was moving. But had there been a battle since 1859 in which the electric light could have been used by the aggressors? The noise of a traction engine alone would be heard long before you reached the enemy. And then there was the unavoidable noise that would be caused by the pulling of horses. What was the weight of our engine? Ours was seven and a-half tons, the engine of continental pattern was four tons. A team pulls one and three-quarter ton on the level road. Even if the weight got down two and a-half tons it could not be taken in and out of camp unless you had a line of macadam. He failed to see its use in attack.

Colonel LONSDALE HALE asked whether the electric beam would penetrate Colonel Crease's smoke. Some people seemed to think Colonel Crease's smoke a fad. In the course of some experiments at Portsmouth, a body of men advanced within 200 yards of a position unseen under cover of the smoke. He brought this forward in connection with the electric light, because it was important to consider. He thought, with this smoke-cloud, which can be made very portable, the electric light would be comparatively useless in the field for search purposes. With regard to pushing forward the specialities of Engineers, he thought there would be little success in this direction until the departments at Chatham were removed to Aldershot - among the rough-and-tumble of Aldershot, in contact with other troops.

Field-Marshal Sir J. LINTORN SIMMONS said it was very difficult to bring up three tons. As for four tons being drawn by four horses, they may as well try to move the hall with four horses. They need not be afraid of a locomotive. Several years ago he saw eight or ten different kinds of locomotives tried at Birmingham. The course marked out was over a mile, over hedges and ditches, and across ploughed fields. In the hedges an opening was made a little wider than the engine, and earth was thrown into the ditches. The locomotives were started, and they went over the fields and ditches. Some of them stuck fast, and were never got out; but the majority of them got to the end of their journey, and did remarkably well.

## ELECTRIC CRANES.*

BY REGINALD BOLTON.

The use of hoisting machinery forms a subject of interest to many engineers, while the question of its economies is of even deeper interest to all those engaged in the transport or movement of materials. The application of electricity to this particular purpose is one that at first sight may not present great apparent advantage, but a consideration of the conditions to be fulfilled will, on the contrary, show that there is no more suitable conjunction of force and duty, and even at the present stage, no purchaser of hoisting machinery can afford to disregard the claims of the conveyance of power by electricity, for reasons which the author hopes, succinctly, to show.

There are three considerations which present themselves, and which, if answered affirmatively, cover the whole subject.

Naturally, the primary one is,

1. Its comparative economy.

The second in order is,

2. Its superior merits.

The only remaining consideration being,

3. Its practicability.

Under the first we have to look into a few of the figures of electric and steam motors on cranes.

Now, an electric motor is in itself a most economical transmitter of power, its efficiency running as high as 90 per cent. in regular work, and if worked under proper conditions, its life may be as long as that of any ordinary steam engine, while under the special safeguards designed by the author its durability would be far more prolonged. But the power must necessarily be generated and conveyed to this motor, and so the question of the economy of the generating dynamo and the power that drives it comes into question. Such directly-connected engines and dynamos as are used on board ship, and in numerous central-station installations on land, have repeatedly given a united efficiency of over 80 per cent. of the horse-power of the steam in the cylinder.

There are a far greater number of cases, however, where such a dynamo would receive its motion direct from a shaft driven by a larger engine, and in such a case an even superior result might be relied upon. It would, in fact, be safe to assume an output of 85 per cent. of the actual power put on to the dynamo

* Abstract of a Paper read before the Civil and Mechanical Engineers' Society, February 18, 1891.

Digitized by Google

pulley, in the shape of electrical force, and as, in the case of shop cranes, or wharf cranes, they would not be remotely situated from the generating dynamo, the loss in transmission would be small and can be stated at 1 per cent. to 2 per cent. only.

In the case of a large dock, with cranes situated at all parts, there would be greater distances to be dealt with, but even these would not exceed the limits of ordinary low-tension circuits, and the system would show a very favourable comparison in losses by transmission, as against the distribution of hydraulic power.

For all ordinary conditions, then, we may deal with the following figures :—

| | | |
|---|---|---|
| One h.p. put into dynamo results in ............... | ·85 | of 1 h.p. |
| Less by loss in transmission two per cent......... | ·0085 of | ,, |
| Leaving the force put into motor as.................. | ·8415 | of a h.p. |
| Output of motor 90 per cent. ........................ = | ·7573 | of 1 h.p. |

Or a total loss of less than 25 per cent.

Now take the comparative case of a steam driven crane, say of two tons power, having two cylinders each 5½in. diameter by 8in. stroke, running at 150 revolutions per minute. Such engines are on full work linked up to cut off steam as late as ⅝ to ¾ of the stroke, and thus exhaust their steam at a considerable pressure. The usual boiler pressure is 70lb. maintained at an average of about 65lb., and wire-drawn by pipes and connections to, say, 60lb. initial pressure. Under above conditions they indicate about 14½ horse-power, but their consumption of steam is very considerable, and cannot be assumed at less than 35lbs. per horse-power per hour. An excellent authority gave, recently, instances of such small high-speed engines absorbing over 40 lbs. per horse-power per hour. The net efficiency is still further reduced by the internal friction of the machines, which even in good engines would average 15 per cent., so that we arrive at a final efficiency of these engines used as motors on cranes of not more than 60 per cent.

On all small steam cranes, however, there is a further waste in the boilers, which, being small and of the vertical type, are far from economical in raising steam, and habitually consume 5 to 7lbs. of fuel per horse-power per hour. In practice no crane is ever continually at work, and during the periods of lowering, changing gear and stops, &c., the fuel continues to burn, and there is also the cost in fuel and labour of raising steam in the morning for the day's work.

It is customary among crane builders to construct the boilers of steam cranes a good deal smaller than would be necessary if the engines were in constant running ; the gain in pressure during the stops and changes mentioned compensating the loss of pressure during working, and the steam gauge is consequently constantly on the move. Now, against these figures we should have, in the case of a direct-driven dynamo, a better engine running with an earlier cut off, and also necessary steam more economically raised. The motor when the crane is standing wastes no power, and the dynamo may be shut down or started at short notice. The crane driver need pay no attention to the crane when standing idle, and he starts without delay in the morning, the power being derived from the shop boilers. There would thus appear to be a very decided economy in favour of the electric cranes, as against steam-driven machines. In the case of overhead travellers, there is the saving due to the absence of long square shafts running in movable bearings, and which, together with the cotton or wire ropes in rope-driven cranes, are kept constantly running even when the crane is out of use.

## THE DISTRIBUTION OF ELECTRICITY, WITH SPECIAL REFERENCE TO THE CHELSEA SYSTEM.*

BY MAJOR-GENERAL C. E. WEBBER.

Before the opening of the discussion, General Webber directed attention to several alterations which had been made in the Paper since it was read.

DISCUSSION (Authorised Abstract).

Mr. KAPP read a communication from Prof. S. P. Thompson, who said one of the most interesting parts of the Paper was that relating to continuous-current transformers. He had often urged the importance of this particular mode of transformation, and in a Paper read before the Physical Society three years ago had pointed out the properties of such machines. According to the theory there given the "coefficient of transformation" was the ratio of the number of windings, and was independent of the speed or the magnetism of the magnets. The effect of the resistance of the primary circuit on the potential difference at the terminals of the secondary was to virtually increase the resistance of the secondary, and if equal weight of copper be used in the two circuits the latter resistance is virtually doubled. Hence constant pressure at the terminals of the secondary can be obtained by supplying the primary from a suitable over-compounded dynamo. In the same Paper he showed that the mutual induction between the two windings reduced sparking to a minimum. He now inquired whether the results arrived at theoretically were confirmed in practice.

Prof. FORBES said most people who had only seen the diagram of the automatic arrangements considered them very complicated. Such had been his own impression, but on seeing the apparatus itself and watching its action, the impression faded away. The amount of attention required by the apparatus is immensely less than in any non-automatic system, and for this reason Mr. King deserved great praise. The installation of continuous-current transformers he considered very interesting, In the data given of the Wolverhampton machine, it stated that the efficiency was 92 per cent. at a load of 40,000 watts. It was not quite clear what was meant by this efficiency, whether it referred to the complete machine or only to the dynamo part of it, Prof. S. P. Thompson had said the E.M.F.s should be in the ratio of the windings, but this did not seem to hold in this machine for the turns were as 200 to 80, whereas the E.M.F.s were as 5 to 1. On these points he asked for explanations. General Webber, he said, had stated that it was not necessary to comply with two of the rules he (Prof. Forbes) had laid down in his Cantor Lectures of 1885. The first of these, viz., that each distributing box should be nearer the station than any lamp fed from it, was still debatable, for it is chiefly a question of copper, and where the distribution is purely at low pressure the rule is still an important one. In high-pressure systems, however, it is not essential, although, as a general rule, the principle is a right one. The second rule, that small groups of lamps should be fed by separate wires, he agreed was not necessary. On the question of frosted bulbs he entirely disagreed with General. Webber's statements, for they are essential to artistic lighting. In no case was it desirable that the naked filament should be seen by the eye Further, he considered that a room illuminated by frosted lamps appeared lighter than one fitted with clear ones, for the illumination is mainly estimated by contrast with the brightest thing present. The intense brightness of a naked filament thus causes other things to appear dark. Little, if any, light was necessarily lost by the use of frosted bulbs, and what was absorbed was due to the dirt which the frosting collects. General Webber's conclusion as to the use of 8 or 16 candle-lamps was one in which he could not concur. Much depended on the size and character of the room illuminated. No general impression was of any use in comparing illuminating power, and to make any satisfactory comparison, some definite test, such as the ease with which small type can be deciphered, must be made. Referring to the Board of Trade regulation respecting declaration of varying pressures at different parts of a system, he said this was not originated by the Board, but was granted on the application of the St. James' and Pall Company. If care be taken in designing the mains the actual pressure need never be less than the declared pressure. Difficulties, however, had occurred in America, owing to the mains not being laid along the shortest routes. Speaking of underground mains he said some method of drawing in the cables was very desirable, especially in a growing system, and thought the chief objection to the "layer and faggot" plan so largely used in New York was its great expense. Bitumen concrete was open to several objections, for it could not be considered an insulator, was not waterproof, and was rather liable to fracture ; the casing might thus fail to provide that protection which it is so desirable should be given to the cable. The Callender "solid system" of embedding cables in bitumen was not to be recommended, for after they are once laid the cables are practically inaccesible. Two such mains which he had recently tested at Bath gave insulation resistances of 30 and 40 ohms respectively. The apparatus in use at Bath for localising faults was, he said, very effective. It consists of a trolley carrying iron plates on which coils of wires connected with a telephone are wound. A varying current, such as produced by a Thomson-Houston Arc Lighting Dynamo, or by an alternator, is sent into the faulty line, and the trolley wheeled along the route. When a fault is passed, a distinct change occurs in the character of the sound emitted by the telephone. In conclusion, he regretted that the cost of the Chelsea system had not been given, for this would have added enormously to the interest of the Paper.

Mr. CROMPTON said the Paper should be one of extreme interest, for it described a system of distribution which is hitherto unique. It was the only complete system of storage on a large scale in which the cells were charged at high pressure and discharged at low presure. Three years ago, in a Paper read before the Institution, he he himself compared the merits of secondary battery transformers with the alternate-current system, and these pointed out the value of batteries. He then proposed to use accumulators in a modified way, viz., utilising them at the times of largest and of least demand. This proposal, he thought, showed considerable foresight, for almost all continental specifications now involve the same idea. Since that time he had prepared tables, showing what proportion of the demand could be economically supplied by batteries under various conditions, and in all cases this proportion is small. The Chelsea system, involving, as it does, a great number of cells, was necessarily very costly, and in his opinion the automatic apparatus was too complicated, and therefore liable to failure. He was disappointed at not finding a statement as to the cost of the system, for the time had now arrived when a comparison of statistics would benefit the whole industry. Part costs, and those of isolated tests, were of no use, and might be misleading ; the monthly bills were necessary to a correct understanding. The St. James' Company and his own had published their figures, and he hoped other companies would do the same. It was important to know both the cost of generating a unit at the terminals of the dynamo, and also what is lost in distribution. On the latter point General Webber says his loss is 28 per cent. Mr. Crompton thought this rather low, for if the accumulators were in perfect order he would expect a loss of 25 per cent. If, therefore, all the losses in switchboards, feeders,

* Paper read before the Institution of Electrical Engineers, January 22, 1891.

distributing mains, service lines, and meters only brought the loss to 28 per cent, General Webber's experience must be felicitous. On the question of underground mains Mr. Crompton said it was a marvel to him how General Webber had arrived at the cost of his (Mr. Crompton's) system, for if he had referred to the 1888 Paper he would have found figures differing widely from those given. In order that a comparison of actual costs might be made the following table was prepared. The bitumen casing he considered an excellent device, and was not at all sure that it was not the best where it can be got in. Probably it would outlast wrought iron pipes. Pipes, however, could be preserved by serving them with jute or yarn and soaking in bitumen. Whilst acknowledging the value of the casing he must qualify it by saying that Callender cable was not the best to use with the casing. Good india-rubber cable gave excellent results. The table shows the culvert system is the cheaper for ordinary sized mains wherever it can be put in; the cost there given cannot be reduced. Referring to the circular issued by the London Chamber of Commerce, which General Webber had criticised, Mr. Crompton said it was circulated with the object of obtaining other peoples' opinions on the subjects dealt with. Considering the imperishable nature of the materials used in constructing culverts, and of the bare conductors themselves, 1 per cent. of the total cost would provide a respectable sum to cover depreciation and the repairs necessitated by wear and tear in withdrawing and inserting conductors. In fact, experienced persons whom he had consulted on the subject considered ½ per cent. sufficient. With covered cables, the depreciation and risk of injury were much greater, cases having occurred where, in attempting to withdraw a cable, the copper had been drawn out of the insulation. Taking all into consideration, he thought 5 per cent. was not too high, and on the whole he was inclined to believe that the covered, rather than the uncovered, system had heen favoured.

Mr. F. KING said he would have been pleased to hear more comments, adverse or otherwise, on the system of distribution described in General Webber's Paper. The probable life of secondary batteries was an important factor in the cost of such a system. In the Paper the positives were estimated to last three years, and the cells had now been in use about 18 months. During this period only 30 single plates out of 57,970 in use, had been supplied to Chelsea, and these had been required through accidents. On the subject of ultimate maintenance rate, he pointed out that in 1888 the E. P. S. Company guaranteed to maintain batteries for 12½ per cent. on the cost price and, judging from the experience gained at Chelsea, he looked forward to a fair margin of profit. If the positives only lasted three years this would mean 7·3 per cent., and if the negatives had a six years' life their cost will be 3·9 per cent., thus making a total of 11·2 per cent. He had reason to hope that both kinds of plates would last considerably longer than the times mentioned above. He was sorry that no remarks had been made on the regulation of pressure, for he believed the system described to be one of the most perfect ever used. The curves traced by the recording voltmeters, and shown in Figs. 13 and 13A, illustrate how good the regulation is. Continuous-current transformers could, he believed, be used as additional sub-stations, and if care be taken to connect the machine to separate feeders the pressure in the distributors could be kept within ½ or ⅜ of a volt. A considerable saving of copper in the mains can also be effected by arranging the transformer so that it supplies current at about one volt greater pressure during the period of greatest demand. In answer to Prof. Forbes' question about the transformation coefficient of the Wolverhampton transformer, he said the 200 turns on the primary was probably a misprint for 400.

Mr. W. HOWARD TASKER agreed with Prof. Forbes that the Callender cables he had recently tested at Bath were defective. In Chelsea, they had got much better insulation, one circuit carrying 3,000 lights showing a resistance of 20,000 ohms, and up to the present time there had been no occasion to withdraw any cable, excepting to put in larger ones. As regards meters, he said the Aron meters, of which 250 were in use at Chelsea, were very satisfactory. Referring to Fig. 10, he pointed out the remarkable increases of load during the last quarters of 1889 and 1890, whereas in the first quarter of 1890 the demand was fairly constant.

Mr. MORDEY, speaking of the fault finder described by Prof. Forbes, said Mr. Henry Sayers had successfully used the same arrangement at Oporto for two years, and he believed Mr. Spagnoletti had also employed a similar device. He was much interested in Mr. King's remarks about continuous-current transformers, and thought they might be of considerable use where long distances were involved. For short distances, however, the triple loss in the generating dynamo and in the primary and secondary of the continuous-current transformer would be serious, and in this connection he inquired the relative cost of working direct and by transformation. He was glad to see that converters had been employed, and he thought the Company would regret that they did not put stationary transformers in. Speaking of the life accumulators, he said the 12½ per cent. guarantee mentioned by Mr. King would be very nice, provided they could get it in a practical shape. When the Company were pressed on the point they rather hesitated, and would only undertake the maintenance under certain conditions, which were difficult for ordinary engineers to fulfil. Unfortunately, there were no men outside the Company's works skilful enough to look after the batteries in the way required.

GENERAL WEBBER, in his reply, said he could not answer Prof. Thompson's questions, for the transformers had only been worked at their full output. The perfect balance of the armatures is, however, an important feature in the machines. To Prof. Forbes' inquiry about the efficiency of the Wolverhampton transformer, he said he understood it to mean that of the whole machine. He said he could not agree with Prof. Forbes on the subject of frosted bulbs, for he was of opinion that the light should pass direct to the thing to be illuminated. On the other hand, the filament should not meet the eye, and the bulbs might be frosted on the portions seen. Such lamps had recently been made. As pointed out by Prof. Forbes, the Board of Trade regulation on the declaration of varying pressures is useful under certain conditions, but in a growing system it gives little or no relief. Its only use seems to be at the boundary of a district. On the subject of underground mains, he said that bitumen casing, although not an insulator, gives assistance to the insulation on the cables. The embedded cable at Bath he had only spoken of in connection with a high tension system, and in such cases their use was justifiable, for the amount of copper was so small that ample allowance could be made for increased demand. The figures he had given respecting the cost of Mr. Crompton's mains had been arrived at by careful estimates prepared by a surveyor and himself, which gave £130 as the cost of 100 yards. In the table given by Mr. Crompton it was hardly fair to put a pipe with a hole 1½in. diameter on the same footing as a 2in. or 2½in. way in a Callender-Webber casing, and if this were taken into account the difference in cost would be rather the other way. This difference would not be large for ordinary sized mains, and as he had pointed out on page 19, bare copper conductors were cheaper when the section exceeded 1½in. Speaking of the cost of the Chelsea system, he said it would be unfair to give figures relating to the initiation of a new system for difficulties and expenses; such as those connected with experimental foundations for machinery, &c., would give a false impression as to the real working cost. He had, however, given figures for the boiler efficiency, and the losses in generation, conversion, and distribution, together with the cost of coal per unit sold, and these, he thought, were the important things. In reply to Mr. Mordey's remarks, he said the system of conversion was not nearly identical with the system with which Mr. Mordey is connected. The real point which determines the system it is best to adopt is the density of supply, but the conditions are so variable that it is difficult to lay down any rules. The question as to how far apart the distributing stations for a given district should be placed, and in what way this depends on the size of copper to be laid down, still awaits an answer, and when this is forthcoming some useful data will have been arrived at.

## PHYSICAL SOCIETY.

The annual general meeting was held on February 13, 1891, Prof. A. W. Reinold, F.R.S, Past President, in the chair.

The reports of the Council and treasurer were read and approved. From the former it appears that there has been a satisfactory increase in the number of members, and in the average attendance at the meetings. During the year a translation of Prof. Van der Waal's memoir on "The Continuity of the Liquid and Gaseous States of Matter" has been issued to members, and it is hoped that the translation of Volte's works now in hand will be published before the next general meeting. The Council regret the loss by death of Mr. W. H. Snell and Mr. W. Lant-Carpenter, and obituary notices of these late members accompany the report. The treasurer's statement shows that the financial condition of the Society is very satisfactory, and that the sales of the Society's publications have increased considerably.

After the usual votes of thanks the following gentlemen were declared duly elected to form the new Council: President, Prof. W. E. Ayrton, F.R.S.; Vice-Presidents, Dr. E. Atkinson, Walter Baily, M.A., Prof. O. T. Lodge, D.Sc., F.R.S., Prof. S. P. Thompson, D.Sc.; secretaries, Prof. J. Perry, F.R.S., T. H. Blakesley, M.A., M.Inst.C.E.; treasurer, Prof. A. W. Rücker, M.A., F.R.S.; demonstrator, C. V. Boys, F.R.S.; other members of Council, Shelford Bidwell, M.A., LL.B., F.R.S., W. H. Coffin, Major-

General E. R. Festing, R.E., F.R.S., Prof. G. F. Fitzgerald, M A., F.R.S., Prof. J. V. Jones, M.A., Rev. F. J. Smith, M.A., Prof. W. Stroud, D.Sc., H. Tomlinson, B.A., F.R.S., G. M. Whipple, D.Sc , James Wimshurst.

The meeting was resolved into an ordinary science meeting, and Messrs. W. Thorp, B.Sc., G. W. Yule, and S. Joyce were elected members of the Society.

A Paper on the "Change in the Absorption Spectrum of Cobalt Glass produced by Heat," by Sir John Conroy, Bart., M.A., was read by Mr. Blakesley.

Prof. Minchin showed some experiments in illustration of his Paper on "Photo-Electricity," read at the previous meeting. In one of these, a seleno-aluminium battery, illuminated by the light of a taper, deflected an electrometer needle, thereby actuating a relay and ringing a bell. He afterwards exhibited one of his "impulsion cells" in action, and showed the change from the insensitive to the sensitive state produced by a Hertz oscillator at a distance.

DISCUSSION.

In the discussion, Mr. TUNZELMANN said Kalischer and Von Uljanin had worked at the same subject, the former being the first to make experiments on a photo-E.M.F. in selenium. His cells were made by winding brass wires on glass tubes and coating them with selenium, which was subsequently annealed. These cells lost their power after some time, and could not respond to feeble lights. By using two wires of different metals we obtained better results. Fritts, in 1883, used brass and gold plates coated with selenium, and Uljanin employed platinum plates deposited so thin as to be transparent. The latter experimenter found that the E.M.F. was proportional to the square root of the intensity of the light. He also observed that the orange-yellow of the prismatic spectrum produced the greater effect, whereas the yellow-green and the green rays of the diffraction spectrum gave the maximum E.M.F. Comparing these results with Langley's observations on the energy of the spectrum, it would appear that the E.M.F. bears no relation to the maximum energy falling on the surfaces. Speaking of the cause of the phenomena, he said the electrolytic dea of Von Uljanin seemed inapplicable to Prof. Minchin's results, and he inquired whether a mixture of selenium and aluminium would undergo a gradual change by exposure to light.

Dr. GLADSTONE said such a change, if it occurred, would be very slow, for nearly all difficult chemical reactions take time to complete. The fading of colours was adduced as an instance of slow chemical change produced by light.

Dr. WALLER thought the subject might throw light on the changes occurring in the retina, and asked if it was possible to separate thermo-electric and photo-chemical effects?

Dr. BURTON said he had suggested that the action of light on the retina was a photo-chemical one, some time ago. But hitherto it had been difficult to obtain substances sensitive to any but the blue and violet rays, whereas the eye was most sensitive to green and yellow light. In the photo-electric batteries, however, the E.M.F. may generate a current, and therefore energy, and the important question seemed to be, where does this energy come from? Is it a chemical change, precipitated by the action of light, or does a direct conversion of light into electric energy occur?

Prof. MINCHIN, in his reply, said he thought his cells really transformed the incident energy. They were usually kept on open circuit, and there appeared to be no deterioration with time, the only change being a sluggishness in developing their maximum E.M.F.

## ALLOYS FOR RESISTANCE COILS.

BY DR. K. FEUSSNER AND DR. ST. LINDECK.

As is well known for the purpose of electrical resistance coils for exact measurements, it is best to use alloys and not pure metals, owing to the large increase of resistance that takes place in the latter when their temperature is raised. For pure metals this increase generally amounts to ·004 for each degree Cent., whilst for most alloys it is considerably less; in German silver, for instance, an alloy of 4 of copper, 2 of zinc, and 1 of nickel, it is only about one-tenth as large.

A series of tests have been conduced by the authors on various materials with the view of determining their applicability for this object. Some of the results for eight different wires are given in the annexed table. As will be seen, this contains first a statement of the constitution of the various wires (in the cases of the first six as determined from analysis at the Government laboratory, for the other two from the manufacturers' certificates), the specific resistance in microhms per cubic centimetre, and the temperature coefficient.

Column I. gives figures for the German silver, ordinarily used for resistance coils by Messrs. Siemens & Halske. Under various conditions this wire shows remarkable changes in its resistance, and such changes tend almost always towards an increase. When the wire is coiled its resistance increases, and the smaller the coil, the greater the increase. Where the diameter of the coil is ten times the diameter of the wire, the increase amounts to ·01 of the original value. After coiling, and when the layers are undisturbed, the resistance still goes on increasing, but at a continually diminishing rate. During the first eight days after winding, the increase amounted to ·0003. Warming the wire for the first time to a temperature of 40deg. Cent. generally increases its resistance by ·0004 of its value. After a long continued heating to a high temperature the effect of a subsequent heating became less noticeable, but never entirely disappeared. Generally the resistance of such wires never becomes quite constant, the variation sometimes amounting to ·0001 in a few days.

For exact measurements a wire of such properties is very unsuitable. What is wanted is an alloy, as far as possible, free from this variability, and also possessed of a low temperature coefficient. First nickelin, which has lately often been used, was tested. The results obtained from two varieties of this wire, as made by Herr Obermaier of Nuremburg, are given in columns II. and III. Chemical analysis shows that they are virtually German silver with somewhat increased proportions of nickel, and that they can therefore hardly justify their claim to a special name. Their resistance is, however, higher, and their temperature coefficient lower than that of ordinary German silver. Tested for constancy of resistance they showed an improvement on German silver, though the above-mentioned faults still existed.

In the fourth column are given the results obtained with Dr. Geitner's "rheotan," a wire lately brought out specially for resistance coils. Chemically it differs from the nickelin of column III. only in the replacement of 4 per cent. of zinc with iron. Its high temperature coefficient makes it less suitable for resistance coils than nickelin. At the same time, from its chemical composition, it can hardly be expected to give much better results with regard to constancy, but owing to our not having any wire of convenient thickness at hand we cannot give the results of experiments on this point.

To explain the continuous alteration in resistance of the above wires, it must be pointed out that the operations of casting, drawing, &c., always produce a tendency towards a crystalline structure. We conjectured, therefore, that the variability of the resistance depended upon the presence of zinc, which is easily crystallisable, and we accordingly looked for an alloy of nickel and copper or nickel and silver only. Whilst still thus engaged, we obtained from Messrs. Siemens and Halske a resistance-coil with the extremely low temperature coefficient of ·00017. By the courtesy of these gentlemen we learnt that the wire of which it was made was obtained from Messrs. Basse and Selve, of Altena, and we received samples thereof for testing bearing the label "patent nickel." Columns V. and VI. give the results obtained for wires of two different thicknesses, the analysis showing that no metals other than copper and nickel were present to any appreciable extent. Tests were carried out as to the constancy of their resistance, exactly as was done with the German silver and nickelin wires. On being wound, the resistance rose as in the former case, though to only half the extent, and on being left to itself for a few days, the resistance of the coil returned to its orignal value, which never happened with the others. On being heated the resistance fell, but a coil which had once been heated for some hours to 150 degrees showed no permanent alterations after subsequent heatings to 100 degrees, and is at present perfectly constant.

On the general behaviour of wires with regard to changes in their resistance we have arrived at the following conclusion. By all mechanical operations, including the winding of coils, the substance of wire is subjected to stresses which harden it and raise its electrical resistance. By a subsequent heating the former condition may be gradually restored, as in the case of annealing. Moreover, in the case of German silver and nickelin wires a gradual change towards the crystalline state or a crystallising out of certain constituents is always going on, and through this the

From the *Zeitschrift für Instrument-Runde*.

Digitized by Google

electrical resistance slowly increases. Under the influence of heat this change goes on more rapidly. In alloys of nickel and copper, which are free from zinc, this tendency to change to the crystalline state does not exist, and, consequently, wires of this sort, after being heated to a certain temperature, possess a definite fixed resistance for any temperature below this.

So far as our observations therefore go, patent nickel is exceedingly well adapted for the construction of exact resistance coils. Its extremely low temperature coefficient is an additional advantage.

We also devoted attention to the manganese alloys lately brought out by the Isabellen factory near Dillenburg, particularly to those varieties which, according to Weston, possess a negative temperature coefficient. For the purposes of our examination we obtained pigs of alloy from the factory, and by means of a saw cut them into strips, which were then drawn into wire. The metal is very tough, and draws well, but sawing it is very difficult. Manganese copper (column VII. in the table) is steel-grey in colour, nickel manganese copper (column VIII.) being pale rose. Our chemical analysis of the two are not yet completed, and we, therefore, give the manufacturers' figures for their constitution. The specific resistances and temperature coefficients given can also only be regarded as preliminary. It, however, appears that the temperature coefficients are in both cases very small, whilst that of the second (column VIII.) is undoubtedly negative. Moreover, the extraordinarily high specific resistance of manganese copper is worthy of notice.

We have, therefore, to distinctly assert that alloys are to be found whose resistance decreases with an increase of temperature. It is obvious that these materials are of great importance in the manufacture of resistance coils, especially if by a combination of such materials a wire can be produced with a zero temperature coefficient. This and other interesting points we hope to be able to clear up on a future occasion.

## PARLIAMENTARY INTELLIGENCE.

### HOUSE OF COMMONS, Thursday, February 12th.

### Electric Railway Bills.

In the House of Commons on Thursday night, last week, on the order for the second reading of the Central London Railway Bill, Mr. T. H. BOLTON, who had a motion on the paper embodying an instruction to the Committee, stated that, as he had given notice of a similar instruction in the case of the South Kensington and Paddington Subway Bill, he would take the discussion upon the latter measure. The Central London Railway Bill, accordingly, was read a second time, and was remitted to a Special Committee.

On the motion for the second reading of the South Kensington and Paddington Subway Bill,

Mr. BAUMANN said before the Bill was read a second time, and before the House proceeded to discuss the proposed instruction, he desired to enter his protest against the promoters of this Bill in regard to the second reading. This Bill proposed to make a subterranean railway from Bishop's-road, Paddington, underneath Kensington-gardens, to a point behind the Albert Hall in the Exhibition-road, a part of London which was commonly known as South Kensington, although, as a matter of fact, the station was, he believed, in the parish of St. John, Westminster. This scheme raised a very important metropolitan question. Obviously this was a Bill which ought not to be sent to a Committee in haste. He thought without demur he should have been allowed to ascertain the feelings of the 60 metropolitan members, and to give London an opportunity of expressing its opinion upon this proposed invasion of Kensington-gardens. But not a day was conceded to him by the promoters. He had never previously experienced any difficulty in meeting with the promoters of private Bills and arranging for the date of the second reading. The London County Council and the Corporation of London were always most obliging in fixing a day which would suit the convenience of hon. gentlemen. The result of the tactics of the promoters of this Bill was that he had not had time to consult with the other metropolitan members, or to ascertain the feeling of London. He should like to know why the promoters of this Bill were so nervously anxious to force the Bill through the House in such a desperate hurry. Promoters of a genuine and popular scheme for the benefit of London, as a rule, invited discussion, and he was afraid the promoters of this Bill thought that the more it was looked at, the less it would be liked. He did not feel justified in attacking the Bill on its merits, but he made this protest in the hope of drawing attention to the fact that Kensington Gardens were to be tunnelled under and a station erected in the heart of the gardens for no other purpose than to put money into the coffers of the Albert Hall. He hoped before the third reading a sufficiently strong public feeling would be aroused to save Kensington Gardens from this fate, and prevent this iniquitous measure becoming law.

Mr. WHITMORE, as one of the promoters of the Bill, regretted that the hon. member had not had the opportunity of ascertaining the feeling of hon. members on this subject. He hoped the House would not interpose any obstacle to the further progress of the Bill as he believed the subway would not interfere in any way with Kensington Gardens. If should appear that any injury, real or sentimental, would accrue, he would join his hon. friend in opposing the Bill on the third reading.

Mr. COURTNEY said that, so far as he knew, the promoters of the Bill had done nothing unusual, and there was no justification for the attitude of Mr. Baumann.

After some further discussion, the Bill was read a second time.

Mr. T. H. BOLTON then moved: "That it be an instruction to the Committee to whom the South Kensington and Paddington Subway Bill is committed, that they consider the propriety of inserting clauses in the Bill requiring payment to the local authority of a royalty, or a share of the earnings of the subway, after fair interest on capital and working expenses have been provided for, as compensation for the right to tunnel under the public streets." He explained that while, as a matter of convenience, he raised this question on the present Bill, it applied equally to the London Central Railway Bill and other schemes involving the construction of tunnels which were likely to come before Parliament. The experiment of the first tunnel railway—that from London Bridge to Stockwell—had proved both an engineering and a financial success. The fact that it is was a success would lead the investing public to have confidence in schemes of this character and ample capital would be forthcoming to carry them out. In view of the many tunnel railways that were likely to spring up all over London the question raised in his amendment became one of very great importance in the interests of the public. The promoters of the Bill under consideration—the South Kensington and Paddington Subway Bill—proposed to make a tunnel under the public streets without the payment of compensation to anyone, and the proposition he was putting forward was that the public had a right to require some compensation for the user of the subsoil under the public street. He knew it would be suggested that the absolute freehold of the soil was not invested in any public body; but that was very much more a purely legal assertion than a statement of any practical value. The shadowy right of the landowner in the public road was hardly worth consideration alongside the right of the public. The public were for all practical purposes the owners of the roads. For the purpose of saving expense, a private company of capitalists came to Parliament and asked Parliament to give them legislative powers to use the subsoil of the road without paying anybody anything for it, and he affirmed that the public had not only a moral, but, to a very large extent, a legal, claim to consideration in connection with the making of these tunnels below the public streets. To require the company to make an actual money payment to the public would, of course, be to place a very heavy burden upon the promoters; but he suggested that it would be reasonable and fair to ask them to pay a royalty, or give to the public a share of the earnings after interest had been paid upon capital and the working expenses were defrayed. He did not believe that a provision of this kind would in any way seriously embarrass the company. He did not propose to order the Committee to put a clause of the kind he suggested into the Bill, but he wished the House to direct the Committee to consider the propriety of inserting such a clause.

Colonel MAKINS said the hon. member had enunciated an entirely new principle in dealing with companies, and he thought it rather hard that this particular company should be selected for the experiment. Powers were never granted by Parliament to any private company unless it was for the public benefit, and Parliament would take care that the public obtained benefit in one way or another. This Subway Company would be in the same position as gas, water, and tramway companies, and yet it had never been sought to make the public partners with these companies in their undertakings. All such companies were rated for the poor, and paid a very large sum into the coffers of the local authorities in the way of rating.

Mr. ESSLEMONT said no Committee would sanction this subway scheme, or any other scheme, unless they considered the project itself to be in the interest of the public, His friend proposed to give the public a share in the profits of a private company if that company was a success. If the company was not a success, however, the public would contribute nothing to the cost of the failure.

Mr. H. LAWSON trusted the promoters would see their way to accept the instruction in the interest of the public.

Mr. ISAACS objected to the proposed instruction, first on legal grounds; and, secondly, on the ground of equity. The subsoil of the roads was vested, not in the public authority, but in the owners of houses on either side. Omnibuses which actually used the surface of the roads were absolutely exempt from taxation, although omnibus companies, as a rule, paid large dividends. These omnibus companies did not even contribute to local taxation for the running of their omnibuses.

Mr. JAMES ROWLANDS pointed out that there was a difference between railway and omnibus companies. The former were granted a monopoly by Parliament, while it was open to any person to start a service of omnibuses upon the public roads. He did not think any reason had been given why the House should not pass this instruction. It was time to decide whether some lien ought not to be put upon these companies for the benefit of the community.

Mr. COURTNEY said Mr. Bolton had undoubtedly brought a very grave question under the notice of the House. There were many different forms in which the interests of the public might be protected in connection with schemes of this character. He would suggest that one form might be to give the public as cheap a service as possible by the new line. Parliament might insert a provision to the effect that when the project made profits to a certain extent the public should get the benefit in reduced fares.

Mr. WALTER JAMES thought the common-sense view was to look upon the promoters of such a scheme as this as the very best friends of the local authority, because unless new methods of locomotion, either underground or overhead, were carried out, the growing wants of the ever-

Digitized by Google

increasing population of the metropolis would compel the local authorities to make more streets.

Mr. BOLTON said that after the representations which had been made to him, and relying upon the Committee giving full consideration to the matter, he would not press his instruction.

The proposed instruction was accordingly withdrawn.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 7, 1891.

**Electrical Statistics.**—A very elaborate series of maps has just been issued by the Thomson-Houston Electric Company showing the location of all the electric light and electric railway plants in the United States, together with the system or systems in use in each place. These maps have been prepared from data collected from original sources by disinterested persons, and has been admirably done, involving, as it does, an enormous amount of work. The statistics of the different systems as gathered from these maps show that the Thomson-Houston system of electric lighting is in use in a very much larger number of plants than any other system in the United States. The following are the exact figures of the different systems as shown by the schedule :—

| | | | |
|---|---|---|---|
| Thomson-Houston | 666 | Excelsior | 25 |
| Westinghouse | 323 | Sperry | 24 |
| Edison | 202 | National | 16 |
| Brush | 199 | Remington | 4 |
| Fort Wayne | 144 | Eickemeyer | 2 |
| American | 67 | Hawkeye | 2 |
| Western Electric | 53 | Standard | 1 |
| United States | 51 | Hochhausen | 1 |
| Schuyler | 49 | Beard | 1 |
| Heisler | 49 | Knowles | 1 |
| Waterhouse | 41 | Mayo | 1 |
| Ball | 31 | Keith | 1 |
| Van Depoele | 31 | | |

Of electric railway plants there are ten distinct systems in use, having a total of 241 installations. The actual number as shown for each system is as follows :—

| | | | |
|---|---|---|---|
| Thomson-Houston | 103 | Short | 8 |
| Edison | 83 | Storage | 4 |
| United Electric Traction | 21 | Westinghouse | 3 |
| Van Depoele | 8 | Bentley-Knight | 1 |
| Rae | 8 | Underground Storage | 1 |

Considering the fact that the first Thomson-Houston electric road was put in operation about July 1st, 1888, its present showing is a remarkable one.

**The Westinghouse Company.**—The Westinghouse Company is very rapidly recovering from its financial difficulties, and this is a matter of congratulation for all who are in any way interested in the electrical business. The prospects are that in a short time the Company will be upon a sound financial basis. It continues to do an enormous business in electric lighting and electric railway installations. Although only three of its roads are yet in operation, a large number are under contract and in process of construction.

**Electric Welding in Canada.**—It is reported from Canada that the Canadian Edison Company, whose factory is now at Sherbrooke, Quebec, but which will soon be transferred to Peterborough, Ontario, has made a contract with the Thomson Electric Welding Company, by which the Edison Company agrees to build all the welding machinery for the Canadian trade.

## AUSTRALIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

SYDNEY, *January* 4, 1891.

An event of great interest to the electrical world took place on January 1st, viz., the switching on of the electric light in the City of Newcastle, the second largest city in New South Wales. The Sydney Electric Light Company, who are the contractors for the plant, had until January 7th to complete their contract, but the local gas company's contract with the City Council expired on the 1st, and the gas company demanded £50 per week and a month's notice, or, in other words, asked £200 for lighting the streets for the seven days between the termination of their contract and the commencement of the new one with the Electric Company. This price the Council considered simply absurd for 400 lamps, and refused it. By working pretty well night and day the electric lighting contractors' representatives succeeded in lighting the major portion of the lights on New Year's night, the plant running smoothly from the first, and the light apparently giving great satisfaction. The main street is lighted by 22 arc lamps of the Brockie-Pell type slung from wire rope in the centre of the street, the effect being very good. These lamps are supplied with current from a Brush dynamo, driven by a Westinghouse engine. In the smaller streets are placed about 400 incandescent lamps of 25 candle-power run in series of 20, and the effect from these lamps is also good, and is a marked improvement on any incandescent street lighting yet seen here. The incandescent plant is on the Westinghouse alternating current-system, this being its first introduction into the Colonies, and consists of two 750 light alternators. The engines employed are of the Westinghouse compound type, and are supplied with steam from a battery of Babcock and Wilcox boilers. The whole plant is very complete, and reflects great credit on all concerned ; and it is to be hoped that the Sydney Electric Light Company will reap the benefit of having carried out such a first class piece of work.

## CORRESPONDENCE.

### ELECTRIC THEORIES—ETHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : I must say a few words in reply to the excellent letter of Prof. Silvanus P. Thompson, p. 464. The point about Ohm's law is not so "transcendental" as he thinks. Debates about mere words are idle, but what seems a mere verbal distinction may prove to involve important principles; just as a slight change of angle on a railway switch may involve an entirely different line of travel. I will show in due course what I mean in this instance, and it will be seen then that my meaning clears off a "time factor," which is involved in that of Prof. Thompson.

I see no objection to his definitions ; the words "in some way or other," are just the point at issue. I am rather doubtful, as to No. 4, whether the words "from the magnet" are permissible. The magnet may be a permanent one, which certainly transfers no energy from itself, and I imagine the same holds for an electro-magnet. I should be more disposed to say "by the agency of the magnet." The energy comes from elsewhere. As to No. 5 I quite accept the definition because it really involves my own contention, that the "primary circuit" is the true carrier of the energy.

I should greatly regret that anyone should imagine that my words implied that Prof. Thompson "shifted his ground" in any invidious sense. I am quite sure that he is, as I know I am myself, sincerely desirous to ascertain "what is truth ;" and would, as surely as I should, scorn any mere dialectic trap, or apparent victory. I merely meant that in the question he put me, p. 375, "with respect to the transfer of energy laterally through the medium, into or out of a conductor," he introduced a matter entirely different from that contained in his words quoted p. 406. I may add that my own words, p. 406, need modification by an added word "that they in no degree transmit the energy *directly* from the source ;" because they do so in the process called induction, as defined in proposition 5, p. 464.

As to the ether, we may ignore it in the discussion ; but none the less it is the real thing which always underlies the word "medium," as Sir W. Thomson says, when treating of Clark-Maxwell's doctrines as to the function of the medium, "it must be ether." However, I shall have nothing to say about it myself, unless as an element of the views I may have to define and oppose.

But I must remark that Mr. Burn's summary of my argument is not complete. I said it had no friction internal or external, and no retarding effect on ordinary matter traversing it. Certainly I do hold that "what has no gravitation can have no inertia," if after gravitation is introduced "or influence upon the motion of matter." I think my meaning is

Digitized by Google

much the same as Sir W. Thomson's when speaking of "a massless fluid; by massless I mean devoid of inertia." Nor am I alone in seeing these consequences and difficulties. Your own editorial article, Vol. XXII., p. 309, indicates the very same doubts.

The question you put, p. 444, "What kind of proof can Mr. Sprague give of the longitudinal theory which he upholds?" I will do my best to answer. It may be that neither theory is capable of experimental proof, though I doubt that; but there is the Euclidean mode of investigation open to us, ending in the phrase, "which is absurd."—Yours, &c.,

JOHN T. SPRAGUE.

## CHELMSFORD LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Our attention has been called to a paragraph in your issue of the 13th inst., *re* Chelmsford lighting. As your paragraph, without further explanation, might lead your readers to suppose that the lighting by the arc lamps has been irregular and unsteady, we beg most emphatically to contradict this statement, and to inform you that the actual question which has been put to us by the Town Council has been the advisability of substituting incandescent lamps for certain arc lamps which are placed in narrow and winding streets, with a view to improving the distribution of the lighting in these streets.

The question is an interesting one in connection with the problem of town lighting, and is receiving our careful attention, but nothing has as yet been decided upon.—Yours, &c.,

February 17, 1891. CROMPTON AND CO. (LIMITED).

## MORE BOARD OF TRADE RULES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice that you state as comment on my letter of last week that the salary of the Electric Inspector of Liverpool is £150 per annum, may I be permitted to correct this figure, as the actual sum paid by the Corporation of this city in accordance with the advertisement in July, 1889, is £160 per annum I do not think it was ever proposed that the Liverpool Electric Supply Company (Limited) should pay the inspector's salary, though, it will be remembered, that in the draft order of 1889 the clause existed stipulating a payment of some £200 per annum to the local authority, which was afterwards eliminated from the Act of Parliament containing the said order.

You will, I think, consider this rather different from the suggestion made in your issue of the 13th inst.—Yours, &c.,

IN STATU PUPILLARI.

# TRADE NOTES AND NOTICES.

"THE ELECTRICIAN"
**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891**

The new edition of our well-known Directory and Handbook will be ready on Monday. The book consists of over 900 pages, and has entailed this year an exceptionally heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

TENDERS WANTED.—The Corporation of Bedford, having obtained a Provisional Order for supplying electricity in the borough, invite tenders for the public lighting, at a price per lamp. Tenders are to be sent to Mr. T. S. Porter, clerk to the urban sanitary authority, Bedford, by the 31st March. Further particulars will be found in our advertising columns.

—— We would remind our readers that tenders for the Glasgow Corporation electric lighting contract have to be in by Saturday, the 28th inst.

DISSOLUTION OF PARTNERSHIP.—Messrs. Wild and Lucraft, trading as the Torbay Cycle Company, 3, Victoria-street, Paignton, Devon, as cycle manufacturers and electrical engineers, have dissolved partnership.

REMOVAL NOTICE.—Messrs. Montagu J. Scott and Co. have removed from Jermyn-street to 134, Regent-street, London, W.

THE "NEW ERA" PENDULUM MOVEMENT.—This rather high-flown name has been given to a very simple pendulum indicator for electric bells. The pendulum principle, borrowed from the old mechanical bell, is worthy of more attention than is commonly paid to it, as such an indicator is much less likely to stick or get out of order than the drop or throw-back patterns. In the movement, of which a sample has been sent to us by the makers' (Messrs. Mix and Genest) representatives, the International Electric Company, a single magnet is riveted to a sheet-iron stamping, which forms a support for a light and freely-swinging pendulum.

## THE PATIN ALTERNATE-CURRENT ARC LAMP.

In June last the Paris municipal authorities had a series of tests carried out on various alternate-current arc lamps, and amongst the competing lamps was that of M. Patin, which excited considerable interest at the time owing to its simplicity and excellent performance.

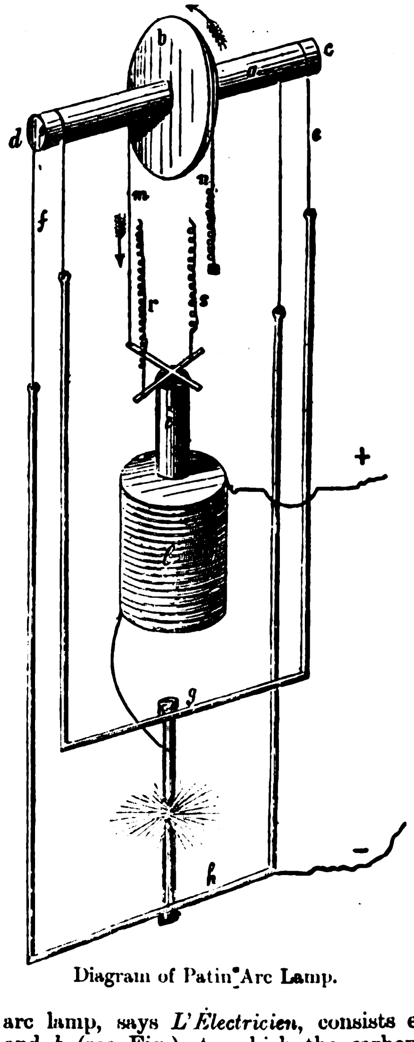

Diagram of Patin Arc Lamp.

The Patin arc lamp, says *L'Électricien*, consists essentially of two frames, *g* and *h* (see Fig.), to which the carbon-holders are attached, and which are joined together by the cords *e* and *f*. These cords are carried round the spindle *a* at the points *c* and *d*, the spindle having at its centre the pulley *b*. Round the groove of the pulley *b* runs the cord *m*, one end of which is attached to the core *i* of the solenoid 1 in the manner shown. The core *i* is also suspended by means of the springs *r* and *s*. The upper frame is sen-

Digitized by Google

sibly heavier than the lower, so that when left to themselves the carbons are in contact. The solenoid 1 is in series with the carbons, and when the current is switched on the core *i* is sucked down, striking the arc. As the arc lengthens and the current diminishes the core is released, and the force of gravity brings the carbons into proximity. These lamps can be made to run without much difficulty with a terminal pressure of only 40 volts. When running several lamps in parallel it is, however, advisable to introduce special regulating coils into each lamp circuit.

## PATENT RECORD.

### APPLICATIONS FOR PATENTS.

**Note.**—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

January 17, 1891.

1,672. W. T. Lord, London. Improvements in laying or running wires for electric lighting.

1,680. A. E. Tavernier, London. A new or improved process for the manufacture of wire for transmitting electric currents.

January 30, 1891.

1,741. H. Howard, London. Improvements in electric welding and in apparatus therefor.

January 31, 1891.

1,779. W. Hartnell, Leeds. Improvements in motors and dynamos for use in mines and other places.

1,788. M. Bailey, London. Improvements in the construction of battery elements.

1,804. G. F. Redfern, London. An improved arrangement of shunt for electric motors. (Wirth and Co., agents for W. Lahmeyer and Co., Germany.)

1,818. J. B. Winder, London. A new or improved preparation of soluble bichromates and sulphuric acid for use in charging voltaic batteries, and for other purposes.

February 2, 1891.

1,844. J. S. Lewis, Yardley. Arm or elbow rests for telephonic purposes.

1,905. L. B. Atkinson, London. An improved method of and means for distributing electric currents.

February 3, 1891.

1,908. D. Maxwell, London. Improvements in electric switches.

1,912. J. S. Lewis, Yardley. An improved galvanometer or instrument employed for measuring, indicating, or detecting electric currents.

1,913. J. S. Lewis, Yardley. An improved electric bell.

1,923. G. Binswanger, London. Improvements in electrical switches.

1,928. C. H. Demuth, Manchester. Improvements in the method of and means for increasing the strength, volume, or intensity of sound during transmission, applicable to telephones, microphones, phonographs, and other sound transmitting and emitting instruments and apparatus.

1,963. M. W. Dewey, London. Improvements in methods of and apparatus for electrically soldering cans and other sheet metal ware.

1,968. H. H. Lake, London. Improvements in and relating to electric lamps or lighting apparatus. (F. V. Macquaire, France.)

1,969. H. H. Lake, London. Improvements in electrical signalling apparatus. (S. J. Burrell, United States.)

1,987. A. M. Clark, London. Improvements in electric lamps. (J. W. Easton, United States.)

February 4, 1891.

1,994. G. Belt, Wolverhampton. An electric light lamp shade.

2,009. E. Berg, Berlin. Electrical thief and fire alarm.

2,010. E. Berg, Berlin. Improvements in signalizing telegraphs.

2,033. W. Lowrie and R. Hammond, London. Improvements in dynamo electric machines.

2,040. H. Müller, London. Improvements in switches for secondary batteries or accumulators.

2,045. R. R. Hutchinson, London. Electrical ore stamping and pulverizing apparatus.

2,046. R. R. Hutchinson, London. Improvements in and relating to electrically propelled vehicles, especially adapted for high rates of speed.

2,061. W. P. Thomson, Liverpool. Improvements in electric lamp holders. (J. B. Moore, United States.)

2,067. C. Baur and W. Dieselhorst, London. Improvements in electrical transformers.

2,081. C. A. Gisborne, London. Improvements in or relating to multiple circuit telegraphy. (D. H. Keeley, Canada.)

February 5, 1891.

2,115. J. Dean and C. Jubb, Halifax. Improvements in or connected with metallic gauze brushes employed in dynamo electric machine

2,152. J. C. Woodburn, Glasgow. Improvements in electric switches.

2,155. J. Nebel, London. Improvements in armatures for dynamo electric machines.

February 6, 1891.

2,180. G. T. Mackley, London. Improved means or appliance for fixing or driving staples or like devices, especially applicable to electrical fittings. (C. Mackley, Germany.)

2,199. G. W. Cox, F. Robinson, and W. H. Gritton, Liverpool. Improvements in automatic electric switches.

2,200. E. Attenborough, London. Improvements in or relating to electro-motors.

2,201. J. E. Spagnoletti, London. Improvements in laying and insulating underground mains for carrying electricity.

2,219. E. E. Lever, London. Improvements in electric arc lamps.

2,221. G. Edward and T. Edward, Glasgow. Improvements in and relating to machinery for covering telegraph and telephone cables and wires with lead or other metallic compounds, also applicable for the manufacture of metal pipes and the like.

February 7, 1891.

2,289. Siemens Bros. & Co., Limited, London. Electrical block signalling apparatus for single line railways. (Siemens & Halske, Germany.)

2,297. C. W. Hazeltine, London. A method of and apparatus for prolonging the life of the carbons in electric arc lamps. [Date applied for under Patents Act, 1883, Sec. 103, July 9th, 1890, being date of application in United States.]

February 9, 1891.

2,334. J. W. Eyre and C. Graham, London. Improvements in and relating to electrical communicators for use on public vehicles and the like.

February 10, 1891.

2,368. G. L. Anders and J. R. Shearer, London. An antiseptic mouthpiece for telephones, speaking tubes, and like purposes.

2,418. J. Matthews and G. B. Cruickshank, London. Improvements in electric accumulators or storage batteries.

2,431. J. A. Colquhoun, Liverpool. Improvements in safety appliances applicable with switches, fusible cut-outs, or other electrical circuit breakers, for the prevention of flashing or sparking across from one conducting part to another.

2,433. J. Perry, London. A continuous current transformer.

2,446. J. Y. Johnson, London. Improvements in or connected with means or apparatus employed in electrolysis. (G. D. Davis, United States).

February 11, 1891.

2,471. T. W. Bush and M. Doubleday, Bridgford. The manufacture of hydrolised lead cells for electrical or storage purposes.

### SPECIFICATIONS PUBLISHED.

## BOOKS, &c., RECEIVED.

"Proceedings of the Royal Society," Vol. XLIX., No. 296. (London: Harrison and Sons.)

"A Dictionary of Metric and other useful Measures." By Latimer Clark. (London: E. and F. N. Spon.)

"Laxton's Price Book, 1891." (London: Kelly and Co.)

"A Treatise on the Law and Practice relating to Letters Patent for Inventions." By Robert Frost, B.Sc. (London: Stevens and Haynes.)

## COMPANIES' MEETINGS & REPORTS.

### India Rubber, Gutta Percha, and Telegraph Works Company (Limited).

The twenty-seventh ordinary general meeting of the Company was held yesterday at the Cannon-street Hotel, under the presidency of Mr. S. William Silver.

The SECRETARY (Mr. William J. Tyler) read the notice convening the meeting, and the report of the Directors and statement of accounts were taken as read.

The CHAIRMAN: In rising to move that the report be received and adopted, I would remark that since we last had the pleasure of meeting you the works have been well employed, and we have found ample requirements for our capital. The report in your hands shows the result to be very satisfactory, notwithstanding the keen competition met with in obtaining orders, and the prices of the raw materials having considerably advanced, which, as a matter of course, have affected the rate of profit. In the submarine telegraph cable branch we have manufactured during the year upwards of 2,000 miles, and I may remark that the item referred to under the head of "Cable on account of contracts," has just been successfully laid by our staff on board the "Silvertown," off the West Coast of S.A. The general trade has exceeded in amount any previous year, being over half a million. I am glad to say the prospects for this year are as satisfactory, and that we have several contracts in view. These remarks apply equally to "Persan" as to "Silvertown." I have, therefore, great pleasure in asking you to adopt the report, which recommends an addition being made to the reserve fund, as this supplies us with the sinews of war, in the absence of a considerable increase in the capital of the Company, the result of which would seriously affect the dividend, as it would increase the number of those who would share it with us. The freehold buildings and machinery have been maintained, and are in the highest state of efficiency. We have in our operations at Silvertown evidence that capital and labour when combined with judgment, and well-directed energy, can be made to render a fair return to the investor for his money, and a just remuneration to the employed. I have to move:—

*"That the report and accounts now presented be received and adopted, and that a dividend of 5 per cent. or 10s. per share free of income-tax, payable on and after the 20th inst. be now declared."*

Mr. NEIL BANNATYNE seconded the motion.

Mr. J. CARTER thought that the Directors ought to have paid a larger dividend, seeing that a similar company to their own—the Telegraph Construction and Maintenance Company— paid last year to its shareholders a dividend of 20 per cent., its £12 shares standing in the market at £46 to £48.

Mr. WEBBER said he entirely disapproved of the balance-sheet on similar grounds. The Company seemed to treat the shareholders in a most arbitrary sort of way in the matter of dividends. They carried forward a balance of £41,236, out of which they could have easily paid another 5 per cent. and have still carried forward a balance of £20,500. This year he found that £25,000 was carried to the reserve fund, bringing it up to £300,000, and he maintained that this amount, instead of being added to that fund, should have gone into the pockets of the shareholders.

Mr. TOINTON also supported this view.

The CHAIRMAN, in reply, said that it was a question for the shareholders themselves to decide, whether they would prefer to have the capital increased, and let their partners divide the profit with them, or to let the reserve fund stand as it did. It was as broad as it was long. He thought they could not have heard his remark about the general day-by-day trade which amounted to half a million.

Mr. WEBBER asked what had been laid out on the buildings account at Silvertown.

The CHAIRMAN replied that during last year about £14,000 or £15,000 had been spent on buildings and necessary extensions.

The motion was then put to the meeting and carried with five dissentients.

On the motion of the CHAIRMAN, seconded by Mr. A. W. JARVIS, the retiring Directors, Mr. Bannatyne and Mr. Henderson were re-elected to their seats at the Board.

Mr. BANNATYNE, in acknowledging his reappointment, said he had been for many years a large shareholder of the Company, besides being on the Directorate, and had studied its proceedings and history during that time, and he would just say, without going into a discussion of details which had been referred to by one or two speakers, who were opposed to the recommendation of the report, that one evidence of the increasing prosperity of the Company, and of the estimation in which it was held by the investing public, was its position on the Share List, which showed that the public appreciated its shares as an investment; and one of the elements in having obtained that position was no doubt the larger reserve fund, which was employed partly in keeping the business going and made the dividend so reliable. If they were to pay away any large portion of that fund, did anyone who knew anything about such companies suppose that the shares would occupy the same position on the market? He did not think so. He had great reason to be satisfied with the progress of the Company for many years and its present position and prospects.

Mr. HENDERSON having also acknowledged his re-election,

General TREVOR proposed and Mr. COCHRANE seconded the re-election of the auditor, Mr. J. Weise, which was agreed to.

A vote of thanks to the Chairman and Directors terminated the proceedings.

### Westminster Electric Supply Corporation, Limited.

The following is the report of the Board of Directors, to be presented to the shareholders at the fourth Ordinary General Meeting to be held at the offices of the Corporation, 32, Victoria-street, S.W., on Wednesday, the 25th inst., at 11 o'clock.

In submitting their report to the shareholders, the Board are pleased to be able to state that the business of the corporation is proceeding in a satisfactory manner. At the present time current is being supplied to the equivalent of about 12,000 lamps of eight candle-power, formal applications have been signed for about 17,000 more, and numerous inquiries continue to be made for the supply of current.

The central station in Millbank-street is now finished, and has been running continuously day and night since November 13, 1890. Current is being supplied from this station throughout the whole length of Victoria-street, in various parts of Pimlico, and also to the Houses of Parliament. The temporary station in Dacre-street is still supplying current to the western portion of the district as far as Belgrave-square and its neighbourhood.

The two other permanent central stations of the Corporation, namely, those in Eccleston place, S.W., and in Davies street, W., have been greatly delayed by the severe frost, which practically rendered building operations impossible for two months. Great progress has however been made, and in both cases temporary buildings have been put up, covering a part of the engine and boiler room space, sufficient to allow of current being supplied while the building operations are being completed. Engines, dynamos, and boilers are now in place at each station, and Prof. Kennedy reports that these will be at work in the course of next month.

The work of laying the mains, like that of building, was seriously hampered by the severe weather. Notwithstanding this, since the work was started in February, 1890, mains have been laid along about 16 miles of roadway and these include a total length of about 75 miles of " ways " into which about 40 miles of copper have been drawn.

In consequence of the great and pressing demand for the supply of electric current, it has been necessary to proceed with greater rapidity than at first arranged with the laying of mains throughout the district. This has led to the calling up of the capital sooner than was anticipated, but will result in an earlier division of profit.

The Board have applied to Parliament for powers to supply electricity in the northern part of the parish of St. Margaret, Westminster, which was not included in the original Provisional Order. Many petitions for the admission of the low-tension system have been signed by residents in that district, and the decision of the Board of Trade is shortly expected. This area, comprising among others, Bridge-street, Parliament-street, Great George-street, Queen Anne's Gate, and part of Whitehall, can be supplied from the existing station in Millbank-street, and consequently if obtained will prove a valuable source of revenue.

To complete the works now in hand, and to provide for such new works as the Directors may consider desirable, they propose to obtain the consent of the shareholders to the issue of the balance of the authorised share capital, £85,235 in 17,C47 shares of £5 each.

## NEW COMPANIES REGISTERED.

**THE CITY OF LONDON ELECTRIC LIGHTING (PIONEER) COMPANY (LIMITED).**—Registered by Ashurst, Morris, Crisp, and Co., 17, Throgmorton-avenue, E.C., with a capital of £100,000 in £50 shares. Object: To carry into effect two agreements made with the Brush Electrical Engineering Company (Limited), and the Laing, Wharton, and Down Construction Syndicate (Limited), respectively, and to carry on in the City of London the business of an electric light Company in all its branches, electricians, mechanical engineers, suppliers of electricity for the purposes of light, heat, motive power, &c. The first subscribers are:—The Right Hon. J. Savory, Lord Mayor, His Grace the Duke of Marlborough, Blenheim, Woodstock, The Right Hon. the Earl of Suffolk and Berkshire, Charlton, Malmesbury, The Hon. A. Chatteris, 23, St. James'-place, J. B. Braithwaite, jun., 27, Austinfriars, E.C., J. C. Bull, Wilcote, Long Ditton-hill, Surbiton, C. Braithwaite, 27, Austinfriars, E.C. There shall not be less than three nor more than five Directors; the first shall be appointed by the subscribers to the Memorandum of Association. Qualification, £250. Remuneration, £1,000, divisible.

**SOCIETE D'ECLAIRAGE ELECTRIQUE DE CANNES.**—This Company has been formed in Lyons with a capital of 1,100,000fr., divided into 2,200 shares of 500fr. each, the object of the Company being to supply electric light and power in Cannes and neighbourhood.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended February 13th amounted to £5,538.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended February 14th amounted to £728.

**COMPANY PROMOTING.**—Some severe strictures upon company promotion will be found in our contemporary *The Sunday Times* for the 15th inst.—many of the companies dealt with being Electrical.

**PORTRUSH ELECTRIC TRAMWAY COMPANY.**—At the annual meeting of this Company on the 2nd inst. at Portrush, the report of the Directors was submitted, in which they report another large increase in the passenger traffic in the past year, the first-class having increased from 7,847 last year to 8,943, and the third-class from 56,822 last year to 73,859; the total passengers carried for the year being 82,802, with receipts £2,573 19s. 5d., against £2,038. 11s.7d. in 1889. Goods and mineral traffic amounted to 316 tons, against 323 tons in 1889, and the receipts to £41. 8s. 11d. against £37. 9s. 9d. Receipts for parcels and miscellaneous traffic have increased from £43. 8s. to £77. 7s., making the total receipts £2,698 15s. 4d., against £2,114. 9s. 4d. in 1889. There has been a reduction in expenditure compared with 1889 of £153. 18s. 9d. This leaves a credit for 1890 of £1,011. 3s. 4d., against £381. 18s. 7d. for 1889. The ratio of expenses to receipts, which was 82 per cent. in 1889, has been reduced to 62 per cent. for 1890. The expenses of the electrical working amounted to £272 for 20,884 miles run, or 3¼d. per mile, while steam power cost £707 for £11,286 miles run, or 15d. per mile. The favourable state of the revenue account is, the Directors state, therefore, largely owing to the increased use of electricity as the motive power upon the line, and a corresponding reduction in the use of steam. The total mileage run shows an increase of 1,288 over the previous year, the respective numbers being 32,170 and 30,882. The Directors charge the balance of £1,011. 3s. 4d. with interest at 4 per cent. on £10,000 of £11,500 for the construction of the branch line to the Giant's Causeway, and the net revenue account has, therefore, been charged with £400 interest on the above £10,000, and with £400 interest on the advance of £10,000 by the Board of Works. Mr. James Stewart Moore, of Ballydivity, has been appointed a Director, in place of Mr. Atkinson, deceased At the meeting Sir William Thomson, F.R.S., and Dr. Traill were reelected as Directors, and the proposals of the Directors were carried.

**WOODHOUSE AND RAWSON UNITED (LIMITED).**—A prospectus has been issued this week, asking the public to subscribe for a further 20,000 ordinary shares of £5 each (upon which, the prospectus states, there is no present intention of calling up more than £?. 10s. per share); 10,000 Preference shares of £5 each, entitled to a preference as to capital and to 7 per cent. preferential cumulative dividend per annum, together with a further 1 per cent. in every year in which the ordinary shares have received a dividend of 10 per cent. or upwards, and £100,000 Five and a-Half per Cent. 1891 Debenture Stock (part of a total issue of £2?0 000). The Five and a-Half per Cent. Debenture Stock is created partly to pay off the existing Six per Cent. Debentures, and partly to pay off the balance of the sum deposited with the Company as a Guarantee Fund. The Debenture Stock will, upon the existing Debentures being paid off, become a first charge upon the entire undertaking. The Debenture Stock is redeemable in 10 years at £105, being 5 per cent. premium, or at an earlier date (but at the same premium) if with the consent of two-thirds of the holders of the stock. The prices of issue for the ordinary shares is 5s. per share premium, and for the Preference Shares and Debenture Stock, par. The prospectus further informs intending subscribers that the objects of the issue are to provide capital for the constantly increasing business of the Company, and to carry out various additional proposals, including a contract for the lighting of a portion of the city of Paris, and further to enable the Directors to pay off the balance of the £75,000 deposited with the Company, which they can now do on advantageous terms. After setting out the dividends which have been paid, &c., one of the concluding paragraphs of the prospectus reads a follows:—"*To give some idea of the extent, and at the same time variety of the operations of the Company, a résumé of last year's work is enclosed with the prospectus, by which it will be seen that almost every kind of article connected with electricity is manufactured at the works of the Company, and in addition to which, as will be seen, important financial operations connected with electrical industries have been completed.*"

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ending February 13, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,493.

# THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

**VULCANISED FIBRE,**

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Finishers, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/8 per lb.

**MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.**

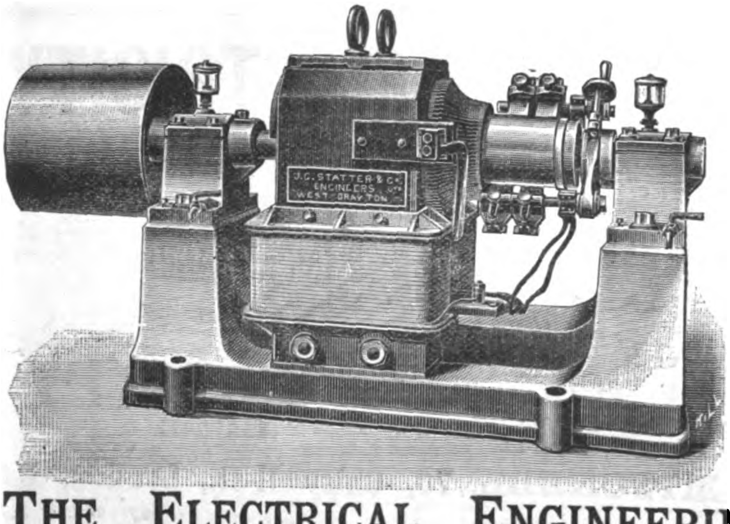
# IMPROVEMENTS IN DYNAMOS.



## STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**
**MACHINES BUILT TO 500 KILOWATTS.**

**THE ELECTRICAL ENGINEERING CORPORATION, LIMITED,**
[STATTER'S] [UNITED]

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 667.—Vol. XXVI. FRIDAY, FEBRUARY 27, 1891. Price Fourpence.

## NOTES.

The election of Dr. Oliver Lodge as President of Section A, for the British Association Meeting at Cardiff, will be hailed with satisfaction on other grounds than his attainments in physical and mathematical science. Dr. Lodge is fully alive to the many shortcomings of the Association. He realises the very unsatisfactory arrangements of the meetings, which greatly diminish the usefulness of the Association both by failing to attract many of the leading men of the day, and by wearying those who do attend. The "root and branch" reformers stay away altogether, and the duty of reorganising the Association in accordance with modern requirements consequently devolves upon such men as the President of Section A.

The letters which appear in our Correspondence columns, with reference to the Barking-road cars speak for themselves as far as the misunderstanding is concerned; and, as we expected, the figures upon which we commented in our last issue were neither official nor taken from the very latest returns. We hope that Mr. Kapp's suggestion that their mere withdrawal will not be so effective as the substitution of correct figures will elicit the true facts. The latest corrected figures will prove the more interesting by comparison with the results of the earlier stages of the work.

The report of the Committee appointed to make recommendations with regard to the electric lighting of the proposed Chicago Exhibition, an abstract of which will be found in another column, contains some figures of interest. The complete publicity which ought to be given in the details of exhibition lighting should afford much useful information as to the economy of various methods of illumination. Unfortunately for us in this country, it is suggested that the tower system, which has often been tried and is far from popular, should again be used. We say unfortunately, because the experience gained with this mode of lighting in the clear air of Chicago can be of little service to an English engineer, particularly to one who has to provide for the lighting of London. When the sun itself cannot succeed in penetrating our fogs for days together, it is unadvisable to place a lamp more than eighteen feet from the ground. But it is not proposed, in the present case, to erect the enormous structures that have been frequently designed and occasionally tried in America, the height of 75 ft. being suggested as the best elevation.

The report of the Chicago committee, asserts, as if it were a well-known fact, that for the best effect, the height of the lamp should be seven-tenths of the radius of the area to be illuminated by it. The study of the distribution of illumination has been very much neglected, and the literature of the subject is very meagre, but we cannot admit that there is any *best* ratio between the height of a lamp and the radius of the area which it lights. The closer the lamps are placed the more uniform is the illumination, and the greater will be the expense. Considering the outermost ray in the present case, the angle of incidence is 55deg., being that angle whose cotangent is ·7. The illumination on the ground is proportional to the cube of the cosine of the angle of incidence, the maximum under the lamp being unity, supposing there is no shadow. The illumination is, therefore, ·1885 of the maximum, and if the light from the other lamps fall on the same spot, the value will be about ·4 of the maximum, that is, the variation of the illumination will be about 60 per cent.

It is proposed to place arcs of 2,000 candle-power 40ft. from the ground and 122ft. apart. Assuming that the lamps really give a mean light of 2,000 candles, the maximum illumination below the lamp would be 14 bougie-metres or deci-luces, or equivalent to one candle at ·895ft., or to $1\frac{1}{4}$ candle at one foot. It is also proposed to place eight arc lamps on the 75ft. towers. With the above candle power, the maximum illumination would be equal to one candle at ·593ft. or 2·85 candles at one foot, that is 32 bougie-metres, or more than two and a-quarter times that of the first case. Since 500 candles at 75ft. distance give an illumination on a plane facing the light equivalent to one bougie-metre, it is evident that 7,000 candles, instead of 16,000 candles, on the 75ft. tower would give the same illumination as the 2,000 candle arc at a height of 40ft.

It is very satisfactory to find that our recent article on Indoor Illumination has called forth some reply, but the letters which will be found in our correspondence columns come from writers who imagine that they have been attacked. We admit that the Brockie-Pell arc lamp, to which, at all events, one of our correspondents evidently alludes, is the nearest approach to perfection, and we have seen the General Post Office sorting rooms, and in describing the lighting there, remarked (*Electrician*, January 30, page 398) that these lamps "run with their usual perfect steadiness." But, on the one hand, the Brockie-Pell lamp has not yet driven all

Digitized by Google

other lamps out of the field; had it done so, in speaking of arc lighting one would, of course, be speaking of no other make. On the other hand, the article alluded to treated more of domestic lighting than of the large buildings. If we were to admit that in each and all of the cases mentioned by "B. P." the lighting could not be improved upon, we should still maintain that at present, average arc lighting would not be suitable, for example, in the reading-room of a club or for any domestic purposes.

ANOTHER letter over well-known initials is very amusing, but is less easy to understand, containing as it does several obscure allusions to chocolate and green colours, which do not appear to refer to the tints of lamp shades, but are connected in some way with candidates and corporations. Allegorical designs are often admirably adapted to cover up lamp holders and wires; but such allegorical language as that used by our correspondent somewhat obscures his meaning. The article in question was of a mildly suggestive character, and contained but a dozen lines about arcs, and those were introductory to the question of dazzling. Fittings were dealt with in only three lines, and the words "glaring copper and ormolu" may have brought down this tirade. A bold criticism of the design of electric light fittings, their gradual development from gas brackets turned upside down, and the massiveness of style and exuberance of ornament which drove people of quiet taste to simple pendants, would be of more interest than use. Let the eye be pleased and deceived, by all means. The use of ground glass lamps for decorative purposes was not condemned; a scientific dictum only was combated. But the gist of the correspondence is that if Brockie-Pell lamps were more generally used, arc lighting would be more satisfactory, and that in the opinion of a gentleman of considerable experience the "artistic and charming effects" have "been brought to such perfection" that no "artistic genius" need further trouble himself "to make electric lighting comfortable and beautiful." He is thoroughly justified in being satisfied with his own work; but a little more originality in arrangement, distribution, and diffusion of light for domestic purposes is what was suggested; and no amount of pretty metal work tacked on to the lamp and its wires will make it more comfortable, and will only contribute in a secondary sort of way to its beauty.

THE sparking distance between conductors under high voltage has of late assumed a considerable degree of importance. The numerous experiments which have been made in this direction cannot, unfortunately, be compared together, since so many different sources of electrification have been used. SNOW HARRIS used Leyden jars; SPOTTISWOODE, a large induction coil with a De Meritens alternate current dynamo; and GORDON, a coil with 10 Grove's cells, but in these experiments it was impossible to estimate the voltage. Sir W. THOMSON and DE LA RUE obviated this difficulty by using merely a series of batteries, the former measuring the volts by an electrometer, the latter relying, with very good approximation, on the number of cells employed. The battery method eliminates all the uncertainties which may be caused by the undulatory or intermittent current and the abrupt changes and discontinuity of the pressure; but the results are not of much use as a guide to those who have to deal with the high voltage of alternate-current supply. Some very careful measurements are now being conducted by able experimenters, and their arrangements are of a thoroughly practical kind; in the meantime, we give in another column an abstract of a paper by Mr. SHAND describing Prof. ELIHU THOMSON's recent measurements. The curves do not exhibit that regularity which might be expected, and more information should have been given about the details of the pointed electrodes, for DE LA RUE found that a terminal of a paraboloidal shape gave a distinctly smaller spark length than a sharp point, and it is clear that the shape must therefore be a matter of some importance. A full account of Mr. DE LA RUE's researches was reproduced in the *Electrician*, vol. ix., from the *Proceedings* of the Royal Institution; the shape of the paraboloidal point is shown on page 103 of that volume. A flat plate opposed to a slightly convex plate has been used by other experimenters, the convexity being only just sufficient to localise the spark.

IN the February number of the *Philosophical Magazine* appear some noteworthy measurements, by Mr. BLATTNER, of the energy efficiency of glow lamps. The energy imparted to the lamp was measured electrically in the ordinary way, and also by calorimeter. Two calorimeters were used, one opaque to both light and heat, the other having glass sides transparent to the light rays. The latter measured all the energy given out by the lamp, except that corresponding with the light emitted; and by comparison of the measurements made with the two instruments it was possible to deduce the energy efficiency, or the ratio of the energy given out in light rays to the total energy given to the lamp. This ratio has been determined by the thermopile method by various experimenters in England and America, and is generally believed to be about 5 per cent. for the glow lamp, and 10 per cent. for the arc. According to Mr. Blattner, the percentage is slightly less than five for the Swan lamp and a little over six for Edison and Bernstein lamps, when these are run at normal brightness. The calorimeter method can hardly be a very accurate one, owing to the many sources of error, and to the difficulty of the measurements, but in the present instance it appears to have yielded good results, and observations have been made of the energy efficiency of the same lamp at several different candle-powers. The light efficiency increases more rapidly than the energy supplied to the lamp, but not nearly so quickly as the candle-power. Thus a 16 candle-power Edison lamp had an optical efficiency of 3·6 per cent. at four candles, and one of 8·5 per cent. at 28·7 candles. While the candle-power increased over seven times, the optical efficiency increased 2·4 times, and the watts supplied to the lamp increased 1·9 times. The optical efficiency increases with the temperature, and may, in the case of a much over-run glow lamp, become as high as 10 per cent., but it must not be supposed that any simple relation connects its value with the ratio between candle-power and the watts absorbed. The change in the character of the light as the voltage is increased would alone be sufficient to prevent any simple law from being true,

Digitized by Google

The results, although of great interest, must be accepted with some caution, as the figures given for the energy supplied to each lamp at the rated candle-power are far too high for glow lamps run at normal brightness, and would seem to show either that the measurements are erroneous in some particular, or that the lamps used were not of modern type.

Although many eminent men of science have vexed themselves over the question whether the lines of force caused by a magnet do, or do not, rotate with it as it revolves, no one, as far as we are aware, has suggested a crucial experiment capable of deciding the matter. This task has been attempted by Mr. Tolver Preston, who, in the February number of the *Philosophical Magazine*, proposes to rotate a cylindrical magnet near a metal disc placed perpendicular to the axis of revolution. If the lines rotate with the magnet the disc will become charged to a higher potential at the edges than at the centre, owing to its behaviour as a disc dynamo. If, however, the field remains fixed while the magnet revolves, the poles will become charged to a higher potential than the middle portion, owing to the tendency to induce currents through the magnet itself. This polar charge will act by ordinary static induction on the disc, the two faces of which will exhibit electricities of opposite kind. Tests made with a delicate electrometer of the electrical state of the disc should therefore decide between the two hypotheses. Unfortunately the experiment can only be made by those who have very delicate apparatus at command, as it appears that otherwise very high velocities of revolution are necessary to produce the effects predicted; but the attempt should be made owing to the great theoretical interest attaching to the question. Perhaps the fact is that the rotation of the lines takes place in accordance with some law of least action. When little waste of energy can take place by the production of induced currents in adjacent bodies, the lines may revolve with the magnet, but otherwise they may remain fixed in space while the magnet turns.

Those of our readers who are able to be present at the meeting of the Physical Society this afternoon will find their attention well repaid, as a glance at the list of Papers announced will show that they are all of interest to electrical engineers. We would also direct attention to the fact that Prof. Fleming will on Friday, March 6th, deliver a lecture at the Royal Institution on "Electro-magnetic Repulsion."

**Newport (Mon.)**.—The Town Council have decided to apply for a Provisional Order.

**Sunderland**.—At a special meeting of the Town Council last week it was resolved to apply for a Provisional Order.

**Mica**.—A great mass of mica is stated to have been discovered in the mountains of British Columbia, near the head of the Tête Jaune Pass.

**Obituary**.—Mr. Walter Glover's numerous friends will regret to hear of his bereavement in the death of his wife, which occurred on the 23rd instant.

**Electrical Bills in Parliament**.—The House of Commons Select Committee which will consider the Central London and City and South London Railway Bills, consists of Mr. Hanbury (chairman), Mr. Halley Stewart, Mr. Barran, and Sir Archibald Campbell.

**Athens**.—The Athens central lighting station continues to extend its operations. At the present moment it has nearly 4,000 incandescents and more than 130 arcs connected up.

**Royal Society**.—Yesterday, the Croonian Lecture, by Mr. F. Gotch and Prof. Victor Horsley, F.R.S., on "The Mammalian Nervous System, its Functions and their Localisation determined by an Electrical Method," was delivered.

**Village Lighting.—A Correction**.—Bernstein's Elektricitätswerke inform us that the lighting of Lockstedt, to which we referred on p. 473 of our last issue, has been entrusted to them and not to the Thomson-Houston International Electric Company, as there stated.

**Madrid**.—We learn that the electric lighting of the Senado (corresponding to our House of Lords), which is supplied with current from the mains of the Electricity Supply Company for Spain, was on Wednesday night inspected by the Queen and suite. The Queen expressed her great satisfaction at the illumination.

**Anglo-American Telegraph Company**.—We are informed that this Company has opened branch offices at Hay's Wharf, Tooley-street, and at 46, Mark-lane, for the reception of telegrams to the United States of America, &c. It is stated that offices will also shortly be opened in Edinburgh, Leith, Dundee, Bradford, and Newcastle-on-Tyne.

**The Telephone in India**.—At Cawnpore the Telegraph Department will shortly complete their new telephone exchange, and it is intended to open an exchange at Mandalay. In Calcutta the Bengal Telephone Company report that on December 31, 1890, 437 exchange and private lines were at work, yielding a revenue of Rs. 76,400.

**Popular Science Lectures**.—The following science lectures will be given at the Royal Victoria Hall, Waterloo Bridge-road, S.E., during March:—3rd, Prof. Marshall Ward on "A Piece of Wood, its Origin, Structure, and Uses;" 10th, Mr. J. E. Flower on "Spain;" 17th, Mr. A. W. Clayden on "Thunderstorms;" 24th, Prof. Roger Smith on "St. Paul's."

**Brighton**.—At a meeting of the Lighting Committee of the Town Council a letter was read from the Board of Trade, requesting to be furnished with a detailed description of the system by means of which it is proposed to supply electrical energy under the Brighton Electric Lighting Order, 1883. It was also resolved that instructions to electrical fitters should be printed for circulation.

**The Electrical Standards Committee**.—The following members of the Electrical Standards Committee were present at the meeting held at the Board of Trade on Friday last:—Mr. Courtenay Boyle, Major Cardew, Mr. Graves, Mr. Preece, Sir William Thomson, Lord Rayleigh, Prof. G. Carey Foster, Mr. R. F. Glazebrook, Dr. John Hopkinson, and Prof. Ayrton. Mr. R. E. Crompton, Dr. Fleming, and Dr. Alexander Muirhead attended and gave evidence.

**Technical Instruction**.—A short Bill relating to technical instruction has been introduced by Sir Henry Roscoe, M.P. It proposes to enable a local authority to make such provision in aid of the technical or manual instruction for the time being supplied in a school or institution outside its district as may, in its opinion, be necessary for the requirements of the district in cases where similar provision cannot be so advantageously made, by aiding a school or institution within its district.

**Birmingham**.—The Public Works Committee of the Town Council, having ascertained that Mr. Henry Lea, of Messrs. Lea and Thornbery, is willing to discharge the duties of electric inspector for twelve months at a salary of £150, recommend that he should be appointed. The committee report that they are conferring with Mr. Lea as to the position of the testing station, and the fees to be prescribed as the fees to be taken by the inspector, and by him paid to the credit of the borough rate.

**British Association**.—The following have been appointed to preside over the sections at the Cardiff meeting of the British Association in August next:—A—Mathematics and Physics, Prof. O. J. Lodge, F.R.S.; B—Chemistry, Prof. Roberts-Austen, F.R.S.; C—Geology, Prof. Rupert Jones, F.R.S.; D—Biology, Mr. Francis Darwin, F.R.S.; E—Geography, Mr. E. G. Ravenstein, F.R.G.S.; F—Economics, Rev. Dr. W. Cunning-

Digitized by Google

ham; G—Mechanical Science, Mr. T. Forster Brown, M.Inst.C.E.; H—Anthropology, Prof. Max Müller.

**Liverpool.**—The Lighting Committee of the Liverpool Corporation at their meeting on the 9th inst. had before them a proposition to appoint a general assistant to the electric inspector. This is due to the rapid increase in the amount of electric testing and inspectional work carried out by this department, which has followed upon the extended operations of the Liverpool Electric Supply Company. Mr. H. J. Roscoe was unanimously appointed. Mr. Roscoe was, till his appointment, in the employ of the Liverpool Electric Supply Company.

**The Sable Island Cable Scheme.**—Our readers will remember that at the end of 1890 an article appeared in *The Electrician* calling the attention of the Imperial and Canadian Governments to the many advantages to shipping which would ensue by the laying of a cable between Sable Island and Halifax. We are pleased to learn that the Canadian Administration have included in the Estimates placed before the Council a sufficient sum for the purchase and laying of the cable.

**Personal.**—The Secretary of State for the Postal Administration of the German Empire, Dr. Von Stephan, attained on January 7th his 60th birthday. Amongst the congratulations and souvenirs which he received on the occasion was a photograph of H.M. the Emperor William II., mounted in gilt bronze and bearing in His Majesty's own hand the following inscription:—"At the end of the 19th century the world finds itself dominated by systems of intercommunication which break down the barriers separating peoples and bind together the nations in new relationships."

**The City and South London Railway.**—According to Mr. Stephen D. Field, a weak point in the London underground electric road is the placing of the armatures on the wheel axles of the locomotives. "Running at a speed of 20 miles an hour, the blow delivered on the wheel, axle, and armature by passing over so much as a grain of sand is equivalent to the blow of a large steam trip hammer." In the absence of any proof of this remarkable statement, and of the presence of any sand in the tunnel, the direct driving of these locomotives is still to be regarded as one of the most important steps that has been made in electrical traction.

**The St. James' and Pall Mall Company.**—The following extracts from the report of the Directors of this Company for 1890 may be of interest. The full report will be found in another column. At the beginning of 1890 the Company had the equivalent of 4,460 eight candle-power lamps connected, on December 31, 1890, this number had risen to 26,500, and it is now 30,000. During the year nearly £12,300 was received for current supplied, which at 7d. per unit means an output of close upon 422,000 Board of Trade units. The total expenses amount to 60 per cent. of the gross receipts, the expenses of generation and distribution amounting only to 42·4 per cent.

**Electric Cranes.**—In the abstract of Mr. Bolton's Paper on this subject in our last issue, the loss by transmission was, by error, put at 2 per cent. instead of 1 per cent. It is probable, however, that it would seldom pay to put down conductors of so large dimensions. The author sends us a further portion of the summary of his Paper, in which he observes that as to first cost, an electric crane of equal power may be made at same cost as a steam crane, the saving of the engine and boiler balancing the value of the motor, which is somewhat high. There is no raising of steam, which would be derived from the shop boilers in most cases; and where the power is taken from the mains it is always ready.

**The Electric Discharge through Rarefied Gases.**—At a recent meeting of the Cambridge Philosophical Society, a Paper was read by Prof. J. J. Thomson on the electric discharge through rarefied gases without electrodes. A vacuum tube was exhibited, in which an electric discharge was induced by passing the discharge of Leyden jars through a thread of mercury contained in a glass tube coiled four times along it. The induced discharge was found to be confined to the part of the vacuum tube which was close to the primary discharge, and it did not show striæ. It was also demonstrated that an ordinary striated discharge is strikingly impeded by the presence of a strong field of magnetic force.

**Hull.**—At a recent meeting of the Electric Lighting Committee of the Hull Corporation, the report of a deputation which visited Bradford was read and adopted. The document stated that the Town Clerk of Bradford informed the deputation that the installation of the electric light in Bradford had been an unqualified success; and that they had never looked back with regret on a single circumstance connected with their adventure. The deputation viewed the central lighting station at Bradford, and other places where the electric light is used. From all they saw and heard, they were convinced that the electric light was "the light of the future," and that its supply should be undertaken by the Corporation; but they were unwilling to say with certainty, until they have had further opportunities of inspection, which system was the safest, most effective, and economical.

**Jubilee of the Chemical Society.**—A meeting in celebration of the jubilee of the Chemical Society took place on Tuesday afternoon at Burlington House. Dr. Russell, the president of the Society, occupied the chair, and among those present were Prof. M. Foster, Lord Rayleigh, M. Gautier, M. Combes, M. Haller, and M. de Clermont, representing the Société Chimique de Paris; Professor Will, representing the Deutsche Chemische Gesellschaft; Dr. Holtz, representing the Verein zur Wahrung Chemische Industrie; Prof. V. Meyer (Heidelberg), Sir Henry Roscoe, Sir William Grove, Sir F. A. Abel, Prof. Frankland, Prof. Odling, Mr. Crookes, Sir Lyon Playfair, M.P., Dr. Müller, Prof. Thorpe, Dr. James Bell, Prof. Dewar, Prof. Meldola, and Dr. Armstrong. On Wednesday evening the members of this Society dined together at the Hotel Métropôle, the Marquis of Salisbury proposing the toast of "Prosperity to the Chemical Society."

**The Hodges Lightning Protector.**—Ever since the delivery of the "Mann Lectures," in the spring of 1888, the revived interest in lightning phenomena which these now famous lectures gave rise to has resulted in an abnormal inventive activity in this direction. One of the latest devices we have seen is that due to a Mr. Nathaniel D. C. Hodges, who breaks the metallic continuity of his lightning rod by the interposition in the path of the discharge of a box of soot placed some six or eight feet up in the air above the roof of the building to be protected. According to Mr. Nathaniel D. C. Hodges, "as soon as the electricity enters a substance of this structure, its particles fly apart, some or all of them being charged, and the potential is greatly reduced." This effect, of course, would depend largely upon the quantity of soot employed; but a cubic foot, Mr. Nathaniel D. C. Hodges asserts, will probably be found sufficient for all ordinary cases.

**Electricity and Fires.**—In the annual report to the Fire Underwriters' Association Chief Inspector McDevitt, of Philadelphia, says that there are over 5,000 buildings in Philadelphia in which electric currents are used for light and power purposes. Of this number 287 buildings have their own apparatus, varying in size from a 20-light installation to one of 4,000 lights. The number of lights furnished by these private plants aggregates 80,258 incandescent and 3,325 arc lights. There are 15 central stations. The number of lights supplied by these stations varies from 2,000 to over 40,000. The electric motors in use are of a capacity ranging from one-eighth to 30 horse-power, and are being rapidly introduced as a more ready motor in place of steam and hydraulic power in propelling machinery. The report concludes as follows:—"No insurance loss occurred in any building in our city during the past year from fire where the cause could be in any way attributed to electric wires."

**The Telegraph in Times of Agitation.**—In 1850, when the question of allowing the public to use the telegraph was being discussed in the Assemblée Nationale, one of the many objections urged against this step was, says *La Lumière Electrique*, the serious consequences to public order that might result from the use of this rapid means of intercommunication for ensuring simultaneous risings. The Government's reply was that the system, being in the hands of the properly constituted authorities, it would more likely be a powerful defence to them. Recent events in Chili and Portugal are confirmatory of this view. In Chili none but Governmental news has succeeded in passing along the wires. In Portugal the failure of the rising at

Digitized by Google

Oporto was due to the fact that the leaders of the conspiracy were short-sighted enough to despatch a number of exactly similar telegrams as a signal. The authorities, suspicious at hearing that so many sick men would not last the night, stopped the messages.

**Electrostatic Measuring Instruments.**—There would seem to be, says *Industries*, some kind of prejudice against the use of electrostatic measuring instruments. Generally, in an alternating-current station, we find the high-pressure leads connected to transformers reducing to 100 volts or so, and a hot-wire voltmeter employed to read by. The transformer takes, say, 30 watts, probably more, and the voltmeter another 30. This means 500 kilowatt hours per annum wasted. At 2½d. this comes to £5 a year, which is the interest on from £50 to £100. A laboratory electrometer was used in electric engineering by Joubert in 1881, and others have been used occasionally since by Profs. Ayrton and Perry, Ryan and Monnier. Sir William Thomson has, however, introduced a number of electrostatic instruments, reading from 100 volts upwards, and engineers who use them do not revert to electro-magnetic or hot-wire voltmeters. Electrostatic instruments not only take no power, but have no temperature errors, and do not need corrections for frequency, and no doubt they will eventually be cheaper than other forms.

**The Electric Lighting of the City.**—At the meeting of the Commissioners of Sewers on Tuesday, the Streets Committee laid before the Commission a letter from the Board of Trade intimating that they were satisfied that the Brush Electrical Engineering Company was in a position to discharge the duties and obligations imposed upon it by the City of London (Brush) Electric Lighting Order, 1890. Mr. Morton, M.P., asked whether the Commission were dealing with the two companies with whom they had contracted in regard to the electric lighting of the City or with the company of which the Lord Mayor was chairman. The chairman said that, as he understood the matter, they had nothing whatever to do with the latter company. At a later stage in the proceedings a letter was read, headed "City of London (East District) Electric Lighting," from the Board of Trade, enclosing the copy of a letter they had received from the Laing, Wharton, and Down Construction Syndicate, on the subject of the syndicate, in view of the provisions of Clause 7 of the order. The letter stated that the Board of Trade, as at present advised, were unable to express themselves as satisfied with the financial position of the undertakers to whom it was proposed to refer the undertakings. The Board of Trade expressed a wish to hear the views of the Commissioners on the subject.

**A New Use for the Hair Pin.**—Under this title a letter appears in an evening paper of yesterday, describing a somewhat dangerous expedient. Dangerous, because fuses generally melt on account of a short circuit which might give rise to fire if not protected by a proper cut-out, and a hair-pin can hardly be considered as such:—"Sir, some unkind people occasionally compare the electric light to a 'red-hot hair-pin,' and no doubt all respectable hair-pins have felt hurt at such language; but now, in a spirit of true Christian revenge, a hair-pin has come to the aid of the electric light. At a dance given recently at a private house in London part of the electric lights suddenly went out, to the consternation of the guests, who, perhaps, may have considered it a judgment upon them; for I regret to add that this dance took place in Lent. It appeared on examination that one of the 'safety fuses' had 'gone.' An electrical young man was present, however, who, borrowing a humble patient hair-pin from some fair neighbour, inserted it in place of the fuse, and turned on the light again. I venture to suggest that the least that electrical engineers can do in return is to adopt 'a hair-pin, gules, proper,' as their crest. If you wish it, I can produce the hair-pin—not necessarily for publication, but as a guarantee of authenticity.—I am, Sir, your obedient servant, A Humble Student."

**University College and King's College Extension Funds.**—A meeting in support of these funds was held at the Mansion House on Monday. The chair was taken by the Lord Mayor, and there were present the Bishop of London, Lord Reay, Sir A. Rollit, Sir Gabriel Stokes, Sir R. Fowler, the President of University College, and the Principal of King's College. The following resolutions were moved by the Bishop of London, Lord Reay, and the President of University College respectively:—1. "That it is essential to the welfare and dignity of a great metropolis like London that its institutions for University teaching should be maintained at the highest standard and in the utmost efficiency." 2. "That University College and King's College, the two institutions recognised by the Government as University colleges in London, have deserved well of this city, and merit liberal support in the interests of the vast population of London." 3. "That a committee be formed, under the presidency of the Right Hon. the Lord Mayor, to receive subscriptions in support of the extension funds of the two colleges, consisting of the committee of the University College Extension Fund, under the chairmanship of Lord Reay, and of such governors and other members of the council of King's College, under the chairmanship of the Bishop of London, as the Bishop may appoint." Among the speakers were Sir Robert Fowler, Mr. B. L. Cohen, Mr. W. H. Preece, and Mr. S. Hill, who reminded the meeting that the professors of University College had for a long time surrendered a large portion of their fees for the maintenance of University College Hospital.

**The Regulation of Factories and Workshops.**—The following are some of the more important features of the Factories and Workshops Bill just introduced by the Government. The distinguishing proposal of the Bill is the establishment of "special rules." Where the Home Secretary certifies that any machinery or process used in a factory, or the state of the ventilation of a factory, is dangerous or injurious to health, or dangerous to life or limb, or that the provision for means of escape from a factory in case of fire is insufficient, the chief inspector may either serve on the occupier a notice proposing "special rules," or a notice requiring him to adopt such measures as appear necessary. In respect of safety, it is required that *every* hoist or teagle shall be securely fenced. Another requirement is that every factory, the construction of which is commenced after this year, must be provided on every story above the ground floor with a means of escape in case of fire, independent of the staircase or other way by which the workpeople usually enter or depart. With regard to accidents, the provision in section 31 of the Factory Act is that notice is to be given in certain cases where the accident "is of such a nature as to prevent the person injured by it from returning to his work in the factory or workshop within 48 hours after the occurrence of the accident." For this it is proposed in the Bill to substitute—where the accident "is of such a nature as to prevent the person injured by it from returning to his work in the factory or workshop and attending to it during a period of five working hours within three days after the occurrence of the accident."

**Barnsley Town Council and the Board of Trade.**—At the meeting of the Town Council on Tuesday the minutes of the Park and Lighting Committee were read. They contained the correspondence which had passed between the committee, the Board of Trade, and the Westinghouse Company, the general tenor of which was as follows:—The Board of Trade having on October 13th approved of the system proposed by the Council, on January 10th withdrew the approval, and asked the Corporation to provide underground mains instead of overhead wires. The Town Clerk pointed out that the change would entail an additional cost of £20,000 on the town; that a contract had been provisionally entered into with the Westinghouse Company, and that if the underground mains were insisted upon the town would not be lighted with the electric light. The Board of Trade replied that they would not decline to approve the proposed system in the present case, but hoped the Corporation would bear in mind the desirability of placing the wires underground. The correspondence with the Westinghouse Company simply amounted to the company throwing up their contract on financial grounds, and the committee recommended that no further negotiations should be entered into with that company. Alderman Blackburn moved the adoption of the minutes, and called attention to the fact that on January 10th the Board of Trade

Digitized by Google

disapproved of overhead wires, and on February 7th approved them. They must, before going further into the question, have informtion what course the Board of Trade would take in the future with regard to the matter; as if the underground wires were insisted upon the Barnsley Electric Lighting Act would be unexecuted, and remain a dead letter.

**An Experimental Storage Cell.**—In a recent issue of the *Electrical Engineer* of New York, Mr. H. E. Dey gives the following directions for making a storage cell for experimental purposes :—Out of a piece of $\frac{1}{16}$ sheet lead cut 21 pieces, each 4in. square, with a projecting lug for connection at one corner, $\frac{3}{4}$ of an inch in height and $\frac{1}{2}$in. wide. Procure 30 rubber bands $\frac{1}{8}$in. thick. Place three of these on each of 10 plates perpendicularly, one in the centre and one at each edge. These are to be the positive plates. Place all the plates together alternately, negative and positive, the bands separating them. Let the connections of one set be all on one side, and those of the other at the other side. Stretch a few bands around the plates, to clamp them together. Cut in a board, or mould in clay, two grooves $\frac{3}{4}$in. wide, $\frac{1}{2}$in. deep, 8in. long, and $2\frac{3}{4}$in. apart, placing one four inches in advance of the other. Stand the plates on end, so that the lugs form feet standing in the grooves. Pour into the groove very hot lead to a depth of $\frac{1}{4}$in. They are now ready to place in the acid. Take a jar containing about a quart of water, and pour in *very slowly*, stirring at the same time, two pounds of sulphuric acid, making it 1·2 specific gravity. Place the plates in a suitable jar, and after the acid is cool, pour in enough to cover them. Connect the intended positive plates with the positive wire of a suitable charging current. The charging pressure should be nearly three volts; consequently it will require two bichromate of potash cells in series. Charge and discharge often, and occasionally reverse the charging current, until it is found that the capacity does not increase. It will probably be about three ampere hours. See that the outside plates are negative with the final charge. The plates may be formed much more quickly by first soaking in a 50 per cent. solution of nitric acid for twenty-four hours. In this case it is advisable to use thicker lead. Rinse off before placing in the electrolyte.

**Sources of Trouble to Telegraphic Communications.**—The following, according to the *Revue Scientifique*, are some of the dangers to which telegraph poles abroad are exposed. The American representative of our European woodpecker, the green woodpecker of California, is, it seems, in the habit of installing its dwelling and its storage places for food in the interior of the red cedar poles that support the wires of the lines of the western United States. Colonel Clowry, an officer of the Western Union Telegraph Company, in a tour of inspection made by him in the far West, found that the summits of a large number of poles were deeply pierced by this bird. In Natal, a bird belonging to the family of the widow birds, seeing the number of tufted trees diminishing, has begun to suspend its nests from telegraph poles. In Brazil we come to a new source of trouble to telegraphic communications, brought about this time by representatives of the vegetable kingdom, the telegraph wires radiating around Rio Janeiro, being covered, it appears, with huge tufts of orchids hanging in festoons and garlands. Nearer home troubles of a different character occur, Thus, at Callahane Petty Sessions the other day, a man was convicted of stealing a telegraph pole, which he had converted into a mast for his fishing boat. In Belgium, the telegraph officials were for a long time troubled by the immense damage done to their lines by mischievous peasants, who freely indulged in the ancient art of stone throwing, using the white china insulators as a target. Prolonged investigation resulted in the evolution of an unobtrusive insulator. A similar difficulty was encountered by the Indo-European Company in its early days, the natives by dint of constant insulator potting becoming crack shots with whatever in that land takes the place of the rifle. European ingenuity has, however, also provided a remedy for this complaint. Overhead telegraph communications are, it will thus be seen, exposed to attacks of all sorts and descriptions.

**Subway Railway Schemes for New York.**—The inauguration of the City and South London Railway has given rise to a decided subway railway "boom" in New York. The Reno system, described in the *Electrical World* of New York of February, is a fair sample of the many which are now being brought forward. The idea of Mr. J. W. Reno is to run four tracks, arranged in two pairs, one above the other, right across New York, the lower line to be devoted to an express service, where "a speed of as high as 40 miles an hour could be attained without causing vibration of the structure." The method of construction is to be as follows :—A trench is to be excavated 3ft. in width and 38ft. deep, and the ground thoroughly supported and braced by a plank lining. The tunnel wall is then to be made by filling in this space with the concrete. When the wall is built up to within 11ft. of the surface, the plank lining will be removed, the trench filled in and the street paving relaid. The other wall of the tunnel will then be similarly constructed. The excavation of the ground between the side walls is to be effected without disturbing the street surface, pipes, or subways, by a steel "cutting edge," resting at each end upon the completed side walls, and forced ahead by hydraulic pressure, while the channel steel roof sections are built in behind it, and the construction of the internal steel structure immediately follows. The ground adjacent to the steel roof is to be solidified by liquid cement forced in under pressure. A row of iron columns 12ft. apart through the centre of the tunnel will support a longitudinal steel girder upon which rest the roof sections. These iron columns will be braced from the side by the transverse girders supporting the track beams. The scheme, of course, contemplates the use of electric locomotives. Power, it is said, could be generated at a central station at an expenditure of two pounds of coal per horse-power hour instead of ten pounds now required on the engines of the New York elevated roads.

**The Electrolytic Generation of Hydrogen and Oxygen.**—In a Paper recently read before the Société Française de Physique, Commander Renard described his investigations on the electrolysis of water on a commercial scale, which he commenced as far back as December, 1887. Taking the back E.M.F. at 1·5 volt, and the total plant efficiency at only 50 per cent., 35·3 cubic feet (one cubic metre) of hydrogen can be produced for every 10 horse-power hours; and taking the coal consumption at 2·2lb. (one kilogramme) per horse-power hour, the cost of fuel for every thousand cubic feet at atmospheric pressure of the mixed gases comes out in France at between 1s. 10d. and 4s. 10d., according to the price of coal. To make the electrolytic production of these gases a commercial possibility, it is necessary to avoid the use of costly platinum electrodes and of airtight partitions for collecting the gases. Commander Renard employs an alkaline electrolyte (caustic soda, 13 per cent. solution) and is therefore able to substitute cheap cast-iron electrodes for platinum. As to the vessels for the collection of the gases, he finds that so long as they have a *capillary reaction* $\Delta$ equal to a few centimetres of water, the hydrogen and oxygen do not mix. Commander Renard employs porous pots of asbestos fibre, which are able to withstand a pressure of from 30 to 50 cms. of water, without permitting the passage of the gases. The actual commercial apparatus used at the Chalais works is as follows :—A large cylinder of common sheet iron serves at the same time as the containing vessel for the electrolyte and as the negative electrode. The positive electrode is a perforated iron tube, fixed on to an insulated lid, which fits hermetically on to the top of the containing vessel. This electrode is surrounded by a large asbestos bag. Two voltameters of this kind have been in continuous work at Chalais for some six months, and at the end of this period both the electrodes and the asbestos bag were in perfect condition. The gases given off are pure, and there is no ozone. According to Commander Renard a battery of 36 large voltameters could generate about 200 cubic feet of hydrogen and 100 cubic feet of oxygen per hour, which could be compressed to a pressure of from 120 to 200 atmospheres in steel tubes, and utilised for therapeutic, laboratory, metallurgical, and other purposes. The *total* cost of these gases, ready for use in steel bottles at a pressure of 120 atmospheres, when produced on a sufficiently large scale, is estimated at from 11s. 9d. to 14s. 2d. per thousand cubic feet.

## ELECTROMAGNETIC THEORY.—V.

BY OLIVER HEAVISIDE.

*(Continued from page 449.)*

§ 26. So far we have considered the two forces, electric and magnetic, producing four fluxes, two involving storage and two waste of energy, and we have defined the terminology when the state of things at a point is concerned. We reckon forces per unit length, fluxes per unit area, and energies or wastes per unit volume. It is thus a unit cube that is referred to, whose edge, side, and volume are utilised. But a unit cube does not mean a cube whose edge is 1 centim. or any other concrete length; it may indeed be of any size if the quantities concerned are uniformly distributed throughout it, but as they usually vary from place to place, the unit cube of reference should be imagined to be infinitely small. The next step is to display the equivalent relations, and develop the equivalent terminology, when any finite volume is concerned, in those cases that admit of the same simple representation in the form of linear equations.

§ 27. The line-integral of the electric force from one point to another along a stated path is the electromotive force along that path; this was abbreviated by Fleeming Jenkin to E.M.F. He was a practical man, as well as a practician. When expressed in terms of a certain unit called the volt, electromotive force may be, and often is, called the voltage. This is much better than "the volts." I think, however, that it may often be conveniently termed the voltage irrespective of any particular unit. We might put it in this way. Volta was a distinguished man who made important researches connected with electromotive force, which is, therefore, called voltage, whilst a certain unit of voltage is called a volt. At any rate, we may try it and see how it works.

The line-integral of the magnetic force from one point to another along a stated path is sometimes called the magnetomotive force. The only recommendation of this cumbrous term is that it is correctly correlated with the equally cumbrous electromotive force. Magnetomotive force may be called the gaussage [pr. gowsage], after Gauss, who distinguished himself in magnetic researches; and a certain unit of gaussage may be called a gauss [pr. gowce]. I believe this last has already been done, though it has not been formally sanctioned. Gaussage may also be experimented with.

The voltage or the gaussage along a line is the sum of the effective electric or magnetic forces along the line; the effective force being merely the tangential component of the real force. Thus, electric force is the voltage per unit length, and magnetic force the gaussage per unit length along lines of force.

§ 28. Next as regards the fluxes, when considered with reference to any area. The flux through an area is the sum of the effective fluxes through its elementary units of area; the effective flux being the normal component of the flux or the component perpendicular to the area. We do not, I think, need a number of new words to distinguish fluxes through a surface from fluxes per unit surface. Thus, we may speak of the induction through a surface (or through a circuit bounding it); or of the current through a surface (as across the section of a wire); or of the displacement through a surface (as in a condenser), without any indefiniteness, meaning in all cases the surface integral of the flux in question.

In contradistinction to this, it may be sometimes convenient to speak of the density of the current, or of the induction, or of the displacement, that is, the amount per unit area. Similarly, we may sometimes speak of the intensity of the electric or magnetic force, using "density" for a flux and "intensity" for a force.

It may be observed by a thoughtful reader that there is a good deal of the conventional in thus associating one set of vectors with a line, and another set with a surface, and other quantities with a volume. It is, however, of considerable practical utility to carry out these distinctions, at least in a mathematical treatment. But it should never be forgotten that electric force, equally with displacement, is distributed throughout *volumes*, and not merely along lines or over areas.

§ 29. Conductivity gives rise to conductance, and resistivity to resistance. For explicitness, let a conducting mass of any shape be perfectly insulated, except at two places, A and B, to be conductively connected with a source of voltage. Let the voltage established between A and B through the conductor be V, and let it be the same by any path. This will be the case when the current is steady. Also let C be this steady current, in at A and out at B. We shall have

$$V = RC, \qquad C = KV, \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where R and K are constants, the resistance and the conductance, taking the place of resistivity and conductivity, when voltage takes the place of electric force, and the current that of current-density. The activity of the impressed voltage is

$$VC = RC^2 = KV^2, \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and represents the Joulean waste per second in the whole conductor, or the volume-integral of **EC** or of $kE^2$ before considered.

§ 30. Permittivity gives rise to permittance, and elastivity to elastance. To illustrate, for the conductor, substitute a nonconducting dielectric, leaving the terminals and external arrangements as before. We have now a charged condenser. Displacement, *i.e.*, the time-integral of the current, takes the place of current in the last case, and we now have

$$D = SV, \qquad V = S^{-1}D, \quad . \quad . \quad . \quad . \quad (3)$$

if D is the displacement, S the permittance, and its reciprocal the elastance of the condenser. This elastance has been called the stiffness of the condenser by Lord Rayleigh. It is the elastic resistance to displacement. The displacement is the measure of the charge of the condenser.

The total energy in the condenser is

$$\tfrac{1}{2}VD = \tfrac{1}{2}SV^2 = \tfrac{1}{2}S^{-1}D^2 \quad . \quad . \quad . \quad . \quad (4)$$

*i.e.*, half the product of the force (total) and the flux (total), between and at the terminals; it is also the volume-integral of the energy-density, or $\tfrac{1}{2}\Sigma cE^2$.

As the dielectric is supposed to be a non-conductor, the current is $\dot{D}$ or $S\dot{V}$, and only exists when the charge is varying. But it may also be conducting. If so, let the conductance be K, making the conduction current be $C = KV$. The true current (that is, *the* current) is now the sum of the conduction and displacement currents. Say,

$$\Gamma = C + \dot{D} = \left(K + S\frac{d}{dt}\right)V. \quad . \quad . \quad . \quad . \quad (5)$$

This is the characteristic equation of a condenser. It comes to the same thing if the condenser be non-conducting, but be shunted by a conductance, K. In a conducting dielectric the permittivity and the conductivity are therefore in parallel arc, as it were. It was probably by a consideration of conduction in a leaky condenser that Maxwell was led to his inimitable theory of the dielectric, by which he boldly cut the Gordian knot of electromagnetic theory.

The activity of the terminal voltage we find by multiplying (5) by V, giving

$$V\Gamma = VC + V\dot{D},$$
$$= RC^2 + \frac{d}{dt}\left(\tfrac{1}{2}SV^2\right), \quad . \quad . \quad . \quad . \quad (6)$$

representing the waste in Joulean heating and the rate of increase of the electric energy. Each of these quantities is the sum of the same quantities per unit volume throughout the substance concerned.

§ 31. Permeability gives rise to permeance, inductivity to inductance, and reluctivity to reluctance.

The formal relation of reluctance to reluctivity with magnetic force and induction, is the same as that of resistance to resistivity with electric force and conduction current, or of elastance to elastivity with electric force and displacement.

Permeance is the reciprocal of reluctance. In this sense I have used it, though only once or twice. Prof. S. P. Thompson has also used the word in this sense in his Cantor Lectures with good effect.

Digitized by Google

If we replace our illustrative conductor by an inductor, supporting magnetic induction, and suppose it surrounded by imaginary matter of zero inductivity, and have an impressed gaussage instead of voltage at the terminals, we shall have a flux of induction which will, if the force be weak enough, vary as the force. If H be the gaussage and B the induction entering at the one and leaving at the other terminal, the ratio H/B is the reluctance, and the reciprocal B/H is the permeance. The energy stored is

$$\tfrac{1}{2}HB = \tfrac{1}{2}\left(\frac{B}{H}\right)H^2 = \tfrac{1}{2}\left(\frac{H}{B}\right)B^2 \quad . \quad . \quad . \quad (7)$$

When the relation of flux to force is not linear, we can still usefully employ the analogy with conduction current or with displacement by treating the ratio **B/H** as a function of **H** or of **B**; as witness the improved and simplified way of considering the dynamo in recent years. I must, however, wonder at the persistence with which the practicians have stuck to "the lines," as they usually term the flux in question.

I am aware that the use of the name induction for this flux, which I have taken from Maxwell, is in partial conflict with an older use. But it is seldom, if ever, that these uses occur together, for one thing; another thing is that the older (and often vague) use of the word induction has very largely ceased of late years. It was not without consideration that induction was adopted and, to harmonise with it, inductance and inductivity were coined.

§ 32. The meaning of inductance has sometimes been misconceived. It is not a synonym for induction, nor for self-induction, but means "the coefficient of self-induction," sometimes abbreviated to "the self-induction." It is essentially the same as permeance, the reciprocal of reluctance, but there is a practical distinction. Consider a closed conducting circuit of one turn of wire, supporting a current $C_1$. As will later appear, this $C_1$ is also the gaussage. That is, the line-integral of the magnetic force in any closed circuit (or the circuitation of the force) embracing the current once is $C_1$. Let also $B_1$ be the induction through the circuit of $C_1$. Then

$$B_1 = L_1C_1, \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where, by what has already been explained, $L_1$ is the permeance of the magnetic circuit, a function of the distribution of inductivity and of the form and position of the conducting core. The magnetic energy is

$$\tfrac{1}{2}B_1C_1 = \tfrac{1}{2}L_1C_1^2. \quad . \quad . \quad . \quad . \quad . \quad (9)$$

by using the first expression in (7), remembering that H there is now represented by $C_1$, and then using (8). This energy "of the current" resides in all parts of the field, only (usually) a small portion occupying the conductor itself.

Now substitute for the one turn of wire a bundle of wires, N in number, of the same size and form. Disregarding small differences due to the want of exact correspondence between the bundle and the one wire, everything will be the same as before if the above $C_1$ means the total current in the bundle. But if the same current be supported by each wire, practical convenience in respect to the external connections of the coil requires us to make the current in each wire *the* current. Let this be C, so that $C_1 = NC$. Then we shall have by (8)

$$B_1 = (L_1N)\,C \quad . \quad . \quad . \quad . \quad . \quad (8a)$$

to express the flux of induction; and by (9), and (8*a*),

$$\tfrac{1}{2}B_1C_1 = \tfrac{1}{2}(L_1N^2)C^2$$
$$= \tfrac{1}{2}LC^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (9a)$$

if $L = N^2L_1$, to express the energy. This L is the inductance of the coil. It is $N^2$ times the permeance of the magnetic circuit.

Again, regarding the coil as a single circuit, $B_1N$ is the induction through it, that is, $B_1$ through each winding. Calling this total B, we have, by (8*a*)

$$B = B_1N = (L_1N^2)\,C = LC \quad . \quad . \quad . \quad . \quad (8b)$$

which harmonises properly with (9*a*).

The difference between inductance and permeance, therefore, merely depends upon the different way of reckoning the current in the coil. With one winding only, they are identical. I should here observe that I am employing at present rational units. Their connection with the Gaussian units will appear later. It would only serve to obscure the subject to bring in $4\pi$, that arbitrary and unnecessary constant which has puzzled so many people.

It will be seen that the distinction between permeance and inductance is a practical necessity. in spite of their fundamental identity. But which should be which? On the whole, I prefer it as above stated, especially to connect with self-induction. Regarding permeability itself, it would seem that this name is more particularly suitable to express the ratio $\mu/\mu_0$ of the inductivity of a medium to that of ether, which is, in fact, consistent with the original meaning, I believe, as used by Sir W. Thomson in connection with his "electromagnetic definition" of magnetic force. But to inductivity, as beforementioned, a wider significance should be attached. As has been more particularly accentuated by Prof. Rücker, we really do not know anything about the real dimensions of $\mu$ and $c$; or, more strictly, we do not know the real nature of the electromagnetic mechanism, so that $\mu$ and $c$ are very much what we choose to make them, by assumptions. The two principal systems are the so-called electrostatic, in which $c=1$ in ether, and the electromagnetic, in which $\mu=1$ in ether. But with these specialities we have no further concern at present.

*(To be continued.)*

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

*(Continued from page 480.)*

§ 14. But suppose the transformer is used for house lighting. The spring or autumn load in a house may be taken at about $\frac{1}{3}$ of the lamps wired running six hours a day; with a maximum load of less than 50 per cent. of the lamps wired. So that 10 horse-power will easily provide for 400 lights wired, and its daily output will be roughly 24,000 watt hours. The loss from $C^2R$ may be neglected except during the six hours at $\frac{400}{3} \times 30 = 4{,}000$ watts when the secondary current is 40 amperes, and $C_s^2R_s = 15$ watts, and about 16 watts in the primary. The loss in $C_p^2R_p$ from the exciting current is about ·5 watt. The all-day efficiency on the stated load is given in Table V.

**Table V.**—*All-day Efficiency of Ten horse-power Transformer on 4,000 watts for six hours.*

| | | |
|---|---|---|
| Total output ................................ | 24,000 | watt hours |
| 24 hours' waste in the core at 400...... | 9,600 | ,, |
| 24 hours' waste $C_p^2R_p$ in exciting at ·5 | 12 | ,, |
| 6 hours' waste $C_p^2R_p + C_s^2R_s$ at 31. | 185 | ,, |
| | 33,797 | |

$$\text{Efficiency} = \frac{24}{34} = 71 \text{ per cent.}$$

It is worth remarking that during the great B.T. *versus* A.T. controversy a few years ago, Mr. Crompton declared that the efficiency of alternate current transformers was no higher than he could get with battery transformers. The champions of the A.T. system did all they could to crush Mr. Crompton, but he stuck to his guns, as his manner is, and after all it seems he was right. If we had chosen a 50 or 100-lighter, such as would commonly be used in a house, the efficiency would have come out nearer 60 than 70 per cent.

§ 15. It may be objected that such a large transformer as 10 horse-power would not be used in the way we have imagined, but would be placed in a sub-station, where during the day a small transformer would take its place, and so save the inordinate waste in the core. The writer may be permitted to doubt whether a sub-station transformer system will pay. The *raison d'être* of the transformer system lies in its great flexibility and economy in mains, whereby a lot of scattered lighting over a

Digitized by Google

large area can be profitably run from one station. This almost necessarily implies the use of a small transformer to every house, with a larger one occasionally where several adjoining houses require light. But the moment we begin to use sub-stations where a light-load transformer is switched on during the day-time, we sacrifice much of the flexibility and increase standing charges for rent and superintendence. In order to save the coal bill appreciably, we must use a very small day transformer so as to run it at least half load. Take an example. Put on a 1,000 watt transformer for 18 hours, and the 10 horse-power for 6 hours. The small transformer would waste at least 130 watts in its core, or $130 \times 18 = 2{,}300$ watt hours, the 10 horse-power wasting $400 \times 6 = 2{,}400$, and the total daily waste will be 4,700 watt-hours as against 9,600, almost exactly half as it happens, so there is a saving of something like 5 B.T. units, and the saving in coal and running expenses might amount to 2d. per unit, or 10d. a day for a sub-station running 400 lights. The saving in a 2,000 light sub-station may be taken at 4s. 2d. a day. The attendant would dispose of at least 3s., leaving 1s. 2d. for rent, interest on secondary mains, and sub-station fittings. Truly there is not much margin.

§ 16. It might be supposed that one attendant could look after four or five sub-stations; but in this favoured country, at all events, town districts are liable to sudden fog, and there would be some risk of damage to the small transformer unless the attendant were ubiquitous; remember that it would be overloaded with one-tenth of the lamps on.

Perhaps, however, every central station, like every railway signal box, would have a number of fogmen attached to it. Signalmen often have considerable difficulty in getting their fogmen out in time, and a central station manager would have precisely the same trouble, with the additional one that the sub-stations would be at a very considerable distance from the central station.

Of course, automatic switches might be devised to save the need for an attendant; but automatic switches in the primary circuit are not pleasant to contemplate.

In country districts, where the transformer system is without a rival, sub-stations are out of the question.

§ 17. In what follows, therefore, we shall assume that the transformer primary will be on continuously, and endeavour to get a higher all-day efficiency by reducing the enormous waste in the core. This can be effected in three ways—(1) the frequency can be diminished, (2) the maximum induction can be reduced, or (3) we can use less iron in the core, in each case increasing the number of turns of the coils to keep the volts up. Now, when we increase the number of turns we either increase the total amount of copper or have a greater drop in E.M.F. over the coils, and we ought to fix on some limit for the latter, as it is as obviously absurd to compare the efficiencies of two transformers having different full-load drops, as it is to compare two shunt dynamos without regard to their regulation. Suppose the maximum loss of volts over the mains were 1 per cent., and allow for 1 per cent. in the house switches and leads, if the loss over the transformer coils at full load is 3 per cent., we should have a total drop of 5 per cent. with evey light on; but as the maximum only amounts to about 80 per cent. of the transformer's full load, the actual drop on the lamps would not exceed 4 per cent., and that very rarely. A large variation in E.M.F. is occasionally deprecated on the score of damage to or inefficiency of lamps, but as a rule lamps are not overrun at the highest E.M.F., and a large drop merely lengthens their lives. It also tends to grumbling on the part of the consumer, and this last factor practically determines the maximum allowable loss of E.M.F.

In addition to the three methods already mentioned, an ingenious scheme for raising the commercial efficiency of transformers on any load whatever to something like 100 per cent. ought to be alluded to here. Like most really ingenious novelties, it hails from America. According to this invention, the house-meter is put on the primary mains, so transferring the whole of the loss to the unhappy consumer. This arrangement certainly has great charms—for the Supply Company. The less efficient the transformer the better they like it.

§ 18. Taking three per cent. as the limiting loss in E.M.F., let us begin by lowering the frequency in the 10 horse-power transformer from 70 to 35 ∿ per second, without making any change in the core. The coils now require twice as many turns, and as we cannot interlink a greater *section* of copper with the core, we must use wires and strip of less than half the section in each case. It would be exactly half were it not that the space required for insulation is doubled. The resistance of each coil will now be at least five times as great as those given in Table III., so that the maximum drop will be $1{\cdot}4 \times 5 = 7$ per cent. If the second plan were carried out we should come to exactly the same conclusion, for to get the same E.M.F. with half the induction would require twice the turns, and the coils would have a full load drop of 7 per cent.

§ 19. Clearly, neither a lower frequency nor a lower induction is any good unless the size of the core is altered. Keeping the core area the same, increase the mean length of the magnetic circuit by 30 per cent. We may take the core to be a square link, and shall find we have increased the area for coils by 110 per cent. Double the number of turns of 10 per cent. greater section than the original wires and strip, will make the resistances practically twice as great (the mean length per turn having been increased by 10 per cent.), and the drop will be 2·8 per cent., just under the limit. But the volume of iron is now 30 per cent. greater. Putting this modification on the same load as the original transformer, we can write down the losses at once. They are given in Table VI.

**Table VI.**—*Modified Ten Horse-power transformer, No. C. 1.*

Maximum $B = 10{,}000$ .................... $F = 35$

Load as in Table V.

| | | |
|---|---|---|
| Total output ................................ | 24,000 | watt hours. |
| 24 hours waste in core at 278 ......... | 5,500 | ,, |
| 24 ditto waste in exciting at 1 ......... | 24 | ,, |
| 6 ditto $C_p^2 R_p + C_s^2 R_s$ at 62 ............ | 372 | ,, |
| | 29,896 | |

$$\text{Efficiency} = \frac{20}{30} = 80 \text{ per cent.}$$

Full-load drop = 2·8 ,,

A distinct improvement has been made, but at the cost of an increase of 140 per cent. in the weight of copper, 30 per cent. in iron, and perhaps 50 per cent. increase in labour. Whether a gain of 9 per cent. is worth this price is doubtful.

§ 20. A better result can be got for the same outlay in materials and labour by the second plan, namely keeping the frequency at 70, and reducing the maximum B to 5,000 gausses. The hysteresis loss at 5,000 gausses is almost exactly one-third of the loss at 10,000, the results obtained by Mr. Vignoles and the present writer agreeing precisely in this respect with those published by Prof. Ewing. The eddy current loss at half the induction is of course quartered. The coils and size of core will be exactly the same as in Table VI. The efficiency of this modification is shown in Table VII.

**Table VII.**—*Modified Ten Horse-power Transformer, No. C. 2.*

Maximum $B = 5{,}000$. $F = 70$.

Load as in Table V.

| | | |
|---|---|---|
| Total output ...................................... | 24,000 | watt hours. |
| 24 hours' waste in core at 163 ......... | 3,900 | ,, |
| 24 hours' waste in exciting at ·5......... | 12 | ,, |
| 6 hours' waste $C_p^2 R_p + C_s^2 R_s$ at 62 | 372 | ,, |
| | 28,284 | |

$$\text{Efficiency} = \frac{24}{28} = 85 \text{ per cent.}$$

Full load drop = 2·8 per cent.

Here is an apparent gain of 14 per cent. in efficiency, but it must not be forgotten that the drop in the original transformer was only 1·4 per cent., and in order to compare it with those given in Tables VI. and VII. it ought to be re-wound to have the same full load drop.

In fact, the coils must be wound with wires and strip of half the section, the turns being left unchanged at 1,120 and 56 as given in Table III. The new coils occupying approximately half the space, the mean length of the magnetic circuit can be

Digitized by Google

reduced by 20 per cent. The efficiency of the arrangement is given in Table VIII.

**Table. VIII.**—*Modified Ten Horse-power Transformer.*

Maximum B = 10,000 F = 70.

Load as in Table V.

| | | |
|---|---|---|
| Total output | 24,000 | watt-hours |
| 24 hours' waste in core at 330 | 7,900 | ,, |
| 24 hours' waste in exciting at 1 | 24 | ,, |
| 6 hours waste $C_p{}^2 R_p + C_s{}^2 R_s$ at 62... | 372 | ,, |
| | 32,296 | |

$$\text{Efficiency} = \frac{24}{32} = 74 \text{ per cent.}$$

Full load drop = 2·8 per cent.

When we consider that this last transformer requires only two-thirds the quantity of iron and one-quarter of the copper taken by those in VI. and VII., we can have no doubt which would be chosen by a supply company.

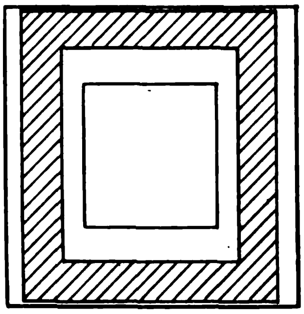

FIG. 4.—Plan of Core of 10 horse-power Ravenshaw Transformer showing portion used in No. 3 shaded.

§ 21. So far the rise in temperature of these various modifications has not been considered. The reason for this apparent neglect is very simple. When we limit the maximum loss of volts at full load to three per cent., it is almost impossible to design a transformer having insufficient radiating surface to keep its temperature below a safe limit. In this respect the transformer in Table VIII. is very much worse than any of the other modifications, yet although it would acquire undesirably high temperature if left on continuously at full load, its maximum temperature on the time load we have assumed would not exceed 30°C. above that of the surrounding air, say an actual temperature of 50°C. Probably no one but a financier would care to run a transformer with so small a margin, and we shall therefore put it out of competition. To complete the set of closed transformers, we still require one having the maximum B = 10,000 and F = 70 with a full load drop under 3 per cent., and the simplest modification of the original transformer by which these conditions can be fulfilled is obtained by reducing the sectional area of the core and increasing the number of turns on the coils in proportion.

§ 22. Suppose core plates of half the width of those in the original transformer are built up into a core of the same depth, so as to get half the sectional area, and made into a rectangular link enclosing twice the area for coil space. This alteration is shown in Fig. 4, which is a plan of the original core, the shaded portion being the new core. The coil space is not quite doubled, but the length of an average turn being now 7 per cent. less; the section of the wires and strip may be reduced in proportion, so that exactly twice as many turns can be wound on, thus doubling the resistance of each coil. The volume of iron in the core is not quite half 6,600 cub. cm.; it is actually 3,560 cub. cm. The sectional area is 29 square cms., and the average length of the magnetic circuit 122 cms. The all-day efficiency of this transformer is given in Table IX.

Thus, of the three proposals for raising the efficiency, the second is the best; but No. C. 2 is only 4 per cent. better than No. C. 3, and the latter uses considerably less material. We shall return to the question of raising the efficiency by lowering the induction after we have investigated the properties of open circuit transformers.

**Table IX.**—*Modified Ten Horse-power Transformer No. C.3.*

Maximum B = 10,000 F = 70

Load as in Table V.

| | | |
|---|---|---|
| Total output | 24,000 | watt hours |
| 24 hours' waste in core at 218 | 5,200 | ,, |
| 24 hours' waste exciting at ·5 | 12 | ,, |
| 6 hours' waste $C_p{}^2 R_p + C_s{}^2 R_s$ at 62... | 372 | ,, |
| | 29,584 | |

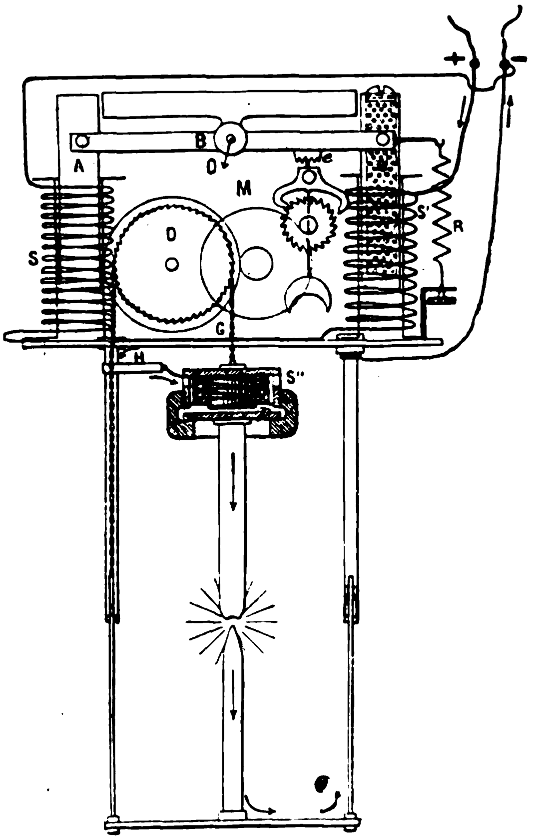
$$\text{Efficiency} = \frac{24}{29{\cdot}6} = 81 \text{ per cent.}$$

Full load drop = 2·8 per cent.

(*To be continued.*)

## THE JAPY-HELMER ARC LAMP.

The Japy-Helmer lamp, with its somewhat complicated mechanism, is a striking contrast to that due to M. Patin, and described in a recent issue (see *Electrician*, February 20th, p. 496).



Japy-Helmer Arc Lamp.

The lamp (says *L'Electricien*) consists of a clockwork arrangement, mounted on the frame of the lamp, and comprising a plate C and a toothed wheel D, which are brought into play at intervals when the action of the current releases the clockwork. The current leaving the terminal traverses the thick wire solenoid S′, and goes to the contact H, whence it passes round the coils of the electromagnet S″, which, when energised, attracts the armature *r*, and strikes the arc. The current then traverses the carbons and reaches the terminal. The fine-wire solenoid is a shunt on the arc. Each of the solenoids S and S′ have soft iron cores A and A′, connected by the balanced beam B pivoted at O. This beam carries a catch *e*, which stops the motion of the escapement when required. When the lamp is out of circuit the spring R keeps this catch pressed against the escapement-wheel. After the arc is struck and the carbons begin to burn away the current in the shunt coil S increases, and the core A is sucked in and the beam B tilts over, freeing the escapement-wheel, and allowing the carbons to feed down. Perhaps the best feature of this lamp is its compactness, a 6-ampere 7½-hour lamp being only 2ft. over all.

A few slight modifications are required to make this lamp work with alternate currents. The number of turns in the solenoids is reduced, and the armature *r* is no longer rigidly attached to the upper carbon-holder, which then merely passes through a hole in the middle of *r*. When the current is not passing, *r* is not attracted, and falls to the bottom of the box-like arrangement shown in the figure, and compressing a spring brings the carbons together.

## ELECTRICITY AT THE CHICAGO EXHIBITION.

The following is an abstract of a Report drawn up by the World's Fair Committee of the Chicago Electric Club, at the instance of the consulting engineer to the Chicago Exhibition authorities. The full text of the Report appeared in the *Western Electrician* of February 14th :—

*General Arrangement of Wires.*—We recommend that the distribution of electric current, for arc and incandescent lighting, for electric railway and power purposes, be through underground conductors exclusively, with the exception of overhead arc light wires for outside illumination, and the railway trolley wires.

*Area to be Lighted.*—From the plans submitted, we find that the indoor area to be lighted amounts to a total of 4,884,750 square feet, and the outside area to 28,000,000 square feet.

*Lighting Grounds.*—Supposing the lamps for outside illumination to be placed on poles, and allowing 15,000 square feet per 2,000-candle-power arc lamp, we require 1,866 arc lamps, or 1,866 horse-power at the power station. Such a distribution would place the lamps 122ft. apart. As the proper height of the electric arc for lighting of large areas is ·7 of the radius of the area to be lighted by one lamp, the arcs should be at a height of

$$\frac{\cdot 7 \times 122}{2} = 42\ 7$$

or practically 40ft. above ground. Should it be decided to light the grounds by a system of towers. about 75ft. high, each tower to be equipped with, say eight arc lamps, and the towers to be placed approximately 400ft. apart, it could be accomplished with about 1,400 arc lamps. This will provide a flexible method of lighting, and make it possible to increase or decrease the number of lights on a certain tower as the circumstances may warrant. It is thought that by this system, all thoroughfares and paths throughout the park can be well lighted, notwithstanding the foliage. By means of the tower system, it will be practicable to connect one tower to the other with a single conductor for carrying the current. This single conductor will be, approximately, 75ft. above ground, and at that height there can be no possible danger, so that bare wire can be used and insulating material can be dispensed with. The cost of one hundred and seventy-five towers, wired and ready to be connected with the electrical apparatus, will be, approximately, $100,000. While the committee is fully aware of the fact that the tower system of general illumination in cities is not the popular form, and is only used in perhaps half a dozen cities in the United States, the advantages of this system under the conditions that will obtain at Jackson Park, where there are but few buildings to obstruct the light, will be very marked.

*Lighting Buildings.*—Although the total floor space of the buildings is only 4,884,750 square feet we think that about 30 per cent. more should be allowed for galleries, upper stories, &c This will practically give us an area to be lighted inside of buildings of 6,000,000 square feet. If we assume one arc lamp for each 1,600 square feet, which practically puts the lamps 40ft. apart, about 3,800 arc lamps or horse-power would be required, to give a general inside illumination. The proper height for these lamps would be

$$\frac{40 \times \cdot 7}{2} = 14.$$

For practical reasons, however, and other considerations, the height of the arc above ground should be increased to say about 18 or 20ft. The total cost for arc light distribution inside the buildings will be $72,000.

While the arc lights will give a good general illuminations, the different exhibits will need a large number of incandescent lights to effectively show each object under favourable conditions. Assuming for each 120 square feet one 16 candle-power incandescent lamp, we get a total of 50,000 16 candle-power incandescent lamps, or 5,000 horse-power. We estimate that the cost of distribution for the 50,090 incandescent lamps, from the generators to the sockets, will be, approximately, $250,000.

*Recapitulation.*

| | |
|---|---|
| For outside arc lighting by towers ... | 1,400 horse-power |
| For inside arc lighting .................. | 3,800 ,, |
| For incandescent lighting .............. | 5,000 ,, |
| Total .......................... | 10,200 horse-power |

*The Proposed Railway.*—In constructing a surface railroad through the grounds of the World's Fair the same can be made unique and ornamental in many respects. The rails could be raised from the ties by means of chains to give a space of 8in., which would be covered with a rich mould, suitable for the planting of flowers and grass, and can be so arranged that the rails cannot be seen except by standing immediately over the centre of the rails. There should be space allowed between the tracks, if it is constructed with double tracks, to allow the erection of ornamental centre poles, either of iron or octagon wood with ornamental brackets, from which the wire could be suspended for conveying the current to the trolleys of the motor cars. If desired, these poles could have various kinds of vines running around them, which would make them exceedingly ornamental and pleasant to the eye. It would also be necessary, of course, to have the railroad enclosed from one end to the other with a neat and ornamental fence. We believe a surface railroad erected on such a plan as the above would be very attractive and something that has never been seen in this country or any other.

*Recapitulation.*—Horse-power required delivered at generator pulleys :

| | H.P. |
|---|---|
| For lighting Exposition at Jackson Park ..................... | 10,200 |
| Electric Railway at Jackson Park ............................ | 700 |
| For power transmission to different buildings, and drive all sorts of machinery at Jackson Park (rough estimate) ............................ | 9,000 |
| Grand total ............................ | 19,900 |

*Recapitulation.*—Cost for distributing the electric current for lighting, exclusive of apparatus, at Jackson Park :—

| | |
|---|---|
| Towers and overhead wire for outside arc lighting ......... | $100,000 |
| Conduits and wires for inside arc lighting ................ | 72,000 |
| Conduits and wires for inside incandescent lighting ...... | 250,000 |
| | $422,000 |

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, February 27th.**

Society of Arts.

*4.30 p.m.* Popular Afternoon Lecture : "The Science of Colour," by Captain Abney, C.B., F.R.S.

Physical Society.

*5.30 p.m.* Ordinary Meeting. Papers to be read : "Proof of the Generality of certain formulæ published for a special case by Mr. Blakesley." "Tests of a Transformer," by Prof. W. E. Ayrton and J. F. Taylor. "Further Contributions to Dynamometry," by T. H. Blakesley. "Note on Electrostatic Wattmeters," by J. Swinburne "Interference with Alternating Currents," by Prof. W. E. Ayrton and Dr. W. E. Sumpner.

Institution of Civil Engineers.

*7.30 p.m.* Students' Meeting. Paper to be read: "Dis integrators," by Bertram Chatterton, S.I.C.E.

Electro-Harmonic Society.

*8 p.m.* Ladies' Night. Concert in St. James' Hall Restaurant.

**SATURDAY, February 28th.**

Royal Institution.

*3 p.m.* Afternoon Lecture: "The Forces of Cohesion," by Lord Rayleigh, F.R.S.

**MONDAY, March 2nd.**

Institution of Civil Engineers.

*2 p.m.* Students' Visit. The Locomotive and Carriage Works of the Great Eastern Railway at Stratford.

Royal Institution.

*5 p.m.* General Monthly Meeting.

Society of Engineers.

*7.30 p.m.* Ordinary Meeting. Paper to be read : "The Balancing of High Speed Steam Engines," by Arthur Rigg.

Society of Arts.

*8 p.m.* Cantor Lecture III. 3. "The Electric Transmission of Power," by Gisbert Kapp.

**TUESDAY, March 3rd.**

Institution of Civil Engineers.

*8 p.m.* Ordinary Meeting. Paper to be read with a view to discussion : "On the Subterranean Water in the Chalk Formation of the Upper Thames, and its Relation to the Supply of London," by John Thornhill Harrison, M.I.C.E.

**THURSDAY, March 5th.**

Royal Institution.

*3 p.m.* Afternoon Lecture : "Modern Chemistry in Relation to Sanitation," by Prof. C. M. Tidy, M.B.

**FRIDAY, March 6th.**

Society of Arts.

*4.30 p.m.* Popular Afternoon Lecture : "The Science of Colour," by Capt. Abney, F.R.S.

Royal Institution.

*9 p.m.* Evening Discourse : "Electro-Magnetic Repulsion," by Prof. J. A. Fleming, D.Sc.

# The Electrician.

**Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny**
**Editorial, Publishing, and Printing Offices:**
**SALISBURY COURT, FLEET ST., LONDON, E.C.**
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher,* "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "Coutts and Co." *All other letters to be addressed to the Editor.*

*All letters intended for insertion in* "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of* "THE ELECTRICIAN" *commence in May and November.*

## SUBSCRIPTION RATES.

**The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—**

| | 3 months. s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.*
**It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 6s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## TRANSFORMER DISTRIBUTION.

MR. SWINBURNE's paper on this subject, just read before the Institution of Electrical Engineers, exhibits in a remarkable manner the versatility of its author, and a mere summary of the headings of the different parts suffices to show the great extent of the ground which he has attempted to cover. The distribution of electricity by transformer sub-stations and low-tension networks, the parallel running of alternators according to orthodox and heterodox views, the theory of armature reactions, and the automatic regulation of dynamos and transformers, the relative merits of the open and closed circuit type of converter, the internal arrangements of supply stations, and the many prospective uses of condensers, when manufactured commercially for employment with alternating current systems, were all subjects of sufficient importance to merit separate treatment. It was courageous to endeavour to dispose of every one of these in the short time which could be devoted to them, more especially in view of the fact that the Institution supplied but very few printed copies of the paper to aid members in following the intricate reasoning which the author had occasion to resort to. It was certainly a pity so many matters were referred to, as by so doing the attention of hearers was somewhat distracted, and the resulting discussion is liable to become wandering and comparatively barren of result.

More than half the paper is devoted to a discussion of the subject of parallel running of alternating dynamos. The action of coupled machines is a matter of the first importance, but one on which great differences of opinion still exist. The experiments which have been made are comparatively few, while all mathematical methods of explanation are obscured by clouds of symbols, and generally involve assumptions of a more or less dubious nature. Even the geometrical treatment of the problem, although in many respects the clearest, is frequently misleading, owing to the fact that the figures are rarely drawn to scale. There still seems a confusion

Digitized by Google

of opinion as to what is really implied by the Hopkinson theory, in which successful parallel coupling is attributed to the presence of. self-induction in the armature. Some engineers appear to imagine that a highly inductive armature necessarily involves a powerful reaction on the field, and a drooping characteristic. This is by no means the case, and, whether it is so or not, depends entirely on the design of the machine. The MORDEY dynamo has the requisite amount of inductance, although its characteristic is practically straight; while in the HOPKINSON theory it is assumed that, in spite of the self-induction of the armature, the electromotive force of the machine is constant whatever the lag of the current may be. It is thus curious that Mr. MORDEY, who has called in question the orthodox theory, lays great stress on the constancy, or stiffness, of the field, a condition which is really assumed in the theory; while Mr. SWINBURNE, who has assimilated the HOPKINSON theory, appears to attribute the successful examples of parallel running to the weakening of the field produced by the reaction of the armature current. According to Dr. HOPKINSON, the tendency of each machine to fall into proper step is caused by the alteration in the output which arises when the phase between the electromotive force and current varies. The spurious voltage due to self-induction, or, according to Mr. SWINBURNE, the voltage due to armature reactions, is of no importance as regards the output of the machine, since it always lags a quarter of a period behind the current, and, consequently, the power corresponding with it is zero.

Mr. SWINBURNE's proposal to disregard the self-induction of the armature, and to take the external voltage of the machine to represent the effective electromotive force, is at first sight attractively simple. It is, no doubt, quite accurate to state, as Mr. SWINBURNE does, that, in an alternator, the effect on the field magnets of the alternating current in the moving armature is the same as that of a steady current in a fixed armature, and that if the current lags the field is weakened, while if it leads the field is strengthened. The behaviour of alternators appears to be reduced to a simple neat rule, and all trouble due to armature self-induction, or to the constancy of this quantity for varying currents and positions of the armature seems to be entirely avoided. Unfortunately, a little consideration shows that the simplicity so gained is more apparent than real. From analogy with steady currents, one would imagine that the external behaviour of a dynamo depends merely on its external voltage and current, and that the relation between these quantities is definite for a fixed speed and excitation of the generator. This, however, is not the case with alternators, for the phase of the current with reference to the voltage is a new condition of supply, whose importance in determining the output is equal to that attributed to volts and amperes. For direct current machines running at a fixed rate, the terminal voltage is perfectly definite if the external current is given, but with alternators it may have very different values, according to the character of the circuit. The terminal voltage is much less closely connected with the output, than is the case with steady current dynamos. By means of condensers it may be raised till it is many times the electromotive force of the dynamo; and, as was shown originally by Dr. HOPKINSON and verified by Mr. MORDEY, it is possible to connect two alternators of very different electromotive forces so as to run in parallel, or so that either drives the other as a motor. There is thus no such thing as the external characteristic of an alternator, unless the nature of the external circuit is defined, but although the terminal voltage is so variable, the electromotive force of the machine is a constant, whatever the phase of the armature current, except in the unusual event of its exerting a powerful reaction on the field.

With the many other important matters alluded to by Mr. SWINBURNE, we have at present no space to deal. His advocacy of distribution by low pressure networks fed from transformer substations, in place of the present system of house transformers, will probably arouse far more attention in the future than just at present; and the many uses to which condensers can be put in connection with alternate current systems will be better appreciated when the difficulties connected with their commercial manufacture are overcome. Directly fairly cheap condensers, capable of withstanding high pressures, are placed upon the market, we believe their importance will be widely recognised.

It is to be hoped that a large portion of the discussion will be devoted to the question of the all-day efficiency of transformers. This is a matter of universal interest, although the public discussion of it appears to have been carefully avoided by those most concerned. Mr. SWINBURNE, in a paper read before the British Association in 1889, astonished everybody by advocating the old open circuit form of converter, and the reasons which he then put forward in support of his views have, up to the present, not been controverted. The present discussion offers the first opportunity which has arisen since that time for debating the question before the Institution of Electrical Engineers, and full advantage should be taken of it.

## THE ELECTRIC CURRENT AND ITS LAWS.

BY JOHN T. SPRAGUE.

§ 1. As these articles have a specific purpose, viz., the comparison of two theories which differ fundamentally, it may save time and misunderstanding if I commence by clearly defining the two theories in such manner as to render the distinctions obvious, and bring out the consequences of the difference.

§ 2. I have had some considerable difficulty in understanding what the new theory really is, and even now I am by no means clear that those who hold it do not differ very materially among themselves. I hope, therefore, that if I am in any way mistaken as to the theory and its limits, my error will be at once pointed out, as I have no desire to set up any "men of straw" for the purpose of overthrowing them.

§ 3. My first conceptions of the new theory were derived from Mr. O. Heaviside's articles on "Electro-Magnetic Induction and its Propagation" (*The Electrician*, Vol. XIV., p. 148, and especially p. 178), where, beginning with "Consider the Electric Current, how it Flows," he proceeds to analyse various conceptions, which I shall have occasion to refer to later on, and probably more than once, because, though I do not agree with his conclusions, his account is thoroughly clear, and in that article does not make wings to itself and fly into the regions of mathematical cloudland.

§ 4. After letting in the ether, "There is reason to believe ('Maxwell's Theory of Light') that it is not the air, but something between the air molecules, that is the electro-magnetic medium" of "transmission of energy and pressure parallel to the wire, all round it," he says, "In the state of steady current through a submarine cable with an iron sheath outside the dielectric, the energy is transmitted wholly through the gutta percha, thus nearly parallel to the wire, except as regards the lines near the wire itself, as they all eventually meet the wire."

§ 5. I shall return to this quotation by-and-by, but just now I want to have a point made clear. In the Editorial Note (p. 444) it is said that I "take uncertain ground when I boldly champion the notion that electric energy is conveyed longitudinally in the direction of the current." It appears to me that this is the case, whatever theory of transmission we adopt.

Digitized by Google

If the energy is supplied from the source, and transmitted to the work, that is longitudinal transmission; it is in the same direction as the current. As far as I can ascertain the real meaning of the new theory, although the current and the energy are transmitted by different agents, the current by and in the conductor, and the energy by the medium outside the conductor, yet the conductor or current holds the energy in bondage; in fact, some such control is inevitable, or why should the energy travel in a definite direction, or go to the intended work at all? That is the essential characteristic of electric energy, that it is linear and controlled in direction, as distinguished from the energy of light and heat, which are radiant, though even they can be to some extent controlled in direction.

§ 6. I should wish someone, say Prof. S. P. Thompson, in continuance of his definitions, to make clear what is meant by his words which I quoted (p. 406), "The energy of a so-called electric current is not transferred longitudinally along the substance of a conducting wire, but is transferred into it sideways;" also his words (p. 464), "The doctrine of lateral transfer." Am I right in supposing that the real meaning is the longitudinal transfer of energy from the source parallel to the conductor, but outside of it, in lines which turn down on the conductor in such number as to supply the energy which we know appears in the conductor as heat?

I wish to be certain of this, because Mr. Heaviside says that Prof. Poynting "holds a different view, representing the transfer as nearly perpendicular to the wire, with a slight slope towards the wire;" and I should like to have some notion how it gets to this perpendicular position, especially as Mr. Heaviside tells us (p. 388, § 15), "the electro-magnetic equations assert that the transference of energy in any isotropic electrical conductor always takes place across the lines of conduction current," and all these lateral, transverse and cross-lines seem to form a complete maze, to which a clue will be useful probably to many besides me.

§ 7. To save time, though not now directly in the course of my argument, I will ask to have another point made clear, which will by-and-bye be of great importance. How does the energy travel which sets up magnetism? Does it go by the "medium?" What is the function of the wire as regards the magnetisation of the core, the setting up of lines of magnetic force and doing work through those lines? There is even a preliminary question. Where does the energy come from which sets up the magnetic charge of the circuit itself? Does it come direct from the source, *viâ* the "medium?" Does it continue on this route after magnetism is set up before going to the waste pipe, or does this energy issue from the conducting wire? I only ask this so that we may know what the new theory really is, as I can answer it all readily enough on the other theory.

§ 8. This magnetic charge of an electric circuit I propose to call the *magnetance*. Here I must digress for a moment; I must confess that I have tried very hard to fully understand what Mr. Heaviside tells us about this (p. 448), but my success is far from complete. I do not quite see whether, in § 25, p. 449, his $g$, which he calls the "magnetic conductivity," but thinks it needs no name, as its existence is doubtful, is intended to be the same thing as what I mean by *magnetance*, which, it seems to me, has a very certain and thoroughly-known existence. But it is likely that this difference arises from his treating magnetism as a *flux*, while I regard it as purely a *stress*. He says: "The idea of a magnetic current is a very useful one," and "the magnetic current $\dot{B}$ is, of course, real." I consider that the idea of a magnetic *current* is a pure absurdity, devised in the effort to set up a magnetic analogy to Ohm's law in electricity, while the true analogy is not to an electric current, but to a condenser charge. This is no matter of words; it involves very important theoretical considerations, which may have equally important practical results.

§ 9. In connection with this, I will make § 21, p. 448, the text of another digression to a point of importance. "All space must be conceived to be filled with a medium which can support displacement and induction." We are told it is a dielectric, and though this medium is the ether, that we may "understand by a dielectric, a medium which supports both the fluxes mentioned." That is, electric and magnetic.

I have now for several years vainly invited a reply to my proofs that electric and magnetic fluxes, lines of force (call them what you will), do not exist and cannot exist in space: that if they did, the force of gravitation would be complicated with their effects, and the cosmical bodies would play all manner of pranks.

Until this is disposed of these "conceptions," however useful for a special purpose, are wanton hypotheses opposed to known facts and the laws of nature; so this seeming digression strikes at the very roots of the theory I am opposing.

§ 10. At first it appeared to me that these new theories converted the "current," not merely into a fifth wheel to the coach, but into a mere incidental encumbrance. Mr. Heaviside (Vol. XIV., p. 179), says "The energy current becomes continuous in the dielectric, goes round an external conductor instead of entering it, as it would in the transient state, and finally reaches the conductor to which the battery is connected, penetrating which it terminates." Again, "With infinite conductivity (of a wire, that is) there can be no current set up in the wire at all" (that is, in the variable stage). As a result, we are told that the conductor has merely the function of a "waste pipe." I think this is the only instance of such an apparatus among the implements of Nature; energy is always expended in useful effect of some sort, never in pure waste; only boys need to work off superfluous energy in pure mischief, and this appears to be the case here. "What, then, is the wire? It is the sink into which energy is poured from the dielectric, and there wasted. All difficulties now disappear." Do they? Then we learn (p. 389 of this volume), that "electrical conductors act, as regards the internal propagation, not as conductors, but rather as obstructors," though it is then explained that they control the energy, as I said (§ 5).

§ 11. Then Dr. Hertz says, "It is very difficult to tell an electrician of the elder school that lightning does not go through copper or iron, but by means of air or gutta percha or insulators," and yet lightning is usually called an electric current. Dr. Lodge, too, says that the conductor does not conduct anything, not even an impulse, and its use is to dissipate energy coming from the medium. Prof. Thompson wrote about "so-called electric currents," and a merely common-sense person may naturally come to the conclusion that Ohm's law was to be thrown into the waste-pipe, or at best stored in a museum of superseded antiquities.

§ 12. Let us then understand that, as Prof. Thompson says, it is still believed, in the new dispensation, that Ohm's law is valid, and that it does yet reveal us the facts of the current, Only the current has no use except to carry off waste energy. Now this point ought to be made a little clearer, and I hope someone will explain my queries (§ 7), and let us know what is the function of the so-called conductor in magnetising, and, above all, why magnetism is proportionate to the ampere turns. It would be interesting to understand why a mere "so-called current" and the convolutions of a waste-pipe are so important.

*(To be continued.)*

## TRANSFORMER DISTRIBUTION.*

BY J. SWINBURNE.

The distribution of electrical power by means of alternating-current transformers can hardly be considered to have reached its final state, and though it may be somewhat difficult to say what system will be in general use ten years hence, there is little doubt that present practice will be largely superseded.

The method now in vogue is simple: it consists of running several independent dynamos, each with its own engine. Each dynamo supplies a few high-pressure mains, which branch off, and supply transformers placed in the houses, or wherever light is required. This system, admirable for country towns or straggling villages, is

* Paper read before the Institution of Electrical Engineers, February 19, 1891.

Digitized by Google

hardly likely to be permanent anywhere else. It has many disadvantages. Except that all the dynamos and engines are in one building, it is nothing more than a collection of little independent installations. Each engine and dynamo supplies its own circuits, which are independent of all the others. In cases of a breakdown of an engine or dynamo, and in many cases of the leads, there is a stoppage till new arrangements can be made at the station. In addition to this, great lengths of high-pressure conductor are required, and this leaves openings for breaking down of insulation. The introduction of high pressures in private houses is dangerous if not well managed, and is in any case expensive, demanding compliance with all sorts of regulations, rendered necessary for the security of the public. The greatest drawback to the present system, however, lies in the waste of power in the transformɛrs themselves. For a long time transformers were supposed to have an efficiency of about 98 per cent. More will be said on this subject presently.

It must be borne in mind that in spite of the drawbacks of the present system of putting transformers in houses, it may be, and probably has been, advisable for electric light companies to begin on that system, even in such places as London ; but I do not think such an arrangement will pay in the long run, and a time will arrive when the mains will have to be changed and a low-pressure supply system substituted. When an electric light company begins, it has to take on houses here and there, where it can get them ; but if its district is populous and wealthy, it should soon be enabled to work on some low-tension or sub-station system ; and then the question is whether it is not better to lay the low-pressure mains at first, instead of beginning on one system and changing to another. Probably none of the existing companies mean to change from one system to another. Their engineers have no doubt gone into the merits of the particular cases, and have come to their conclusions with great deliberation, and I do not think it well to offer any criticisms lightly.

*Parallel Running according to Orthodox Hypothesis.*

To begin at the beginning of my somewhat extensive subject, the first question is that of running machines in parallel. There are few matters of greater importance to engineers, and few on which opinions differ so widely. One says that machines will not run in parallel unless they have large self-induction ; another that it is necessary to have iron in the armatures ; another that they will only run together if they have no self-induction, or as little as possible. Others say that there is no difficulty in running them in parallel. No engineer who employs direct currents denies the advantages of running machines in parallel ; if independent running is advisable in alternate systems, it is equally advantageous in the case of direct currents, and direct-current stations should have separate circuits for each little district, each district being run by one dynamo. I do not think, therefore, independent running is a-lvisable.

In 1884 Dr. Hopkinson showed that alternate-current dynamos could be run in parallel, or could be run as dynamo and motor, and even that a machine giving a high pressure could be run as a motor off a circuit of lower pressure. In his Paper he assumes that machines have "self-induction." He points out that the self-induction varies, but that it would be impossible to work out the calculations if the "self-induction" were taken as variable. For some reason or other, Dr. Hopkinson's calculations have received little application. That is to say, engineers have not taken actual cases and worked them out. Calculations have been made in which the various quantities have appeared in the form of letters, and diagrams have been drawn in which they are represented by lines whose lengths have been chosen at random. The geometrical treatment of many problems of this kind shows most of the actions very clearly to students, but is not always of value in practical work, as in most cases some lines are so long and others so short that it would be difficult to avoid large errors. The result of this is that few of us, if any, have had a definite idea of how much "self-induction" a machine should have to make it work well in parallel with others. The general impression is that it is somewhat difficult to design a machine whose "self-induction" is large enough, and that most failures to run in parallel are due to deficiencies in this respect. I am using the term "self-induction" under protest, as I prefer to look at the question from another point of view. But whatever goes on in a dynamo, if the no load electromotive force is treated as constant, a value for a constant coefficient of self-induction can be assumed which would produce results somewhat similar to those found in practice. To overcome the difficulties arising from deficient self-induction in the armature circuit, Dr. Hopkinson has proposed to insert it artificially, in the form of chøking coils, or to use induction couplers to compel synchronism. Without knowing that it had been done before, I described a similar arrangement to the Institution a few years ago.

In the spring of 1890 Mr. Mordey read a most important Paper, in which he described some experiments on alternate machines. He argued from them that self-induction was deleterious, and that machines would run together best if they had none. In the discussion, Dr. Hopkinson pointed out that the experiments were quite in accordance with his theory, and that there was nothing that could not be foretold by it.

To begin with, it is necessary to get a clear idea of what is required for parallel running. It is not exactly the same as the case of alternating motors, neither is it the same as two machines of equal pressure coupled in parallel by themselves. If all the machines are coupled to two main conductors, we may consider them one at a time, and take each dynamo as coupled to a system whose pressure and variations of pressure are independent of it. Suppose the effective pressure to be 2,000 volts, for example : we have to consider a pair of mains with 2,000 volts, and we have to couple on a dynamo to add so many amperes to it. Such a machine must not be excited to give 2,000 volts on no load, being then thrown into circuit with full steam turned on immediately afterwards. It should be excited to give somewhere about half load with 2,000 volts at the terminals, and should then be thrown in. Steam can then be turned on, and the excitation raised to its normal value. The machine should be so designed that any excessive power that the engine may give shall not only not throw the machine out of step, but shall not increase the armature current to such an extent as to damage the insulation by excessive heating.

The power absorbed by a dynamo working on a parallel system is

$$P=\frac{B^2 r}{2 i^2}-\frac{A B r}{2 i^2}\cos 2\pi n \tau+\frac{A B L}{2 i^2}\sin 2\pi n \tau,$$

where A is the maximum station electromotive force—that is to say, the station pressure is $A \sin 2\pi n t$—B is the maximum "impressed" electromotive force in the armature, $r$ is the armature resistance, the impedance of the machine, and $\tau$ the angle of lead. This equation is taken from Dr. Hopkinson's Paper. When the dynamo is doing its proper share—that is to say, under normal conditions—

$$B=I c,$$

where I is the impedance of the whole circuit when the machine is isolated, and working at full load on an external resistance, and $c$ is the maximum value of the current. To find how much the driving power may increase for a small increase of current, we may differentiate with respect to $c$, and then find the value of L which makes the result a maximum.

$$c=\sqrt{\frac{A^2+B^2-2 A B \cos 2\pi n \tau}{i^2}}$$

$$\operatorname{Cos} 2\pi n \tau=\frac{A^2+B^2-i^2 c^2}{2 A B}$$

So,

$$\frac{dP}{dc}=\frac{A B r}{2 i^2}\cdot\frac{i^2 c}{A B}+\frac{A B 2\pi n L}{2 i^2}\cdot\frac{d \sin 2\pi n \tau}{d 2\pi n \tau}\cdot\frac{d 2\pi n \tau}{d \cos 2\pi n \tau}\cdot\frac{d \cos 2\pi n \tau}{dc};$$

and in the case of a dynamo working on resistance, or on a station load when supplied with just its right share of power,

$$\cos 2\pi n \tau=\frac{A+r c}{B},$$

$$\text{and } \operatorname{cosec} 2\pi n \tau=\frac{B}{L c}.$$

So,

$$\frac{dP}{dc}=\tfrac{1}{2} A+c r,$$

$c$ being the maximum, not the effective current. It will be observed that L has disappeared altogether.

This shows that for a very small increase of power the increase of current will be the same, whatever the self-induction of the machine may be. It would not matter if the machine had none. A machine with no self-induction would (Mr. Mordey notwithstanding) short-circuit the mains if the engine supplied too little power ; in fact, at full load it would be giving its minimum possible output, and any attempt to diminish this would be disastrous.

Discussing the question of a very small increase is not exhaustive ; an engine may supply a large proportion more than its share of power to one machine. For instance, suppose it supplies twice the normal power. Many engines could not give such an excessive power, but in others which have expansion gear controlled by a speed-governor, it is easy to get double power if the station is running at a slightly slower speed than that for which the governor is set.

These matters are always made much clearer by taking practical examples and working them out. The great difficulty is to obtain accurate data. I should prefer to discuss such machines as those described in Mr. Mordey's Paper read here a short time ago. Without wishing to say anything in disparagement of his excellent Paper, I must point out that an account of experiments should contain full particulars of the machines on which the experiments were made. Such omissions are exceedingly common in electrical

Digitized by Google

Papers. Mr. Mordey has not given us the details of the field magnets, air space, armature coils, or exciting coils; he has not even given us the currents in the different experiments. I have found similar omissions whenever I have tried to gain information from any of the numerous experiments which have been made on alternate machines in America. Mr. Mordey does, however, say that about half the drop in his machines is due to resistance, and half to self-induction. The machines give an output of 2,000 volts and 20 amperes, and when fully excited give 2,200 volts at no load. This would correspond to a self-induction of 0·05 henry.

Suppose, first, that the self-induction were such that $2\pi n L = r$: on increasing the power supply, the effective current increases evenly, and when the power supplied to the machine is doubled, the effective current is only about 44 amperes. It is necessary, however, that the machine should stand decrease of load, as well as increase, without injury. Keeping the same self-induction, let us decrease the load to zero with the full excitation on. The current gradually diminishes to just below 15 amperes, and then increases to just over 20 again.

These figures are extremely troublesome to work out from Dr. Hopkinson's equations, as the angle is so small that an error in about the sixth place of decimals will vitiate the results.

Many people prefer diagrams such as those used in mathematical books when dealing with harmonic variations. Mr. Blakesley has applied these diagrams to the discussion of alternate dynamos and motors, and Messrs. Kapp, Fleming, and others have applied them too. The chief drawback is that it is not always easy to draw such figures to scale. They are generally drawn with the values taken at random, to give ideas of the principles involved. So far as I know, no scale diagram of this sort has ever been published. In the case of the 40,000-watt machine such diagrams can be applied but with 100,000-watt machines, which will probably be the standard size, the diagrams are almost illegible.

Fig. 1 is a diagram to scale. The lines are all rotating positively. The diagram is made as follows:—The pressure in the mains, A, is drawn first. Instead of the maximum, it is simpler to draw the effective pressure—in this case 2,000 volts. From the end $e$, $2\pi n L c$ is drawn at right angles to it to $f$; and then $r c$ from $f$, parallel to A, B, is drawn to join the ends of A and $r c$, as shown. The lines are all pressures; but the instantaneous current is in

Fig. 1.

step with the pressure $r c$ and with the pressure A, so that the power is proportional to $B\, r c \cos f d m$. I use the expression "in step" to mean co-phasally synchronised. Thus two machines may be running at the same speed without being in step; just as soldiers may take the same number of paces per minute without being in step.

To find the current at double load, produce $i c$ to $g$, so that $d g = 2 i c$. Through $g$ draw a straight line cutting B at $k$, at an angle, $g k d$, equal to the angle $d e f$. The line $g k$ is the locus of the end of the line representing the pressure spent over the resistance and self-induction of the armature with currents giving double load. It is unnecessary to go into the proof of this. With $m$ as centre and A as radius, describe arc cutting $k g$ at $h$; join $d h$. Then the current at double load is to 20 amperes as $d h$ is to $d e$. In this case the double-load current is not much more than 40 amperes.

To find the current at half-load, bisect $d e$, and through point of bisection draw a straight line parallel to $h k$, and proceed as before. The no-load line, of course, passes through $d$.

Let us now assume the self-induction to be 0·05. The resulting diagram is shown in Fig. 2. The double-load current is almost exactly 40 amperes.

Take now the case of a 40,000-watt machine with a self-induction of 0·1. At double load the current is 50 amperes, and at no load it is only 1·6 amperes. If the machine has a self-induction of much more than 0·1 quadrant, the current at double load begins to increase rapidly. It is thus clear that the self-induction may have any value between 0·008 and 0·1 and the machine will work perfectly in parallel.

We have only taken small machines. Mr. Kapp recently described a 60,000-watt machine with an armature resistance of 1·74 ohm, and a self-induction of 0·0955—say of 0·1. We may see how it will work in parallel. The pressure is 2,000 volts, and the frequency 80. This case cannot be shown clearly in a diagram, as $r c$ is very small in comparison with $2\pi n L c$ or B. The result is, however, that the machine cannot possibly take double power from the engine; it falls out of step first. Now 60,000-watts is not a large output for central stations, and it is probable that 100,000 will be about the size adopted. The "time constant" of such a machine is considerably greater. We thus find that according to the self-induction hypothesis the difficulty does not lie, as commonly supposed, in getting enough self-induction in the armature; the trouble is that there is generally too much. But in machines from 25,000 to 50,000 watts it is exceedingly difficult to make dynamos that will not run perfectly in parallel, so great is the permissible margin of self-induction. It must be carefully borne in mind that so far the armature has been supposed to have a constant coefficient of self-induction, and the pressures of current are assumed to vary harmonically.

The orthodox hypothesis thus tells us that with ordinary sizes of machines it is exceedingly difficult to design them so that they will not run in parallel. Either, therefore, all ordinary machines run

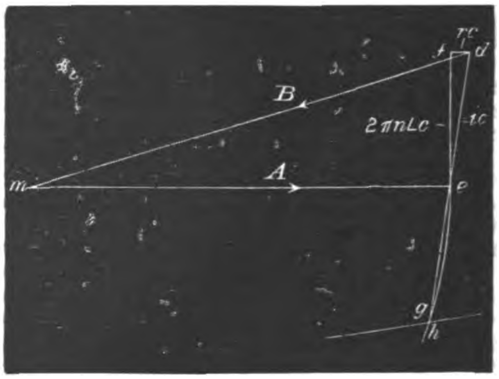

Fig. 2.

perfectly in parallel, or the assumption that alternating currents follow sine laws, that machines have coefficients of self-induction constant throughout each period, or that they have coefficients of self-induction constant for different armature currents, is too far from the truth to be useful; or, in legal language, one or some or any or all of them must be wrong.

*Parallel Running according to Armature Reaction Theory.*

Last year I had the honour of reading a Paper before this Institution on armature reactions in direct-current machines. In it I showed how the performance of large machines could be foretold; and the whole question of the effect of the armature current on the field magnets was discussed with some minuteness. I cannot pretend to treat alternate-current machines with the same exactness, but still a great deal is to be derived from the study.

It has sometimes been assumed that a machine has self-induction in the armature, and also that there are armature reactions to be considered, and the two actions are treated as if their joint effects had to be taken into account. This view is, I submit, erroneous.

Fig. 3.

Imagine a battery with its cells connected to a number of contact pieces, and imagine the middle cell connected with a terminal, to represent one terminal of the machine, and the other terminal represented by a rubbing contact which is moved backwards and forwards over the cell contacts by a crank and connecting-rod. This gives the analogue of a hypothetical machine with no self-induction. If a choking coil is put in circuit, the hypothesist's alternating machine would be produced. To get a constant coefficient of self-induction in a real machine would be almost impossible. If a coil passes between two cheeks of laminated iron, its coefficient of self-induction is constant. In a dynamo, however, half the iron is cut away, the remainder forming the pole-pieces, and this remainder is not laminated. Even if a dynamo gave a curve of sines at no load, therefore, the reasoning already given would not be accurate, as L would vary considerably from one part of the period to another.

The term "self-induction" is also used somewhat loosely. Engineers do not generally think of electrical inertia now. By a self-induction 1 in an electric circuit, is meant that if there is a

Digitized by Google

current of 1 in it, it is interlinked with one line of induction. The idea of self-induction is naturally inseparable from the notion of magnetic induction being interlinked with the circuit. Another way of looking at it is to say that if the current increases there is a back electromotive force proportional to the rate of growth of the current, and to the self-induction of the circuit. In an alternate dynamo the first definition is meaningless, because there is a field produced by the magnets; so, when the machine is still, there may be a large number of lines of induction through the armature coils without any armature current. If the second definition is taken, there is likewise an electromotive force produced by the passage through the field, apart from the effect of the armature current.

Take the case of a machine like the Siemens, with coils passing between poles. If there is a continuous current in the armature, in some positions it will assist the field-magnets, and in others it will to some extent weaken them, while in intermediate positions it has no effect on the magnets as a whole. In an alternate-current machine, though the armature current is alternating, relatively to the field-magnets, it is direct. If a series of instantaneous photographs of the armature current could be taken, each part of the air space would have its direct current.

Fig. 3 is a diagram of the field-magnet poles of a machine. There are supposed, for simplicity, to be twice as many pairs of poles as there are armature coils. If one side of a coil is between each pair of poles, if there were no armature current the fields would be inducing a maximum pressure. If the pressure curve of such a machine were traced, and placed in the diagram of the poles, it would be as shown in Fig. 4. The positive direction of the current or pressure in the armature and field-magnet coils is shown by shading, the negative by dotting. If electricity flows in the armature when the sides of the coil are in the active fields, one side of the field between the poles is strengthened and the other weakened, as shown in Fig. 3. This action is fully explained in the case of direct currents in my Paper already referred to; but in alternate machines the action is much more complicated, for there is no longer a continuous succession of conductors each carrying the same current as it passes any given position. If the pole-pieces were laminated, the distribution of field would vary as each conductor passed; but as it is not laminated, Foucault currents developed in the pole-pieces tend to check variations under influences varying from 200 to 600 per second. The field thus becomes stronger on one side. The curve of pressure thus gets displaced, as shown in Fig. 5.

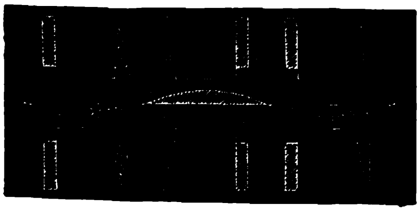

Fig. 4.

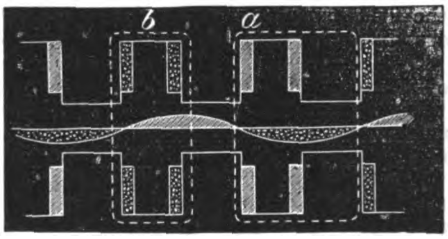

Fig. 5.

Fig. 6.

If the external resistance is non-inductive, this may be regarded as a current curve. It will be seen that each magnet is now exposed to the back induction due to the armature current. A circuit, *a*, taken round the field-magnet circuit is interlinked with the whole wave. The line integral is not changed if it is taken round any other circuit, so that the sides are the same distance apart as they are in *a*. A circuit taken as shown at *b*, however, includes only half a wave; so that from Fig. 5 both the cross and the back induction could be completely worked out. In most machines it is impossible to make such a diagram accurately; but in others, such as drum armatures, with poles and coils of given widths, it is not so complicated.

The effect of the armature current, then, is first to make the current lag relatively to the position of the field-magnets, and then to lessen the pressure as a whole. It thus resembles the effect of the insertion of artificial self-induction.

I think to call all this "self-induction," and to assume the harmonic law just to make calculation easy, is disguising the real nature of the action, and may lead to very serious errors. The armature reaction theory is also infinitely easier to understand, and to follow in one's head. The result of it is, in short, that if the current lags, the field is weakened; if it leads, the field is strengthened. If the current is in the direction agreeing with the electromotive force of the machine, it tends to lag, owing to cross induction; if it is against the electromotive force of the machine, as in the case of a motor, it tends to cross-magnetise the fields in the opposite direction.

We may now examine the question of parallel running from the armature reaction point of view. Though it may be out of its proper place in the Paper, the question of motors may be to some extent discussed at the same time.

Suppose, as in the first case, a pair of terminals in connection with a station, so that the electromotive force on them is independent of any current, or of the machine under discussion connected to them. It is necessary to keep clear, for the moment, of any ideas connected with L. The armature circuit must be regarded as devoid of "self-induction."

A machine without friction may be imagined, and when its field-magnets are separately excited, so as to give an electromotive force exactly equal to that of the mains when it is connected so as to be in step, it runs as a motor taking no current. At each instant the electromotive force of the machine is exactly equal to the electromotive force of the mains, so no current passes. On putting on some load the machine begins to lag. As soon as the machine lags, a current passes through the armature. The current due to the difference of two equal alternating electromotive forces is not in step with either of them. This is shown in Fig. 6, where two pressure curves are drawn a little out of step. The current through resistance is proportional to the shaded parts. If the electromotive force of the machine were still the same as that of the mains, it would still develop no power as a motor, because at some parts of the period it would be supplying power to the mains, and at other parts the mains would be supplying power to the armature; for at any instant the armature current would be equal to the difference of the two electromotive forces divided by the resistance of the armature. The average current curve is shown in Fig. 7. The electromotive force of the machine does not, however, remain equal to the main electromotive force, merely differing from it in phase, but is decreased by the reaction of the armature current on the field-magnets. The average current curve shows that there would be considerable back induction, or many ampere-turns tending to weaken the field. This weakening of the field by the armature reaction allows the main also to supply a current against the electromotive force of the machine, so that it acts as a motor, and power can be taken from it. If the load is altered, the machine will increase or decrease its lag, so that its effective field is reduced to just the right value to allow the machine to absorb electrically the power taken from it mechanically. As lag is necessary in order to weaken the effective field, so the current in the armature is no longer in step with the electromotive force of the mains. The result of this is that it is not at the maximum value at the same instants as the electromotive force is; so that

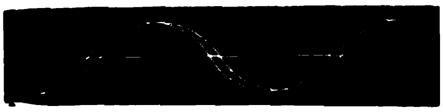

Fig. 7.

the power taken by the motor is less than the product of the effective electromotive force of the mains and the effective current of the machine. The electromotive force and current may be so much out of step that the power of the motor is small, though the armature current is large. The availability of the machine as a motor thus depends on the resistance of the armature, and on its reaction on the field. For instance, if the machine has very little armature resistance, a very small reduction of its electromotive force will allow a large armature current to pass. If, on the other hand, the armature resistance is high, the armature must have a large reaction on the field so as to reduce the effective electromotive force. If, at the same time as the load is put on, the field of the motor is artificially weakened by reducing the excitation—for instance, by the insertion of resistance in the field circuit—the electromotive force of the machine may be reduced enough to allow current from the mains to act in step with the main electromotive force. For instance, if the supply circuit is of 2,000 volts, and if an ordinary separately excited 2,000-volt machine is connected, and excited so as to give 2,000 volts with the same frequency, and if this machine is loaded as a motor with 40,000 watts,

or 54 horse-power, it will lag until the field is weakened enough to let enough current pass to give the power. This current will be more than 20 amperes. But if the machine as a dynamo can give 20 amperes with the loss of 100 volts in the armature, due to the resistance, and if the machine is excited so as to give 1,900 volts on open circuit at the normal speed, and is then thrown into the circuit at an instant when it is in step, and a load of 38,000 watts, or 51 horse-power, taken out, it will remain in step; for the electromotive force of the machine is always just enough below the main electromotive force to allow the right current to pass. The effective current is then 20 amperes. The main circuit thus supplies 2,000 volts and 20 amperes; 2,000 watts are lost in overcoming the resistance of the armature, and 38,000 are available at the pulley. The losses by friction and Foucault currents are here neglected for the sake of simplicity. In practice a little less than 51 horse-power would be obtained for external use. If the field has not been weakened by reducing the excitation, the effective current—that is to say, the root of the mean square of the current, or the current as measured by an electro-dynamometer—would be more than 20 amperes, so that there would be extra loss of power in the armature.

If the machine is to be worked as a generator in parallel with the main circuit—that is to say, if it is to supply power to the mains instead of to take it from them—the same reasoning holds good. If the machine is excited so as to give 2,000 volts at no load, and is thrown into circuit at an instant when it is in step—if the engine supplies just enough power to overcome friction, there will be no armature current, as the electromotive force of the machine will, at every instant of the period, be exactly equal and opposite to that of the mains. If the engine supplies just a little too much power, the machine will begin to lead, and an armature current will pass, which will strengthen the fields by reaction, and the machine will at some instants act as a generator, because its electromotive force is now a little higher, as the armature current has strengthened its field. Similarly, if the steam of the engine were completely shut off, the machine would lag until it worked as a motor. If now the steam is turned on until the dynamo supplies 40,000 watts to the mains, the machine will increase its lead until the armature current strengthens the field enough to give the full output. The armature current must be out of step with the electromotive force of the machine.

In these examples back induction has alone been considered; but the effect of cross induction must also be taken into account. Cross induction, in the case when the machine is working as a dynamo, makes the current lag. This weakens the field, and counterbalances to some extent the effect of the leading current, due to the pressures being out of step. A still greater lead is therefore necessary to make the machine work as a dynamo. Suppose, however, that the field excitation is strengthened to balance this back induction, as well as the loss by armature resistance—that is to say, suppose it is excited to give 2,000 volts, and 20 amperes on resistance, in spite of the armature reactions—it will run in step on the mains.

*(To be continued.)*

## THE STRIKING DISTANCE OF ALTERNATING ELECTROMOTIVE FORCES.*

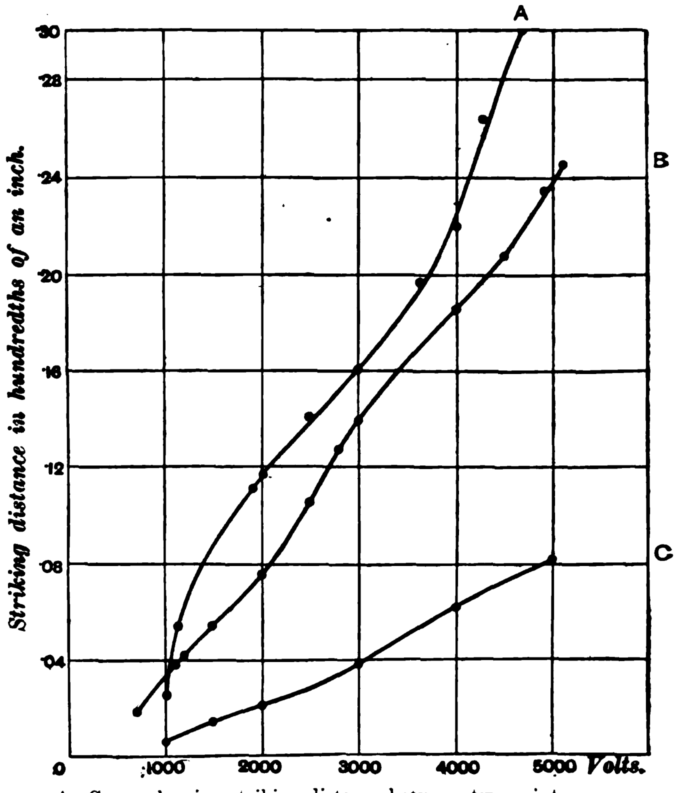
BY ROBERT SHAND.

Prof. Elihu Thomson, while engaged upon experiments involving the use of alternating currents having a pressure of several thousand volts, found it necessary to ascertain the spark lengths which the pressures he employed were capable of producing, and also the charge of spark length produced by increase in the density of the air through which the discharge occurred.

It is well known that numerous and elaborate experimental inquiries have at different times been made, having for their object the determination of the ratio of spark length or striking distance of a discharge of electricity in air (and various other gases) to the electromotive force producing it, and the determination of the law governing the increase of striking distance with decrease in the density of the air. For the production of the high electromotive force required in the experiments, plate machines, Leyden jars, the Ruhmkorff coil having a vibrator in the inducing circuit, and voltaic batteries, consisting of a very large number of elements, have been employed. The results obtained have been represented by formulæ, and arranged in tables which can undoubtedly be applied with certainty to cases the conditions of which correspond with those obtaining in the experiments the results of which they represent.

* From the *Electrical World* of New York.

None of these experiments, however, afforded data fitting the special cases occupying the attention of Prof. Thomson, who, therefore, with the object of satisfactorily deciding the matter, caused to be made at his laboratory experiments, the results of which are graphically recorded on the accompanying diagram, which explains itself. The discharges took place inside a spherical glass vessel five inches in diameter, and having three openings fitted with brass caps and leather collars. Through two of the openings, situated opposite each other, passed the discharge rods. The third opening could by means of a tap be opened to the outer air or connected with a pipe leading to a pressure pump. To indicate the distance separating the electrodes between which it was arranged the discharge should occur, one of the rods had a screw thread of one-fortieth inch pitch cut along that part of its length which worked through an opening in the glass sphere. It was also fitted with a graduated disc, which rendered small fractions of a revolution of the rod readily observable. Wires from the secondary terminals of a small transformer were led to the discharge rods, the potential difference between which could be varied between the limits of 600 and 7,000 volts. The voltmeter used was one of Sir William Thomson's vertical scale electrostatic instruments reading to 6,000 volts. An ordinary steam pressure gauge having large scale divisions was calibrated and used for the measurements of air pressures.



A, Curve showing striking distance between two points.
B, " " " point and sphere.
C, " " " two spheres.

In making the experiments the electrodes were brought toward each other until contact was indicated. The position of the discharge rod carrying the graduated disc was noted, and it was then withdrawn to a distance indicated by the number of revolutions of the rod.

The primary circuit through the transformer being closed, the pressure was increased until discharge occurred, the potential difference indicated by the voltmeter at the instant of such discharge being noted. In order to have the points of the voltmeter move steadily over its scale without vibration, it was found necessary to increase the pressure very slowly.

When observing the effect of increased air density on the spark length, the air pressure and electric pressure were maintained at a constant value and the electrodes moved nearer together until discharge occurred; the spark length was then the remainder of the distance the electrodes would have had to move through before making contact.

The object in using pointed electrodes was to find the lowest potential difference capable of producing the spark; consequently the points were made as sharp and as perfect as the means at command rendered it possible to make them. It is obvious, nevertheless, that however great the care exercised, they must necessarily be more or less imperfect after each restoration. To this cause is undoubtedly due, in large measure, a somewhat irregular form of the curves showing spark lengths where a point or points were employed.

Digitized by Google

An inspection of the point and sphere curve shows a discharge through ·019 of an inch of air produced by a potential difference of 700 volts. It serves to show the delightful uncertainty of points. This one was, doubtless, well made. When compared with point curves, the smooth, regular character of the sphere curve is noticeable, also the fact that the decrease of potential difference per unit length of air sparked through, with increase of potential difference and spark length, is more marked than in the case of points.

It was observed that when the spark occurs under pressures exceeding one atmosphere, the slope of the curve grows less steep as the spark length is shortened by increase of air density. It would thus appear that the dielectric strength of air is not simply proportional to its density for pressures above two atmospheres. At pressures below two atmospheres, however, it would appear to be approximately so. A remarkable elongation of the spark was effected by heating the electrodes ; the elongation was greater than the rarefaction of the stratum of air included between the heated electrodes would appear to explain.

The results of these experiments being required for application under practical working conditions, no special care was taken to dry or filter the air in which they were made.

## PARIS NOTES.

(FROM OUR OWN CORRESPONDENT.)

PARIS, *February* 25, 1891.

At the meeting of the Société Française de Physique on Friday last, M. Hospitalier made some remarks on electricity meters which, in view of the fact that he is one of the committee engaged in examining the instruments sent in to compete for the Paris municipal prize, were of considerable interest. The meters have, I understand, all undergone the preliminary tests, and a select few are now being further examined. M. Hospitalier divides electric meters into two classes, namely integrating and registering instruments. The first class he further divides into time counters, current meters, energy meters, and integrating conductivity meters, according as they measure T, $E\int I\,dt$, $\int E$, $I\,dt$, $E^2\int \frac{1}{R}\,dt$.

The instruments belonging to the three last sub-divisions are not all equally suitable, and M. Hospitalier showed by a series of curves that if the pressure is below the normal, the price of the kilowatt-hour will come out differently for different instruments. Thus, the indications of a watt-hour meter will not be affected by variations of pressure ; but in the case of an ampere-hour meter the consumer is charged for more energy than he receives, since such an instrument takes no account of the diminished pressure at which the current is supplied, and the same holds good, only more so, in the case of a "mho-hour meter." "Mho-hour meters" are, therefore, the least suitable apparatus of all. With regard to watt-hour meters, it must be remarked that although variations of pressure do not affect their indications they affect the consumer in a most injurious manner. If he is wired with 100 volt lamps, no amount of current at 90 volts pressure will make his lamps burn brightly, and if the pressure rises to 110 volts there are lamp breakages to pay for. An ideal meter, therefore, would be one which, as was pointed out by Prof. Forbes at the Society of Arts in January, 1889, registered according to the *quality* of the energy supplied. M. Hospitalier concluded his address with brief descriptions of several meters, such as the Elihu Thomson, Hartmann and Braun, Richard, Batault, and Laurence-Scott, which had been brought out since his Paper of 1888.

The experiments on the de Meritens cell, which re being carried out at the Ecole de Physique et de Chimie, have already resulted in demonstrating that the cell works just as well without as with the platinised lead foil on the carbons.

I have just learnt that Woodhouse and Rawson United have purchased M. Mildé's concession for the sector starting from the Madeleine and comprising the St. Lazare Station, the Boulevards Malesherbes, Haussmann, the Arc de Triomphe, de l'Etoile, and the Porte d'Asnières. The same firm also intend founding a French manufacturing branch. The Brush Company, Mr. Ferranti, Messrs. Mather and Platt, the Thomson-Houston Company, and the De Khotinsky Company, all propose, I believe, to go in for genuine manufacture in France if they find that they are able to obtain protective rights under the new customs tariff.

As the question whether electric supply is a paying business or otherwise is as much a moot point with you as with us, it may not be without interest to give a few figures relating to the profit and loss account of the municipal station at the Halles during the first three quarters of 1890. The plant at this station comprises six 50-kilowatt Edison machines and three 110-kilowatt Ferranti alternators, the high and low tension mains being kept entirely distinct. The outlay at the generating station amounted to £23,900, and the mains cost £16,500, a total expenditure, therefore, of over £40,000 was incurred. As the alternating plant has only come into operation quite lately, its earnings do not figure in the balance-sheet. Taking the low-tension supply only, we find that its working expenses amounted to £6,920 and the receipts to £11,840, leaving a balance of £4,920, and reckoning depreciation, water, and miscellaneous expenses at £3,200 we arrive at a net profit of £1,720, which means that the low-tension plant earns a net revenue of 10 per cent. on the money sunk on it.

The large shop known as "Old England" has just been switched on to the mains of the Société Anonyme d'Éclairage Electrique, which employs the five-wire system. The installation comprises 14 8-ampere, and 22 6-ampere arcs and 50 16 candle-power incandescents. The Gare d'Orléans is about to be lighted by electricity on the Ganz system. At Marseilles the gas company propose to erect a number of miniature electric lighting central stations, each one to serve a block of buildings, and the motive power to be derived from gas engines.

## VIENNA NOTES.

(FROM OUR OWN CORRESPONDENT.)

VIENNA, *February* 21, 1891.

The Empress of Austria is building a magnificent château in Corfu, supplied with every luxury, and among others the electric light. The contract has been given to the International Electric Company. Their manager, Mr. Max Déri, will personally supervise this installation.

In Vienna the effect of the electric light in St. Stephen's-place, Kärnterstrasse and Ring has been curious. Formerly these streets were practically deserted after half-past seven, though in the daytime filled with fashionable pedestrians. Since a large number of the best shops have introduced the electric light these streets have quite altered their evening character. Instead of being deserted early they are now crowded till quite late.

The Austro-Hungarian State Railway Company have decided to light their express trains by electricity. The first experiment is to take place with a train of eight carriages, and Tudor accumulators are to be used. The towns of Mähr and Chozen have decided to adopt the electric light. The Mähr installation is to consist of 28 1,000 candle-power arcs and 2,400 16 candle-power glow lamps. The sugar factory in Tobischau, the large brewery in Liesing, near Vienna, and a large number of factories in Bohemia are also introducing the electric light.

An interesting power transmission installation has been carried out near Linz. There are two factories belonging to the Klein-münchen cotton mills. These lie on the Traun Canal, 2 kilometres distance from each other. In the one, lying higher up the canal, new turbines with larger power were put up, resulting in a loss of power in the lower factory. The upper factory had now more power than required, whereas the lower factory had not enough. This has been equalised now by putting up an 80 horse-power dynamo in the upper factory and transmitting the current by 6mm. copper wires overhead to the lower factory. The additional horse-power obtained is 60 or 75 per cent. of the original 80 horse-power.

In the telephone world there is not much doing at present. The various exchanges are flourishing, and the new Vienna-Brünn trunk line has been opened and works well. Prag has been connected with the Bohemian coal district, and Reichenberg with some of the neighbouring small towns. This year Prag is to be connected with Brünn, also perhaps with Pilsen, and a new wire is to be added to the existing line, Vienna-Prag. This seems almost a pity. Conversation between Vienna and Prag is so good now that the line is most extensively used. If a second wire be added it is to be feared that induction will interfere with the present satisfactory working. Over 200 calls a day take place, and as the charge is at least 1fl. per call the gross annual receipts are very considerable, and show a large net profit on the cost of the line, which was about £10,000. By far the largest number of calls take place between exchange subscribers.

The Vienna Compressed Air and Electric Company have received a concession from the Town Council for supplying the various workshops with power, either compressed air or electricity. There was a fight in the Town Council as to whether the town should not monopolise the business, but finally it was decided to grant the concession, though the terms seem to an outsider rather onerous.

The Hungarian Minister of Commerce is now being approached with a view to the granting of a concession for the construction and working of the proposed electric railway between Vienna and Buda-pest. The undertaking is under the patronage of the Commercial Bank of Budapest, and the initial expenditure necessary to carry out the scheme is estimated at 38.000,000fl. The railway would consist of a double line 250 kilometres long, and the current would be furnished by six generating stations placed at intervals of 40 kilometres.

# CORRESPONDENCE.

## ELECTRIC THEORIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I accept gladly Mr. Sprague's amendment to proposition No. 4, of p. 464, substituting the words "by the agency of the magnet" for the words "from the magnet," as these words satisfactorily embody what I desired we might both agree to. Now what we are agreed as to preliminaries, the course is cleared for a discussion of the *some way or other* by which the energy is transferred. I therefore propose to write in support of the modern views in your next issue, unless in the mean time Mr. Sprague himself sees fit to begin to set forth his own views.—Yours, &c., SILVANUS P. THOMPSON.

[Prof. Thompson will find that Mr. Sprague begins with his first article in the present issue, and we therefore invite him to hear Mr. Sprague first, and to prepare for championing the cause of orthodoxy at a later date. Meanwhile, if any ambiguity should arise as to terminology and definitions, we will forward to Mr. Sprague any suggestions which may clear the way, since the controversy, important as it is, is largely "one of mere interpretation of terms," as Prof. Thompson put it in a former letter.—ED. *E.*]

## ELECTRIC THEORIES.—ETHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think Mr. Sprague is mistaken if he supposes that Sir W. Thomson has suggested that there is such a thing as a "massless" fluid really existing in nature. In his Presidential Address to the Institution of Electrical Engineers, 1889, Sir W. Thomson introduces the idea of a "massless" fluid to illustrate the distribution of alternating currents in a conductor; but he makes it perfectly clear that this is merely for the sake of mathematical analogy. In the last two lines of page 21, *Journal* of the Institution of Electrical Engineers, Vol. XVIII. (referring to the above), he says, "The analogy I have just sketched cannot be considered as in any respect a physical analogy."—Yours, &c., J. GRAY.

National Liberal Club, Whitehall-place, S.W.

## THE BARKING ROAD CARS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The Secretary of the General Electric Power and Traction Company (Limited) informed me of his intention to publish his letter to me of the 20th and my reply of the 21st inst. I answered that I had no objection whatever, but must request him in this case also to publish my letter to the Company dated the 20th, which was written and sent a day before I received his letter. In case he should not do so, I enclose copy of it, and shall feel obliged if you will publish it with the other letters. You will see that the moment I discovered that my tables were given under a misapprehension, I did spontaneously what any gentleman would do, namely, offered to correct the figures, and that there was no need for Mr. Mackenzie's threat of legal proceedings to make me do what was right and just.—Yours, &c., GISBERT KAPP.

[COPY].

Erba, Wimbledon, February 20, 1891.

Messrs. The Electric Traction and Power Company (Limited), Maldon-crescent, Prince of Wales-road, Kentish Town.

Dear Sirs: I was surprised to hear last night from your Mr. Snell that he considers the figures I gave in my Cantor Lecture, with reference to the Barking Road Tramway, incorrect. When, towards the end of last year, I applied to Mr. Frazer for information about the working of battery cars, I was under the impression that this gentleman was the member of your Company who had the entire control of your traction work, and I, therefore, took the figures which he gave me as authentic and correct. If, however, as Mr. Snell asserted last night, the figures are not correct, it appears desirable that the necessary corrections should be made in the tables I gave at the Society of Arts lecture, and I shall do this if you will kindly supply me with the exact figures.—Yours faithfully, GISBERT KAPP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Herewith I beg to hand you copies of correspondence between Mr. Gisbert Kapp and myself, relative to particulars given by him concerning our Barking installation.

As the report of this lecture appeared in your last publication, I shall be glad if you will find space in your columns for the publication of the enclosed in this week's issue.—Yours, &c.,

W. G. M. Mackenzie, Secretary,

THE GENERAL ELECTRIC POWER AND TRACTION COMPANY (LTD).

London, Feb. 24, 1891.

[COPY.]

The General Electric Power and Traction Company (Limited), New Broad-street House, 35, New Broad-street, London, E.C., February 20, 1891.

GISBERT KAPP, Esq.

*Re Cantor Lecture on Monday, 16th inst.*

Dear Sir: I am requested by the Managing Director to draw your attention to the enclosed printed matter with reference to data relating to the Barking-road electric installation, which is the property of the General Electric Power and Traction Company (Limited). The figures thus given are entirely misleading, and the publication of them is calculated to seriously injure our interests, as well as those of the North Metropolitan Tramways Company, and we must request you accordingly to withdraw the Tables 4 and 5, and the statement made by you based thereon, at the next Cantor Lecture in such a public manner as will be likely to reach all persons before whom the original tables and statements have come.

If the statements have been based upon information obtained from Mr. Frazer, we may call your attention to the fact that he left the Company's employ in July last, and has since had no opportunity of acquiring any knowledge as to the improvements that have taken place since then, which renders the data published by you still further misleading.

In the event of your failing to comply with our request, we shall, in the interest of our shareholders, be compelled to consult our solicitors on the subject.—Yours faithfully,

(Signed) W. G. M. MACKENZIE, Secretary.

[COPY.]

31, Parliament-street, S.W., February 21, 1891.

The General Electric Power and Traction Company, 35, New Broad-street, E.C.

Dear Sirs: In reply to your letter of yesterday, the statements to which you object were based on figures obtained from Mr. Frazer, and were given at the Society of Arts distinctly on his authority, and not on mine. After your explanation, which puts a totally new complexion upon the matter, I am, of course, myself, desirous to withdraw from my lecture any statement or table the accuracy of which is questioned; and I shall on Monday withdraw the two tables 4 and 5 and statements connected with them. At the same time allow me to point out that in your interests, as well as in mine, withdrawal alone would not be so effective as withdrawal combined with the substitution of the correct figures, and I should feel obliged if on Monday you would send me a telegram authorising me to state that when the lectures appear in print the obsolete figures of Mr. Frazer's will be replaced by figures corrected up to date and supplied by you.—Yours faithfully, (Signed) GISBERT KAPP.

## THE INSULATION OF THE BATH ELECTRIC LIGHT CIRCUITS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It having been represented to me that my remarks on Major-General Webber's paper on the distribution of electricity at the Institution of Electrical Engineers, as reported in the technical journals, may give rise to a false impression, I beg to enclose for insertion a letter from the electrician-in-charge at the Bath Electric Light Works, the correctness of which I have not the slightest reason to doubt. According to this, the defective insulation was not due to the mains, but from faults in the lamp-posts, which alters my view of the suitability of the insulation. The defective circuits were arc-light circuits. The tests of the other circuits were quite satisfactory, as shown by the accompanying figures:—

*Insulation-resistances of Incandescent Circuits.*

| | | | |
|---|---|---|---|
| Circuit No. 1 | ......... | Over | 15·89 megohms. |
| " 2 | ......... | " | 15·89 " |
| " 3 | ......... | About | 5·73 " |
| " 4 | ......... | " | 3·99 " |
| " 5 | ......... | " | 0·89 " |
| " 6 | ......... | " | 0·89 " |
| " 7 | ......... | " | 0·89 " |
| " 8 | ......... | " | 0·53 " |

*Insulation-resistance of Private Arc-light Circuit.*

About 0·19 megohm.

The incandescent circuits included the transformers when the above figures were obtained.—Yours, &c.,

GEORGE FORBES.

34, Great George-street, Westminster, S.W.,
February 24, 1891.

Digitized by Google

[Copy.]

Bath Electric Light Works, Dorchester-street, Bath,

T. O. Callender, Esq. February 21, 1891.

Dear Sir,—In reply to your inquiry with reference to the visit of Prof. Forbes here, I beg to inform you that all the tests made were on circuits with lamps in series, or transformers connected, and that no tests were taken of the mains by themselves. The two results to which you specially refer, viz., resistances to earth of 40 and 60 ohms, were on the public arc lines supplying 36 and 45 lamps respectively, and Prof. Forbes knew when testing that his figures included lamps and leading-in wires, and did not give, by any means, the actual insulation resistance of the mains. The low readings in question arose, as a matter of fact, from faults in the lamp posts. They had just been localised by means of the fault-finding apparatus to which he refers, and on being put right on the following day the resistances were ·124 and ·146 megohm. It may be well to point out that Prof. Forbes tested all our circuits, 11 in number.—I remain, dear Sir, Faithfully yours,

(Signed) Martin C. Olsson, Electrician-in-Charge,

## INDOOR ILLUMINATION.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The concluding paragraph of "Problems connected with Indoor Illumination" in your last week's issue should cause quite a flutter among the members of Art Guilds and other culture excrescences, as showing still something to be done before the realisation of the beautiful is complete. But what *is* it all about? *Cacoethes scribendi* I fear, with the usual symptoms.

Nowhere in the world has electric lighting, in all its artistic and charming effects, been brought to such perfection as in large numbers of London houses, and yet the writer of this somewhat discursive article holds up his hands imploringly for some artistic genius to make electric lighting comfortable and beautiful. Artistic genius, indeed! what about all those who have been toiling in the field while this carping critic has possibly been engaged in arc lighting among the Cimmerii? Prof. Forbes also comes in for a great amount of unnecessary criticism because he advocates the use of ground-glass lamps, but the artistic genius of the future who is so hysterically appealed to would most certainly be of the Professor's opinion; and it has often been said that, although obscured lamps *may* absorb a great amount of light, they *appear* to give a greater body of light; and if the eye is deceived, what more does one want?

I trust some kind friend who has time, or who devotes special attention to the study of backward youths, will show the writer of "Problems Connected with Indoor Illumination" the different works that have been done in London during the last five years. The campaign colours of rival candidates for fame are strung up on many a house; the black and white, of course, he is at liberty to inspect, the ubiquitous chocolate and white, also the blue and white must be seen; the green and white should certainly not be neglected, nor the wooden board of a Corporation despised, while many of undoubted taste and ability scorn such soapy allurements. Our critic will thus have a better opportunity of considering the "physiological questions" that "do not often come into the work of an electrical engineer," as I am afraid his present knowledge of the subject is not much greater than the Marchioness's acquaintance with beer. "She once had a sip of it."—Yours, &c.,

31, King-street, Covent Garden, W.C., J. B. V.
February 25, 1891.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The writer of the article on "Problems Connected with Indoor Illumination," in your issue of 20th inst., makes the statement that "great improvements must be made in arc lamps and carbons before they can be admitted for interior use." I agree that there is a great prejudice against arc lighting in this country, but as both lamps and carbons very closely approaching to perfection are now to be found in the market, I cannot help thinking that this prejudice will soon disappear and the question generally of arc lighting prove worthy of discussion, for it is in this form of lamp that the *economic* illumination of halls and large lofty rooms must be sought. It is fortunate for arc lamp makers that there are at the present moment many persons who do not agree with the author of your article, and possibly that gentleman's opinion might be changed if he were to pay a visit to the sorting rooms of the General Post Office, in St. Martin's-le-Grand; the large hall and passages of Winchester House, Madame Tussaud's Exhibition, Messrs. Spiers and Pond's new shops in Water-lane, or any of the numerous other places I could mention, where "absolutely steady" arc lamps of various powers are used for interior lighting.

When I say that a single arc lamp has displaced 500 (five hundred) gas jets for illuminating the entrance hall and grand staircase at Madame Tussaud's Exhibition, I cannot more strongly emphasize the importance of this kind of lamp being used in all cases where large units of light are required.

I am quite aware that even the best arc lamps in the market do not always burn so well as could be desired, but this is due in some cases to the carelessness or ignorance of the trimmer, and in others to inferior carbons being made use of with a view to greater economy, rarely, if ever, to the lamp itself.—Yours, &c.,

Blackheath, February 24, 1891. B. P.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am afraid facts are against the writer of the article in your last issue on "Problems Connected with Indoor Illumination," as far as his remarks on arc lighting are concerned, and he must be somewhat unobservant if he does not see that absolutely steady arc lighting is the rule and not the exception nowadays. I see the "prejudice" against arc lighting for interiors of even moderate dimensions fast disappearing; moreover, the writer to a journal like yours should know that "*prejudice*," however "deeply rooted," can never long delay progress, and has no place in the vocabulary of the scientist. This is an age where very short work is made of a prejudice.—Yours, &c.,

February 24, 1891. Progress.

[These letters are referred to in our editorial columns.—Ed. *E.*]

## TRADE NOTES AND NOTICES.

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891**

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The Handbook Division contains a mass of most useful information. The Directory Division consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

Tenders Wanted—Extension of Time.—Our advertisement columns contain an announcement that the period for sending in tenders in connection with the Glasgow Corporation electric lighting scheme has been extended from the 28th current to the 14th proximo.

Erratum.—In our notice on page 466 (*The Electrician*, February 13th) of the dissolution of the co-partnery carried on by Messrs. Mathew Edwards and David Reid under the style of James White, of Cambridge-street and Sauchiehall-street, Glasgow, by an unfortunate printer's blunder the former gentleman's name appeared as Mathew Hall. This has caused Mr. Edwards some annoyance, which we much regret.

Endolithic Ivory Company (Limited).—We are notified that the Endolithic Ivory Company (Limited), of Pomona-buildings, Fore-street, E.C., were awarded the only prize medal and diploma for address tablets and switch-board labels at the Exhibition recently held in Edinburgh.

Personal.—Mr. William Leslie, consulting engineer, 93, Hope-street, has been appointed agent in the Glasgow district for the Gülcher (New) Electric Light and Power Company (Limited), Battersea Foundry, London.

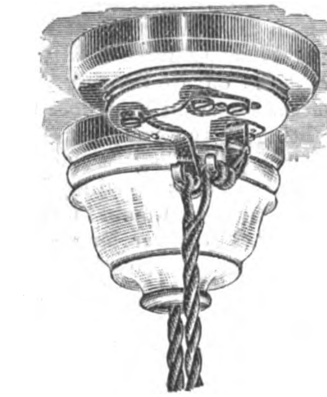
Digitized by Google

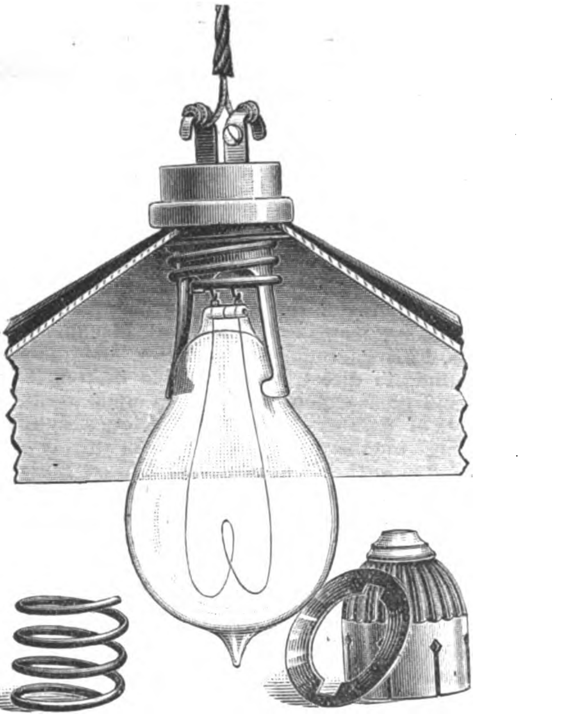
REMOVAL NOTICE.—Messrs. J. W. Gray and Son, electrical engineers, have removed from 115 to 86, Leadenhall-street, London, E.C.

BANKRUPTCY.—The *London Gazette* of Tuesday announces that a receiving order has been issued in the affairs of Leslie Watt Winnall and William Howard Winnall (lately trading as Watt Winnall and Co.), electrical engineers, of Bromley-street, Stepney, London, E.

CONSOLIDATED ELECTRIC COMPANY, LIMITED (IN LIQUIDATION).—A meeting of the shareholders will be held at Messrs. King and Read's, St. George's House, Eastcheap, London, E.C., on March 26th, at 3, to receive an account of the winding up.

D. AND S. PATENT SUSPENSION PENDANTS.—The common forms of cord grip present several disadvantages: some kinds do not allow for variations in the size of the conductors, while the common method of knotting is apt to throw an uneven stress on the wires. Messrs. Dorman and Smith have sent us a specimen of a simple contrivance capable of bearing a considerable weight. The ends of





the conductors are fastened under screws, and an inch or so is wound two or three times round the projecting horns shown in the illustration. The base and cover are of porcelain, and contain a fuse. In the lamp-holder shown, the same arrangement is adopted. The shade-holder is provided with a spiral spring easily screwed on and off, and is not liable to break the shade through over-screwing, as it slips back when over-screwed.

WOODHOUSE AND RAWSON ELECTRIC MANUFACTURING COMPANY (LIMITED).—At a meeting held on February 9th a resolution passed at a previous meeting that the Company be wound up was confirmed; and it was further resolved—"That T. H. Lambert, Albert Hoster, and F. L. Rawson be liquidators; and that the liquidators be authorised to carry into effect the agreements made between the Company of the one part, and the Woodhouse and Rawson Electric Supply Company of Great Britain (Limited), Woodhouse and Rawson (Limited), Woodhouse and Rawson United (Limited), and the British Electric Light Company (Limited), of the other part."

MESSRS. NALDER BROTHERS.—This firm, which has recently removed to No. 16, Red Lion-street, Clerkenwell, close to Farringdon-street station, has issued a supplement to the third edition of their catalogue of electrical instruments. They are making several Post Office pattern instruments, including portable galvanometers and resistance coils, and they have a new pattern ballistic galvanometer with two controlling magnets, and an astatic needle system. The Holmes leakage testing board for central stations, and other new instruments, are also described.

THE STANHOPE WATER ENGINEERING COMPANY.—We are in receipt of a printed circular containing illustrated particulars of the new Stanhope Water Softener and Purifier, manufactured by the above Company, for which it is claimed that an economy of from 20 to 25 per cent. is obtained.

THOMSON-HOUSTON ELECTRIC COMPANY (BOSTON, MASS.).—We have received from this Company a handsome catalogue well printed and fully illustrated, giving some interesting statistical information relating to the electric lighting and railway systems in use in the United States, in each case showing a large total in favour of the Thomson-Houston systems. The figures given for electric lighting show that this system is used in 666 installations in the various States of the Union out of a gross total of 1,985—a proportion of about one-third of the entire systems in use. This proportion is still larger in the case of electric railway systems, as out of a gross total of 230 no less than 103 are installed on the Thomson-Houston principle. Included in the book are a series of maps of the States, showing at a glance the positions of the various installations, and it is needless to say that the points shown in red (representing the Thomson-Houston installations) occupy a conspicuous position on the maps. The book marks a distinct advance in catalogues of electrical companies. There are 114 large folio pages in all.

## COMPANIES' MEETINGS & REPORTS.

### City and South London Railway Company.

The thirteenth ordinary general meeting of the proprietors of this Company was held on Tuesday at Winchester House, Old Broad-street, Mr. Charles Grey Mott presiding.

The SECRETARY (Mr. H. H. M. Smith) read the notice convening the meeting, and the report of the Directors and statement of accounts were taken as read.

The CHAIRMAN: Gentlemen, in moving the adoption of the report, I have to say that I have the pleasure of meeting you at last with a line open and at work. Now you all know that in new undertakings of this kind, where so much is novel, and where you cannot fall back upon past experience to guide you, there is always a feeling of uncertainty that however much you may have studied matters, and however much care you may have exercised in the execution of your works, that in all the arrangements you have been making, there may yet be something which you have overlooked, and which after all, may render your labours and your care of no effect. In an undertaking so new in all its parts as this has been, we were especially open to such a possibility, but I am thankful to feel that, in the experience which we have had of this line since its opening, we have the satisfaction of knowing that no serious defect in our calculations has been apparent. I consider that for a line new in point of construction, in working, and in fact in all its arrangements, it is an unqualified success. You will recollect that the principle of construction of this line had never before been adopted; but we successfully overcame all obstacles, and we have now a railway which, so far as we at present see, has been satisfactorily made. There will no doubt be certain minor points with regard to which improvements can from time to time be made, but we can congratulate ourselves in point of construction it has turned out satisfactorily. The next and most important question is the motive power. You know we were told that electricity was new for a line of this kind, and that it would probably fail. A great many objections were taken outside to the course we proposed to adopt, and, I confess, it was with very considerable anxiety of mind that I and my co-Directors came to you and recommended the adoption of a system which was so absolutely untried. It is satisfactory to feel that we have not been disappointed. The success of our running these engines has been decidedly marked. We have had no serious drawbacks. You have seen in the newspapers a great deal about the breakdowns on this railway, but I venture to assert that with such a new system and with the enormous number of trains that we have run, it is surprising that the breakdowns have been so few and unimportant as they have been. We have now carried by the line, with perfect safety, 900,000 passengers since we opened the line two or three days before Christmas, and we have run our trains 60,000 miles over the line. We have received in money £7,500, or a sum equal to 15 passengers per train mile. Of course, in a metropolitan system like this, you expect a much larger number of passengers than you would do, for example, in the case of the London and North-Western and Great Western systems, where it is only 3½ passengers per train mile. But, considering that it is so new, that we have never advertised once in any way, that we have only dealt with the traffic which has come to us—and we have been compelled to deal with that—we have done nothing to attract traffic to the line, we may say that on the whole it has been very satisfactory. We have not encouraged it in any way, because we felt that the first thing we had to do was to work satisfactorily what

Digitized by Google

came to us voluntarily, and, therefore, you must not be surprised that the receipts are not so large as we had hoped, and as, I have not the slightest doubt, they will be in the future. You will no doubt wish, if I can, that I should say something about the expenses of the line. Well, I do not feel justified in really making any definite statement on this subject. You must know that at the commencement of a railway of this kind there are a great many extra expenses, because we had to make security doubly secure, but as the line is now settling down to more steady working we trust week by week to reduce the expenses, and find out from experience various small economies. But we have had so short an experience that it would be utterly wrong for me to give you anything like an approximate statement of the working expenses of the line; but so far as I have investigated the matter I feel quite sure that, as regards the motive power (of course I may be making a mistake), when we come to settle down we shall find that the cost of working the line by electricity will be decidedly cheaper than it would be by steam. The receipts of the line per train mile run I can deal with, because these are ascertained facts at the present moment. Our actual receipts per train mile run have been 2s. 6d. Now, the receipts on large railways, such as the North-Western and Great Western, amount roughly to something under 5s per train mile—or double what ours are at the present moment. But you must remember, on the other hand, that the trains we are running are only about one-fourth—perhaps, one-fifth—of the weight of those which are run upon those lines, and that, therefore, we have really, weight for weight, nearly double the actual earnings per train mile run of those railways, and I have good hopes and expectations that we shall raise our receipts per train mile to an amount similar to that earned by them. Then you will at once see that we stand in a very much better position to deal with our traffic, having only one-fourth of the weight to move in order to earn the same money as those Companies. These are about the only approximate figures that I can place before you. I hope when we meet next that we may be able to deal more definitely with the cost of working the line; but as yet we have only five or six weeks' traffic to go by, and I could not give you any actual information as to receipts and expenditure. We have found in the course of our operations that we could work the line more economically and with greater regularity if we had additional sidings underground. Of course we did not know, until we tried, what was absolutely requisite on this head, and we therefore propose, as mentioned in the report, to construct some additional sidings at the Stockwell end of the railway. We shall make a small portion of the Clapham Extension line, so that the money we propose to spend in providing these additional underground sidings will not be wasted. The Board of Trade suggested in their report that, as a matter of security, it would be desirable that we should have a fourth engine and dynamo. At Stockwell depôt we have a reserve engine, and we considered it sufficient; but still, looking at all the possible risks connected with electricity, upon which no one has very correct knowledge, we thought it better to comply with the Board of Trade's suggestion. We have, therefore, an engine and dynamo to be put up in the engine house, and they are now in course of construction. We shall then be supplied with power double what we ordinarily require, and if we ever carry out the Clapham extension that plant will come into use and save expenditure afterwards. Then we find also that we are short of rolling stock. We want a little more, in order to multiply the number of trains. You know that at certain times of the day, morning and evening, our trains at present are over crowded. We are gradually increasing the number of trains, and we hope to be able very shortly to give such a service at those hours as will enable us to deal with the traffic completely and satisfactorily. But in order to do this we should want some additional rolling stock, and we propose to order some additional engines and carriages. In all undertakings of this kind, I daresay, those who have had any experience of them know that at the end of their construction there is generally between the Company and the contractors a difficulty which unfortunately too often ends in legal proceedings—in a long arbitration or a lawsuit. Our contractors, as is usual, made certain definite claims upon us for extra works, about which there were differences of opinion between our engineers and them. The dispute might have resulted in a long and expensive lawsuit, but not desiring to have any contentious matter with them, and, above all, not desiring to waste any money in that way, we had a friendly conference with our contractors the other day, and I am glad to say that, after fairly discussing the subject, we have arrived at a settlement which has been approved by both parties. I refer to the contractors for the construction of the line itself, not to those for the other works and rolling stock, &c. We have settled the whole matter with them, and have arranged for the payment of the retention fund, and the balances due to them. This is so far satisfactory that we are, at all events, saved heavy law expenses, and both sides are satisfied. I had perhaps better now deal with the extension of the line to Islington, referred to in the report. I confess for my own part—and I think my feelings are shared by my co-directors—that if we could have avoided extensions of any kind at the present moment we should have done so. We got, as you know, power for the Clapham extension, but we have not exercised it, and we do not intend to proceed with that line until we are satisfied that it is going to add to and improve our present returns. But we find in working this line that there are certain circumstances, and which, as far as we can see, using our best judgment and discretion, make it desirable that the line should be extended in the direction in which we now propose to ask Parliament to grant us powers to do. We have, of course, learned a great deal in the last few months as to the probable traffic of the future of this line, and we have applied our best knowledge, derived from all that information to the subject and have come to the conclusion that it is in your interests that power should be asked for that extension and that it should be made. We have certain difficulties to deal with in regard to our city traffic at the present moment, which this line would help us to get over. We want the middle of the day, as well as the early morning and evening, to be filled up by traffic, for which we have abundant room and for which the expense will not be much; and we do not think that it can be filled up by the traffic from the district where the line now is. It will have to be supplied by traffic from a more populous area. We have chosen a line where the traffic is great, and I am sure it will prove most remunerative. But in addition to this it will attract exactly that traffic of which we are now deficient, and consequently greatly improve the value of the property. Much as we object to go in for extensions—and no one objects more than I do to hastily extending the line in its early days—still we think that there is no doubt at all that this would be a good line, and my advice is that you should go for this proposed extension. In the Bill you are only asked to approve the application for powers to construct the works, but we shall have to come to get your consent to carry them into execution. We want merely now to obtain the Act authorising them. I think these are all the important questions that I need bring before you. There are a few shares which are stated to have been forfeited, as you will observe from the report. Some of these have since been claimed and paid up, but there are certain others which from various causes are not likely to be paid up. There are 15 of them, and therefore there is no alternative but to forfeit them, which we propose to do by a formal resolution after this meeting. I now beg to move—

"*That the report and statement of accounts for the half-year ended December* 31, 1890, *be and they are hereby adopted.*"

Mr. ALEXANDER HUBBARD seconded the motion.

Mr. DRAKE said he thoroughly concurred in acknowledging that the line was a tentative one; that it was, in point of fact, largely a new departure, and he was pleased to have it as the opinion of the Board that the shareholders might take it for granted that the motive power was satisfactory, and that it had now passed out of the range of mere experiment. No doubt there would be many difficulties to face in the future, as there had been in the past, but after the experience which had been gained in dealing with the concern in its initial stages, they might rest assured that those difficulties would be grappled with successfully by their able engineer. As a resident at Clapham, he would like the extension in that direction carried out. He did not think that Stockwell was an adequate terminus for the line. The bigger scheme now proposed required very careful consideration. They did not want the success which was within their grasp to be swamped by an extraordinary scheme of the kind, but he was sure that the Board would give them, when the time came, every opportunity of discussing its details. He had much pleasure in supporting the resolution.

Mr. SYDNEY SHEPHERD asked whether it was possible to enlarge the King William-street station, so as to provide two sidings instead of one.

Mr. TRESS BARRY, M.P., asked whether their present engines could carry more weight than they now do. He wished to get some idea of the expense of getting the proposed Act of Parliament, because there would no doubt be great opposition to it.

The CHAIRMAN, in reply, said it would be extremely difficult to enlarge King William-street station because the Monument was so close, and they would not be allowed to go near it. They had the matter under their careful consideration. They were quite aware of the difficulties of having so small a space there, but he was afraid it was not capable of being greatly improved. This was one of the questions involved in the proposed extension, which would help them to overcome the difficulty, but it would not do for him to discuss the plans at present. They would observe that the approach to the station from the City was exceedingly bad. Everyone had to get over one of the very worst crossings in the City, and undoubtedly it did great damage to their traffic. They would be able by their proposed extension to give access to King William-street station from the Lombard-street end, which would get over the difficulty they complained of.

Mr. SHEPHERD asked whether it was possible to run four cars instead of three?

The CHAIRMAN said the question was now under the consideration of the Directors and their engineer. As regarded Mr. Barry's question, as to whether their engines could carry more weight, he could only say that the Board were satisfied with the present power of their locomotives. They were not so fast as, perhaps, was desirable, but they were considering whether they could not in the new engines have additional power and speed from them. He did not suppose that their Bill would be very costly. They had now before them all the opposition to it, and there was no very serious question raised in it. Most of the petitions were really based on a misunderstanding of their whole line.

The motion was carried unanimously.

The CHAIRMAN then proposed, and Mr. HUBBARD seconded, the re-election as Directors of Mr. Walter Robinson and Mr. Sampson Hanbury, which was agreed to *nem. con.*

The auditors were afterwards reappointed, and a resolution was carried forfeiting the 15 shares in arrear of calls.

The adjourned extraordinary general meeting was afterwards held for the consideration of the Company's Bill before Parliament.

The CHAIRMAN briefly recapitulated his views as to the advisability of proceeding with the proposed extension, remarking that if the shareholders disapproved of the Bill the Directors would be relieved of all responsibility. At the same time, they advised the proprietors to allow the scheme to go on. He concluded by moving a resolution approving the Bill.

Mr. HUBBARD seconded the motion.

Mr. COURT said that having, since the adjournment of the last meeting, gone fully into the question, it seemed to him that they could not do better than support the Directors in going to Parliament for the Bill, on the understanding that the shareholders did not commit themselves to the work of the extension at the present time. The Board now only asked their approval to obtaining Parliamentary sanction for the construction of the work.

Digitized by Google

Mr. BROAD objected to the Bill, and he thought that the Directors ought to devote their time and energies exclusively to the development of the traffic of the present line.

A SHAREHOLDER thought that if the enterprise were made a separate undertaking, bearing the cost of the Bill itself, that would obviate all difficulties.

The CHAIRMAN said it would be impossible to say what the Bill would cost, but he should say, considering the nature of the opposition to it, possibly £2,500. If it had been unopposed, probably £700 would have passed it. They had given the proprietors their best advice in the matter, and it was for them to use their discretion. He might say that it had been suggested (and he thought it was an advisable thing to do) that they should take power, if necessary, to make the new undertaking with a separate capital, so that the present one would in no way be subject to it.

Mr. GODFREY suggested that the question should be deferred.

The CHAIRMAN said although the Board were decidedly averse to unnecessary extension of the line, it must not be taken for granted that they did not think that the proposed project was very important. They attached, in fact, very great importance to it. He could not publicly give them all their reasons for saying so, but, from the knowledge they now possessed, such was the opinion of the Directors. If they put the matter off, they would find themselves one day in a position which they would very much regret.

A SHAREHOLDER asked what the line would cost.

The CHAIRMAN said that the present line cost about £240,000 per mile; but where they proposed to go in the City they would have to purchase expensive property, and it would be impossible to say what it would cost.

Mr. DRAKE asked if the Directors were unanimous with regard to the scheme.

The CHAIRMAN replied in the affirmative.

Mr. GODFREY said he would, under the circumstances, support the resolution.

The motion was then put and declared carried, with one dissentient.

Mr. BROAD demanded a poll, but being informed of the hopelessness of gaining his object, he did not persist in having it taken.

Afterwards, a resolution was carried enabling the Directors to take power if they thought necessary to construct the proposed extension as a separate undertaking.

On the motion of Mr. GODFREY, seconded by Mr. BROAD, a vote of thanks was passed to the Chairman and Directors, and the proceedings terminated.

## The St. James' and Pall Mall Electric Light Company (Limited).

An extraordinary meeting of the shareholders of this Company will be held at Winchester House, Old Broad-street, E.C., on Monday, March 2nd, at 2.30, when the following resolutions will be proposed :—

1. "*That the capital of the Company be increased to £200,000 by the creation of 20,000 shares of £5 each, to be called Preference Shares, and to be entitled to a Preferential Dividend at the rate of 7 per cent. per annum on the amount for the time being paid up on such shares, payable out of the net profits of the Company for each year.*"

2. "*That the Articles of Association before the meeting be adopted as the Articles of Association of the Company in lieu of those at present in use as such.*"

In the event of the above resolutions being carried, a further extraordinary general meeting will be summoned to confirm the resolutions passed at the meeting so as to make them special resolutions.

---

An ordinary general meeting will be held at 3 o'clock, to consider the accounts, balance sheet and report of the Directors; to elect two Directors in place of those retiring; to elect auditors for the ensuing year and settle their remuneration.

The following is the report of the Directors, which will be presented to the shareholders :—

The Directors, in submitting their annual report for 1890, with accounts as certified by the Company's auditors, congratulate the shareholders on the satisfactory progress made by the Company during the past year.

At the commencement of the period under review, the number of lights connected amounted to the equivalent of about 4,460 8 candle-power lamps. This number gradually increased up to September 30th, when the number of lamps connected amounted to about 12,150. In the last quarter of the year remarkable progress was made, and on December 31st the lamps connected amounted to about 26,500, and this total has since been increased to about 30,000.

On July 23rd last, a prospectus was issued inviting subscriptions at par for 3,670 ordinary shares. All these shares have been taken up, the bulk of them being subscribed for by the Directors and their friends, the shareholders subscribing for a very small number. On January 9th, the balance of the original issue of shares, viz., 980, was allotted. These subscriptions have enabled the Board practically to complete the existing station, which is now in every way working satisfactorily.

Of the £50,000 Debentures, which, as will be seen from the accounts, were outstanding on December 31st, £43,000 have since been converted into ordinary shares under the powers contained in the Debentures. On the conversion of the balance of £7,000 of the Debentures, the capital account of the Company would stand as follows :—

| | | | |
|---|---|---|---|
| 19,980 Ordinary shares of £5 .................... | £99,900 | 0 | 0 |
| 100 Founders' „ „ £1 .................... | 100 | 0 | 0 |
| Making a total of .................... | £100,000 | 0 | 0 |

The conversion of these Debentures places the Company in a position to at once raise moneys for the purposes of the northern station, which the Company has to erect to satisfy the requirements of the district covered by the Provisional Order granted by the Board of Trade, and approved by Parliament during its last Session.

The question of the amount of damages payable by the contractors for delay was referred by consent to the arbitration of Mr. J. Fletcher Moulton, Q.C., who awarded the sum of £1,806. 11s. 6d. to the Company for loss of income. The Directors, being of opinion that this sum represents the equivalent of depreciation up to December 31, 1890 (a large part of the machinery having been in work for but a short period), have written this amount off capital expenditure.

By reference to paragraph 2 of this report it will be seen that the station has practically been at work for three months only in 1890, and that the dividend has been earned during that period. The Directors have therefore, after consultation with the Company's auditors, charged £963. 3s. 1d., being one moiety of Directors' fees and management salaries for the year, to capital expenditure. On statement III. it will be seen that the account of capital is charged with £65,981. 11s. 9d. as expended to December 31, 1889. The balance-sheet at that date displays that this sum is made up of capital and general expenditure, from which is deducted a small sum received for current supplied, &c.

During the first six months of the year the Company's revenue showed a debit of £183. 7s. 11d. During the last six months the profit amounted to £5,161. 8s. 8d., which, after deduction of the debit referred to, leaves a balance of £4,978. 0s. 9d. to be dealt with. Of this sum £2,412. 8s. has been provided for payment of interest, and out of the balance of £2,565. 12s. 9d., the Directors recommend a dividend of 5s. per share, free of income-tax, on the 9,000 ordinary shares in existence on December 31, 1890, absorbing £2,250, leaving a balance of £315. 12s. 9d. to carry forward.

The experience gained since September has satisfied the Directors that the shareholders possess a very valuable property, which will yield a large steadily increasing income on their investment.

The Directors regret the loss of their esteemed colleague, Mr. James Hemmerde, who died in the autumn of last year; they have, under Article 84, appointed Mr. Egerton H. Clarke to a seat on the Board in his stead. Two of the Directors, namely, Mr. Eustace J. A. Balfour (the Chairman) and Mr. Latimer Clark, F.R.S., retire under Clause 79 of the Articles of Association, and, being eligible, offer themselves for re-election. The auditors, Messrs. Deloitte, Dever, Griffiths, and Co., also retire, and, being eligible, offer themselves for re-election.

Referring to the notice of the extraordinary general meeting, should the shareholders adopt the suggestion of the Directors to increase the capital of the Company by the creation of Seven per Cent. Preference shares, it is the intention of the Directors to offer 10,000 of such shares to shareholders now on the register in the proportion of one preference share to every two ordinary shares. It being necessary to alter the Articles of Association to entitle this Company's shares to a quotation on the Stock Exchange, the Directors have taken the opportunity to remodel them.

## The Westminster Electric Supply Corporation (Limited).

The fourth ordinary general meeting of the shareholders of this Corporation was held at the offices, 32, Victoria-street, S.W., on Wednesday, February 25, 1891, under the presidency of the Right Hon. Lord Suffield, K.C.B.

The SECRETARY (Mr. Frank Iago) read the notice convening the meeting.

The report of the Directors and statement of accounts were taken as read.

The CHAIRMAN: Gentlemen, I am sorry to see so few shareholders present. Still, I may say that nothing could be more satisfactory in my opinion, and that of the other Directors, than the state of your affairs, so far as we have been able to investigate and explain it. The dreadful state of the weather has, no doubt, prevented a great many from coming to the meeting, but I think what we have got to say to you will be acceptable to all concerned. The Report, which has been sent to each shareholder, will have already made you acquainted with the fact that the business of the Corporation is going on satisfactorily. Since our last general meeting, on November 5th, the Millbank-street central supply station has been completed, and current has been supplied therefrom continuously, day and night, in a most satisfactory manner. It frequently occurs that when a station is first opened some unexpected flaw, either in the machinery or the mains, is brought to light, causing a serious break down, but I am happy to be able to inform you that this has not been our experience. Some slight irregularities in the light did occur for a few days, but this was before we got on to the batteries. Since then, the the light has been perfectly steady and satisfactory, notwithstanding the unusual demand throughout the whole of several days in consequence of fogs. You will hardly need to be told that fogs, however unpleasant they may be from a sanitary point of view, are from an electrical point of view a very different matter. We find that our heaviest loads come on during fogs, so that to us they are a source of profit instead of loss. I am glad to be able to inform you that since taking over the Millbank-street station from the builders we find that we have every reason to be satisfied with the work, and that the building is in every way suitable to our requirements. Here I may say that a very distinguished engineer, Sir Wm. Thomson, who was accompanied by Sir Douglas Dalton, went over that station the other day, and he not only expressed himself satisfied with it, but I think he said it was the best he had ever seen.

Digitized by Google

We have now sufficient plant and machinery erected there to supply all the lights likely to be required for the next six months, and as the demand increases so shall we increase our machinery. I may here point out a great advantage which the Westminster district possesses over many others, which is, that within it are a large number of offices, in addition to private houses and shops and that these offices, requiring, as they do, to be lighted in the winter months, through many hours each day before the chief part of the lighting of the private houses comes on, enables us to use our Millbank-street station to great advantage. We are, at present, supplying from the Millbank-street station some 9,000 lamps of 8 candle-power each. The cost of running at that station is now about £60 per week. This includes the cost of coal, water, stores, salaries and wages. To this has to be added £90 per week for maintenance, depreciation of machinery and mains, establishment charges, rent and sinking fund on buildings, &c., making in all £150 per week. At the beginning of the month of January, the income per week for current supplied had already reached £150, which has now increased to £200, so that even in this early stage, a profit is already being made. Of course, as the days lengthen, the same ratio will not be kept up, nevertheless it is to be noted that though the days have been lengthening of late, and the demand for current has, in the case of other Companies which have been longer established, been falling off in consequence, our receipts have augmented. This is, of course attributable to the increased number of lights which are daily being installed in the district. The temporary station in Dacre-street, at the back of these, offices which is supplying the remainder of the lamps on circuit, has been of great service to us, in enabling us to supply current to the Western portion of our district, while the station at Eccleston-place was being built. In a few days the Eccleston-place station will be delivering current, and the temporary station will then be closed as soon as possible. I may tell you that yesterday some of the Directors visited Eccleston-place, as well as the new station at Davies-street, and were very much gratified by the progress made there. There has been great delay on account of the frost, but things are really progressing in a most satisfactory manner now, and, as I have said, we shall be able to deliver current in a few days. At our Davies-street station great progress has been made, and from there we expect to be supplying current by the end of next month. Had it not been for the severe and prolonged frost, which brought all building operations to a standstill for two months, current would have been supplied from both Eccleston-place and Davies-street before now. You will observe, by looking at the map on the walls, with what rapid strides the work of laying the mains has proceeded since you were last called together. There were then about 11 miles laid. To-day, notwithstanding interruptions, there are about 18 miles completed. This includes the principal streets throughout the district, in which there is the greatest demand. The others will be completed in the order in which the demand arises. I should mention that our consumption of coal already bears favourable comparison with that of the most economical of the older established companies, and that when the condensing plant, now on order, is erected, which, in the case of the Millbank-street station, will be in the course of the next two months, a still greater saving will be effected. Now, as to the question of capital and expenditure, you will see from the accounts sent with the report the expenditure under the different heads to the 31st December last. Owing to the demand for light caused by the stoppage for about two months or more of the supply of the only other company having powers in the same district as ourselves, it was considered desirable by the Board to increase the amount of copper in the mains, especially in the Mayfair district, for which large numbers of applications have been received. This has largely increased the expenditure on mains, but of course will result in the earlier sharing of profits, as we shall be enabled to take on a much larger number of lights without delay. The Board are pleased to say that so far the whole of the works, whether of buildings, mains or plant, have been carried out well within the estimated cost, and that the total cost of the works to give enough current to supply the whole of our districts for some time to come will not exceed the amount of capital asked for in the original prospectus of the Company, viz., £300,000. The amount actually subscribed was £214,765, in 42,953 shares of £5 each, leaving a balance of £85,235 in 17,047 shares of £5 each. To provide for the extra cost of laying mains, completing the present work in hand, and making provision for any extra work the Board may consider it desirable to enter upon, they suggest to the shareholders that the balance of capital should now be issued. They feel justified in asking them to increase their holdings, as there is no doubt of the future financial success of the undertaking. The Directors have also passed a resolution to issue, if required, £100,000 Debentures at 5 per cent. interest, to run for a term of ten years, but not to a greater extent than an amount of one-third of the share capital for the time being. I will now say, gentlemen, and I think it is a very gratifying thing to be able to do so, that the calls on the shares have been very well paid up. Out of the whole number that have been made, there remains but a very small balance still to be paid, and I have no doubt that they will come in shortly.

I now beg to move the adoption of the report and accounts for the past year. If any shareholder has any question to ask, we shall be pleased to give him every information in our power.

Mr. BOULNOIS, M.P., in seconding the resolution, thought it was unnecessary for him to travel over the ground which had been so very well covered by the Chairman; but perhaps the shareholders would like to hear something about the inner working of the Corporation. He was not going to reveal anything, or tell them the details of what was done at the Board meetings; but he wished the shareholders to know that he had never sat at any Board of Directors where there was more unanimity evinced. They had their discussions, but there were no differences of opinion amongst them, all their proceedings ever since he joined the directorate having been conducted with the utmost unanimity. He might say further (and he was sure he interpreted the views of his co-Directors), that no staff could exhibit more ability, more zeal, or more loyalty than theirs from the highest to the lowest. They were especially happy in having so able an engineer as Prof. Kennedy, so skilful a manager as Captain Bax, and so active a secretary as Mr. Iago. As far as he could see, there was a great future in store for the Company. What the shareholders would have to do—and he admitted that it required some patience—was to have confidence in the Board they had elected—a confidence which, he believed, would not be placed in vain.

Mr. COOPER asked whether the item in the general balance sheet—"expenditure during the year but applicable to future business £3,957," should be charged to capital or to revenue.

Mr. WALLACE, in reply, said that in starting a new Company of this kind there was a vast amount of work to do which would become remunerative in future years, such as getting the customers, on advertising, travelling, and the work of the staff employed in making arrangements for the future. Now, of course, that could not be placed at once to capital account, because it was not, strictly speaking, a capital charge, but it would be written off the profits in future years. At the next meetings perhaps they would be able to give some account of it.

Mr. MARK STEWART, M.P., asked whether it was intended to issue any debentures just now, and if so whether this was provided for in the Articles of Association.

The CHAIRMAN, in reply, said that they had no intention of issuing debentures without giving the shareholders an opportunity of subscribing for them, nor had they any immediate necessity for them, although they had taken power to issue them, according to the custom of other companies, in their Articles of Association.

Mr. BROWNE MARTIN thought that they must know that in all companies there was power taken to issue debentures. By issuing them at 4 or 5 per cent., companies gained a very great advantage, because, in an undertaking like theirs, if they borrowed capital, they must pay 7 per cent. upon it, whilst if they issued debentures they would have to pay only 5 per cent., which was a clear benefit of 2 per cent. to the shareholders.

The motion was carried unanimously.

Mr. S. R. SCOTT said that it would be within the recollection of most of them that, when the allotment of shares took place, there was a surplus not applied for. The time had now come when, having a great deal of money to spend in laying down mains and building stations, so that they might at as early a date as possible begin to reap the profits of their work, they thought it desirable to issue the balance of their share capital and, accordingly, he had great pleasure in moving

"*That the Directors be authorised, at their discretion, to issue all, or any part of the* 17,047 *shares.*"

A SHAREHOLDER seconded the motion.

The CHAIRMAN, in reply to a question, said that the shareholders would certainly have the option of taking up the issue.

The motion was agreed to *nem. con.*

The auditors, Messrs. Cooper Bros. & Co., were, on the motion of Mr. F. A. WHITE seconded by Mr. J. W. SCOTT, unanimously reappointed.

Mr. S. R. SCOTT proposed, and Mr. LEWIS THOMAS seconded a vote of thanks to the Chairman and Directors for the care and ability which they displayed in looking after the interests of the shareholders.

The resolution was carried unanimously, and

The CHAIRMAN having briefly acknowledged the vote, the proceedings terminated.

---

## Liverpool Electric Supply Company (Limited).

The annual meeting of the shareholders of this Company was held on Tuesday at the Law Association Rooms, Cook-street, Mr. Arthur Hill Holme, CC., Chairman of Directors, presiding.

The Directors' report stated that the amount of net profit available for dividend was £4,878. 9s. 6d., and out of this sum they recommended a dividend of 3½ per cent., which would absorb £4,074. The expenditure on capital account during the year had been £54,019. The number of lamps supplied from the Company's stations on January 1, 1890, was 6,700, and on January 1st of this year 11,750. It was anticipated that during the present year there would be still greater progress in this direction, with corresponding advantages as regarded profits. The Directors had applied for Parliamentary powers to extend the present area of supply to London-road, Prince's-road, Prince's-park, and Sefton-park. The assent of the Toxteth Local Board had been given, but the Liverpool Corporation withheld their assent, as the Directors were unable to accept the conditions which were sought to be introduced into the Draft Order.

The CHAIRMAN, in moving the adoption of the report and statement and accounts, remarked that the Company had made a considerable addition to their business during the past year. They had also adopted all the latest improvements in electric lighting, and everything possible had been done to secure a good and steady light. In this they had succeeded, with the result that they were now giving their customers a supply of electricity second to none in England. They had increased their number of fixed lamps from 6,700 to 13,074, although they had engines of sufficient power to supply 25,000 lamps. The Directors had written off a sum of 3 per cent. for depreciation on all underground mains laid since the commencement of the Company, including those which were not yet in use. Serious thoughts had been expended on a project for extending the business of the Company, and, as stated in the report, they were contemplating carrying the electricity to London-road, and to Prince's and Sefton Parks. They had had considerable difficulty with the Corporation as to a Provisional Order for London-road, but permission for the other areas had been readily granted by the Toxteth Local Board. The Directors saw the importance of taking the light to London-road, for there was a demand for it, and they would have diffi-

Digitized by Google

culty in attending to their business if an opposition company occupied so important a position as London-road. The necessity of making a call upon the shareholders would probably not occur before January next, and then the call, it was anticipated, would not exceed 10s. per share.

Sir DAVID RADCLIFFE seconded the Chairman's motion, which was unanimously agreed to.

Messrs. Von Sobbe and Samuel H. Holme were then re-elected as Directors, and the remuneration to the Directors was, on the proposal of Mr. CHARLES BIRCHALL, increased from £150 to £250.

## Manchester Edison-Swan Company (Limited).

An extraordinary general meeting of the Manchester Edison-Swan Company (Limited) was held on Monday at the Victoria Hotel, Manchester, for the purpose of considering the advisability of obtaining additional capital by the issue of debentures or otherwise.

Mr. VERNON K. ARMITAGE (the Chairman of the Company), who presided, explained that the meeting was called in accordance with a promise made by the Directors that the shareholders would be consulted before any scheme involving any considerable expenditure of money was entered upon. There had recently been a very marked dimunition in the demand for small installations of the electric light, and the Directors thought that, in view of the large number of Provisional Orders which had been recently granted to local boards and corporations, it was desirable that they should have the ability, if they had the opportunity, to do such large work as the carrying out of such Provisional Orders would involve. Another reason why it was thought that it might be necessary to raise additional capital was, that at present they were seriously handicapped in their competition with other companies by the circumstance that they were not manufacturers as well as installers. With facilities for making what they required, they would save much money which at present went to manufacturers of fittings, &c. The Directors felt that if they were placed in a position to raise such money as they might consider necessary, there was a future for the Company, especially in a place like Manchester, where a Provisional Order for electric lighting had been obtained. He thought there was not the smallest doubt that for the current year they would make 7 or 8 per cent. on the capital that had been called up.

In reply to a question by Mr. F. B. ROSS, the CHAIRMAN stated that it was not yet known what amount it might be necessary to raise. That would depend altogether on the extent to which they were entrusted with orders. Their manufacturing work would be carried on in a small way to begin with.

Some discussion followed, at the close of which, without any formal resolution being passed, it was left to the Directors to obtain such additional capital as they consider necessary.

## Telegraph Construction and Maintenance Company (Limited).

The following is the report of the Directors, to be submitted to the members at the twenty-seventh ordinary meeting to be held at the offices of the Company on Tuesday, March 3rd, at one o'clock :—

The accounts for the year show a net profit of £113,681. 4s. 8d., after charging the interest on the Debentures. To this sum must be added £37,483. 7s. 3d. brought forward from last year, making a total of £151,164. 11s. 11d. From this amount is deducted the interim dividend of 5 per cent., paid July 15, 1890, amounting to £22,410, leaving £128,754. 11s. 11d. to be dealt with. Of this sum the Directors propose to distribute a dividend of £1. 16s. per share, absorbing £67,230, being at the rate of 15 per cent., and making, with the amount already paid, a total dividend for the year of £2. 8s. per share, or 20 per cent., free of income-tax, leaving £61,524. 11s. 11d. to be carried forward to the next account.

During the past year the cable factories at East Greenwich and at Wharf Road have been fully occupied, and the increase in the general business at the latter works mentioned in the last report has been fully sustained ; a length of over 9,000 miles of telegraph wire has been insulated for submarine cables and land lines during the year.

The company's ships have duplicated the Eastern Extension Telegraph Company's cable between New South Wales and New Zealand, have repaired and partially renewed the lines across Cook Strait, have partially renewed the Madras-Penang Cable, and have quadruplicated the Eastern Telegraph Company's line down the Red Sea. A cable has also been laid between the north-east coast of England and Sweden for the Great Northern Telegraph Company, and repairs have been effected in the German Government cable between Greetsiel and Valentia.

The factories at East Greenwich and Wharf-road and the Company's steamships are in efficient working condition.

The retiring Directors are Sir George Elliot, Bart., and Mr. Philip Rawson, who, being eligible, offer themselves for re-election. The meeting will have to appoint auditors for the ensuing year. Mr. John Gane (of the firm of Messrs. Gane, Jackson and Jefferys), and Mr. Patrick A. Glegg (of the firm of Messrs. Welton, Jones and Co.), who retire, offer themselves for re-election.

Notice is given that the transfer books of the Company will be closed from the 23rd inst. to the 3rd proximo, both days inclusive, preparatory to the payment of dividend to all shareholders on the register on the 23rd inst.

## Keswick Electric Light Company (Limited).

The following is the Directors' Report to be presented at the annual general meeting of this Company, which was adjourned from January 31st, and will be held at the Court House, Keswick, to-morrow (Saturday) at 4 p.m. :—

In presenting their first report, the Directors have to congratulate the shareholders that the experimental portion of the history of their undertaking has been successfully passed, and that the arrangements for the distribution and supply of electricity from their station for illuminating purposes have obtained such general favour that the demands of consumers now far exceed the capabilities of the Company's original plant. They have, therefore, been compelled to increase the productive power of the station by the addition of another dynamo, and are making arrangements for the introduction of a second turbine.

The accompanying statements show the condition of the Company's accounts to December 31, 1890. The profit and loss account extends over 11 months, and shows a credit balance of £31. 15s. 8d., sufficient to allow of a small dividend, but your directors consider that for the present this balance should be held in reserve.

It will be remembered that the station commenced to run on February 1, 1890. On that date only a portion of the present consumers were in a position to use their lights, owing to the incompleteness of the works and the want of connection of a large proportion of the lamps with the outside mains. In some cases this continued for several months. The receipts, therefore, contrast unfavourably with the expenses, the latter being the full cost of the working from the date of the opening of the station, without any compensating diminution during the time of the shorter output.

The Directors feel the importance of curtailing as far as possible the capital expenditure, and have charged to the profit and loss account some items which might legitimately have been included in the capital outlay.

The total number of lamps now connected with the station is 705, including one 500 candle-power arc lamp.

On October 13th last, a circular was issued to the shareholders offering them, *pro rata*, the unissued shares of the Company, in order that the necessary provision might be made for meeting the Company's increasing business. The shareholders have in response accepted £1,000 of these shares, leaving £1,645 still for disposal. It was hoped that the whole number would have been taken up, so that further necessary expenditure would be amply met by calling up only one-half of the amount.

## Taunton Electric Lighting Company (Limited).

The report of the Directors of this Company for presentation at the fourth annual meeting is as follows:—

"The number of shares allotted is 2,556, on which the sum of £12,780 has been received. During the year the new buildings in St. James's-street, referred to in the last annual report, have been completed. These buildings, with the new machinery and plant laid down, make the works of the Company quite a model depôt. But the completion of these works took a much longer time than had been anticipated; and during the early part of the year there was the expense, for a time, of running two works, in consequence of which the cost of coal and other items was very much higher than would have been the case under normal conditions. Further than this, the work of the construction of the new circuits in the town was much delayed in consequence of the stringent requirements of the Board of Trade; thus retarding the whole business of the Company for several months, during the most important part of the year for constructive work. Under all these exceptionally adverse circumstances, it will hardly be matter for surprise that the accounts show a deficit on the year's working of £438. 17s. 5d.; but now that the works are in good order, and the business of the Company constantly increasing, there is every reason to believe that the next year's working will show a different result. Towards the close of the year it was found necessary to obtain more capital than the issue of ordinary shares secured, and your Directors therefore determined to issue £5,000 Debentures, such sum to include the previous issue of £3,000; and they confidently appeal to the present shareholders to come forward and take up this issue of £5,000 Debentures. Since the issue of the last annual report, Mr. John Withycombe has resigned his seat on the Board of Directors, in consequence of his having gone to reside at Minehead. Your Directors appointed Mr. Arthur A. Chapman to fill the vacancy thus created, and they ask the shareholders to confirm the appointment. The Directors who retire by rotation are Messrs. Alfred Lewis, H. G. Massingham, and A. Steevens; the two former offer themselves for re-election. The auditor, Mr. Albert Goodman, retires; but being eligible, offers himself for re-election."

## NEW COMPANIES REGISTERED.

**MAZAPIL COPPER COMPANY (LIMITED).**—Registered by Jordan and Sons, 120, Chancery-lane, W.C., with a capital of £50,000 in £10 shares. Object: To acquire the Mazapil Copper Mines, Mazapil, Zacaticas, Mexico, and to carry on generally the business of miners, smelters, &c.

**SOCIETE ANONYME D'ELECTRICITE INDUSTRIELLE.**—This Company has just been formed in Paris, with a capital of 4,000,000fr., represented by 8,000 shares of 500fr. each. Of this number 7,600 are considered as fully paid. The object of the Company is to supply electric light and power, and to manufacture and sell the De Meritens battery.

## CITY NOTES, &c.

**BELL'S ASBESTOS COMPANY (LIMITED).**—At the third annual meeting, held on Monday last, the Directors' report for the year ended December 31st last, which showed a net profit of £18,095, and recommends the payment of a dividend of 5s. per share, being, with the interim distribution, 15 per cent. for the twelve months, leaving £2,034 to be carried forward, was carried. The trade of the Company in manufactured asbestos and machinery had exhibited a decline during the twelve months, but the Directors believe that this is only temporary. The Chairman referred to some adverse criticisms which had been made upon the Company's system of working, but assured the shareholders that there was no truth whatever in the statements referred to, and he complained of the way in which the tittle-tattle of irresponsible sections of the press was listened to and acted upon by persons in high places, resulting in a loss of business to the Company. This would, however, he felt sure, right itself in the long run.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended February 20th amounted to £6,114.

**BRUSH ELECTRICAL ENGINEERING COMPANY.**—This Company notifies the payment of a half-yearly interim dividend at the rate of 6 per cent. per annum on the Preference shares.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended February 21st amounted to £718.

**SANITAS COMPANY (LIMITED).**—The Directors of this Company have resolved to recommend the payment of a final dividend of 5 per cent., making, with the interim distribution, 10 per cent. for the year 1890, besides the addition of 2½ per cent. to the reserve fund.

**LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).**—It is intimated that the coupons on their debentures due March 1st next will be paid on presentation at the banking-house of Messrs. Glyn, Mills, and Co., Lombard-street, E.C.

**MUNTZ'S METAL COMPANY (LIMITED).**—The Directors have resolved, subject to the approval of the accounts by the auditors, to recommend the payment of a dividend of 7½ per cent. for the half-year ended December 31, 1890, making 10 per cent. for the year, and a bonus of 5 per cent. on the ordinary shares, and a dividend of 2½ per cent. on the Preference Shares, making 5 per cent. for the year.

**SOCIETE ANONYME D'ELECTRICITE INDUSTRIELLE.**—This Company has just been formed in Paris, with a capital of 4,000,000f., represented by 8,000 shares of 500f. each. Of this number, 7,600 are considered as fully paid. The object of the Company is to supply electric light and power, and to manufacture and sell the De Meritens battery. (See *The Electrician*, February 13th, p. 463.)

**STOCK EXCHANGE.**—The Committee have appointed Tuesday, March 3rd, a special settling day in the Eastern Extension, Australasia, and China Telegraph Company (Limited) £320,000 Four per Cent. Mortgage Debenture Stock, and have ordered this security and shares Nos. 1 to 66,750 of Elmore's French Patent Copper Depositing Company (Limited) to be quoted in Official List. Application has been made to the Committee to allow shares Nos. 142 to 6,459 of the Notting Hill Electric Lighting Company (Limited) to be quoted in the Official List.

**THE WESTERN COUNTIES AND SOUTH WALES TELEPHONE COMPANY (LIMITED).**—The Company have posted warrants for the dividend upon Preference Shares at the rate of 6 per cent. per annum. for the half-year ending December 31st, 1890.

**WEST INDIA AND PANAMA TELEGRAPH COMPANY.**—The traffic receipts for the half-month ended Feb. 15th were £3,213, as compared with £3,585 for the corresponding period of 1890.

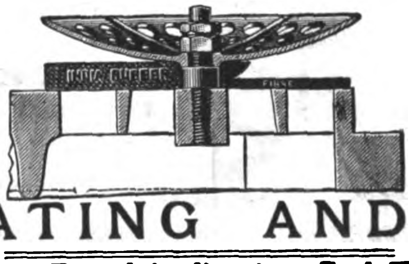
**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ending February 20, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,928.

**WEST AFRICAN TELEGRAPH COMPANY (LIMITED).**—Notice is given that the half-yearly interest on the £300,000 Five per Cent. Mortgage Debentures, due on March 1st next, will be paid on and after Monday, March 2nd, by the National Bank of Scotland, 37, Nicholas-lane, London, E.C. Coupons must be left three clear days for examination.

**CRICKET.**—The Cricket Club of the Electric Construction Corporation, formerly known as the E.P.S.C.C., held their third annual smoking concert at Limehouse Town Hall, on Friday last, the 20th inst. The Managing Director, Mr. Joseph Ebb-Smith, presided; he was supported by several well-known friends of the Club. Among those who regretted their inability to be present were the Chairman, Sir Henry Mance, and Mr. J. Irving Courtenay, from whom letters of apology were read. During the evening the best batsman of the season (Mr. A. Shaw) was presented with a handsome bat, and the best bowler (Mr. J. A. Munro) with a travelling bag. A most enjoyable evening was spent by all present.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 20th Sept. 1886.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue get them from you as required.—Yours faithfully, JAMES WESTOLL."

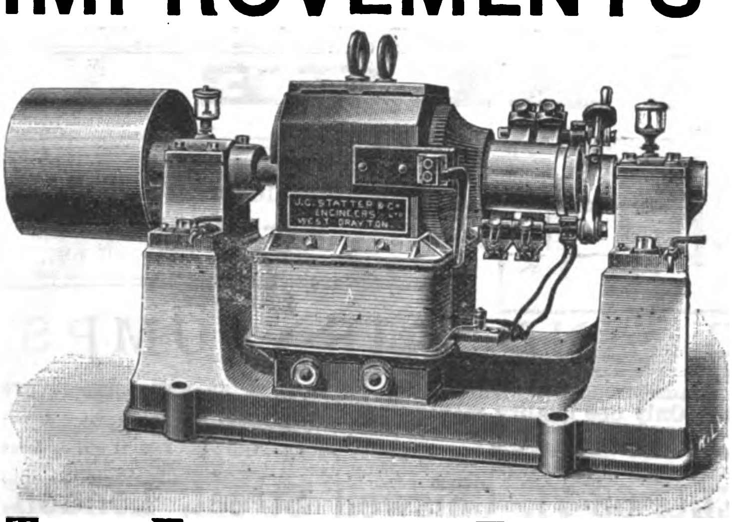
# IMPROVEMENTS IN DYNAMOS.



## STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**

**MACHINES BUILT TO 500 KILOWATTS.**

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 668.—Vol. XXVI. FRIDAY, MARCH 6, 1891. Price Fourpence.

## NOTES.

The fact, published for the first time at the Physical Society on Friday last, that Mr. Blakesley's method of measuring power is equally true whether the alternate currents vary according to a pure sine law or not, is one of very great importance, as several experimenters have shown that the current variations occurring in practice are in many cases far from sinuous. It is, however, very important to note that the method is only accurate in the case of a transformer on the assumption that the induced voltages in the primary and secondary circuits are strictly proportional to each other at every instant of time. This will not be the case if the secondary circuit is inductive, and in particular it is not true if there is magnetic leakage in the transformer. Such leakage is known to take place in all transformers used in practice, and is shown by the drop in the electromotive force acting in the secondary circuit, which occurs as the load is increased. The waste due to hysteresis, calculated by such a method, may differ considerably from that which really occurs, so that the results announced by Prof. Ayrton, relating to the waste for different loads, must at present be accepted with great caution. Of course, if these results can be taken as correct, the controversy about the merits of open and closed circuit transformers is put upon an entirely new basis.

The discussion on the Papers read at the last meeting of the Physical Society having been postponed until the members have had an opportunity of seeing them in type, the adjourned discussion on Mr. Swinburne's Paper at the Institution of Electrical Engineers will intervene, and it is possible that the solid facts which were interspersed amid a tangle of complicated mathematics on Friday last at South Kensington may receive some attention on Thursday next at Westminster.

It is fortunate for the members of the Institution of Electrical Engineers that mathematicians who turn their attention to engineering problems have another outlet for their discoveries, for it is not one engineer in twenty who can take in the meaning of an abstruse mathematical Paper by hearing bits of it read, and seeing a few of the equations chalked on the blackboard to be wiped off again a few moments after, and replaced by others. It would, indeed, be but a small compliment to the talents of the authors if their work could be appreciated by a *viva voce* rendering alone, unless, indeed, the audience were composed of trained mathematicians accustomed to follow such discourses.

The assertion of Prof. Ayrton that the losses in the iron core of a $2\frac{1}{2}$ kilowatt transformer fell off on full load to the insignificant amount of three watts, though it is enthusiastically welcomed and confirmed by the designer, will not be readily received among engineers without some very much more intelligible explanation than has yet been given. It is to be hoped that such an explanation will be speedily forthcoming, and that other perplexed transformer makers may soon learn whether Ewing's theory of magnetisation is to be discarded, or whether the method of testing only takes into account certain matters that are of interest to mathematical minds, and ignores others that are of considerable importance to engineers. Mr. Mordey, in speaking of his thermometric method, has applied to it some rather strong expressions, such as "conclusive," "absolutely, and entirely correct." He, too, must give us considerably more information as to whether the temperature which he measures "with a shilling thermometer" is uniform all over the transformer, although he warms the iron at one time and the copper at another.

The question of nomenclature, to which attention is called in our correspondence columns, is one of considerable importance. Several of our leading physicists have shown themselves to be very fond of creating new titles for various units, and, pruning down the names of distinguished men, have applied them to most of the electrical quantities. This branch being exhausted, they have turned their attention to mechanical units, and have offered us microbarads and megaboles. Mr. Heaviside has a third style, and coins words from the ordinary language of science by a systematic use of suffixes. Some of the results have been happy, but there should be a limit to this fascinating diversion, if only on account of the difficulty of keeping the continually increasing vocabulary in mind. Mr. Heaviside's terms are sufficiently original to be free from any danger of clashing with others, but the name "gauss" has certainly been used before for the unit of magnetic induction, although it has not come into such general use as Mr. Evershed suggests in our correspondence columns, and it is not clear to whom he refers in speaking of "the powers that be." The Paris Congress is the only such power, and it has merely given an international *cachet* to names which have already attained some degree of popularity.

Life is short we know but it is long enough to allow the use of the simple expression "one line of force" without the need of any special monosyllabic name. Civil engineers do not

Digitized by Google

feel the want of a name for "one gallon per minute." The difficulty in connection with magnetic lines arises, as we have pointed out before, when we come to "half a line of force," and for this reason only, some name, or at all events, some better mode of expression might be looked for. A special committee of the British Association has been appointed to consider the magnetic units and their names, and their report, when published, will no doubt carry great weight at the next Paris Congress, and introduce a little order where chaos at present exists.

UNIFORMITY in the use of symbols is quite as important as an accepted system of names, Mr. HEAVISIDE has expressed a wish that the "antique," or "Clarendon" type, by which he invariably expresses vector quantities, shall be exclusively used for that purpose in mathematical expressions. MAXWELL used German characters, which have a clumsy appearance, are difficult to write, and are alarming to the uninitiated. By common consent, the symbols **B**, **H**, **I** are used to express induction per square centimetre, magnetising force, and intensity of magnetisation respectively. These quantities may or may not be used with a vector signification. There is an unfortunate lack of uniformity among writers as to the symbol for current; some use I, a relic of the old "intensité du courant," and others use C. It is to be hoped that these and other symbols will soon be definitely settled.

WHILST the religious sect which he founded has been celebrating the centenary of JOHN WESLEY, how many of his followers have been made aware that he was the author of a work on electricity. This curious *brochure* was published in 1759, under the title of "The Desideratum: or, Electricity made Plain and Useful by a Lover of Mankind and of Common Sense." The titles of the sections are decidedly suggestive—"Electricity the Soul of the Universe;" "The Cat in the Oven, curious Electrical Experiment;" "A Person with Small-pox cannot be Electrified;" "Electricity the greatest of all Remedies." The reverend author goes in for a serious argument to demonstrate that it is "just as *innocent* to keep our rooms tight from lightning, as from wind and water." One of the entries is as follows:—"Exp. 32. A Person standing on the Ground cannot easily kiss an electrified Person standing on the Rosin." About half the volume is taken up with narratives of cures supposed to have been wrought by electrifying, the diseases being of the most varied kind, from fistula to epilepsy. Even the cure of moral diseases is attributed to electricity. "*Felons* are speedily cured by drawing Sparks. If any disorder be superficial this Operation suffices: But if it lie deeper, then the giving of Shocks is found to be more effectual." The good old divine had probably little idea what mischief his well-meaning recommendations of electricity might work. Happily, in science more weight is attached to proven facts than to the authority of a great name. And Wesley's attempt to intervene in science was less successful than his intervention in ecclesiastical organisation.

**Tunbridge Wells.**—The Town Council have resolved to apply for a Provisional Order.

**Institution of Civil Engineers.**—At the last monthly ballot Prof. Ewing was elected a member of this institution.

**Electric Traction in Austria.**—An electric railway is to be laid down between Herculesbad and the nearest station on the Vienna-Orsova Railway.

**Old Students' Association.**—The Old Students will hold a smoking concert this evening at 8 o'clock at the Masons' Hall Tavern, Masons'-avenue, Basinghall-street, E.C.

**Dresden.**—The Royal Court House is to be lighted by electricity. About 1,000 glow lamps will be employed, and a battery of Tudor accumulators is to be put down.

**The St. James and Pall Mall Company.**—It is reported that the results of the borings to a depth of 260 feet in Mason's-yard, Jermyn-street, give a yield of water of more than 1,000,000 gallons a week.

**Royal Institution.**—Prof. Victor Horsley, F.R.S., will give a lecture on "Hydrophobia" on Friday, March 20th, in place of Prof. W. E. Ayrton, F.R.S., who is unable at present to give his promised lecture on "Electric Meters, Motors, and Money Matters."

**Obituary.**—We regret to learn of the death, on the 8th inst., at Bonny, West Coast of Africa, of Mr. J. Carruthers Allan, Superintendent, African Direct Telegraph Company. Mr. Allan was aged 25 years, and was the eldest surviving son of Mr. William Allan, of Dumfries.

**The Proposed Pacific Cable.**—According to a *Times* telegram of March 4th, the United States Senate defeated the Conference report on the Diplomatic Bill, which provided a subsidy for the Hawaiian cable. The Diplomatic Bill finally passed, omitting the cable subsidy.

**The London Overhead Wires Bill.**—An instruction to the Committee on this Bill was carried in the House of Commons on Friday evening last, by 16 votes, requesting them to assimilate the provisions of the Bill to the provisions of the law as it affected the provinces generally.

**Aranjuez.**—One of the largest central stations in Spain is about to be erected at Aranjuez by the representatives of the Allgemeine Elektricitäts Gesellschaft, of Berlin. The capacity of the station will be 30 arcs and 1,200 incandescents. The motive power will be derived from a waterfall.

**Telegraph and Telephone Wires in Budapest.**—According to the *Zeitschrift für Elektrotechnik*, the total length of the telegraph and telephone wires in Budapest is nearly 57,000 miles. The telephone wires alone account for only 1,638 miles, the number of telephone subscribers being 1,245.

**Reorganisation of the French Telegraph Service.**—M. de Selves, Director-General of Telegraphs, has just issued a circular letter to various postal telegraph officials relative to the reorganisation of the system of delivering telegrams, and calling upon them to answer a series of questions by March 31st.

**Electric Traction Concessions in Pittsburg.**—The Pittsburg municipal authorities have hit upon a decidedly novel method of taxing electric traction. All electric street railway companies seeking concessions are required to agree to furnish electric power free of cost to the mechanical street sweepers.

**The Proposed Permanent Electrical Museum.**—*Electrical Plant* has been informed that a committee will be appointed by the council of the Institution of Electrical Engineers to fully consider the proposal recently put forward in its columns that a permanent electrical museum should be founded under the auspices of the institution.

**Institution of Electrical Engineers.**—A general meeting of the students of this institution was held on Friday last, when Mr. Stanley Bone read a Paper on "Electric Lighting Safety Apparatus," some specimens being shown by the General Electric Supply Company. At the next meeting, on March 13th, Mr. H. B. Little will read a Paper on "Modern Telegraphy."

**Long Distance Telephony in Spain.**—The Madrid paper, *La Epoca*, says that among the projects in the portfolio of the Minister of the Interior is one which will shortly be published, inviting public tenders for the construction and working of long distance telephony in Spain. The project consists in telephonically uniting, within a very short period, the various large towns of Spain and placing them in communication with Madrid.

Digitized by Google

**The Kensington and Paddington Subway.**—In reply to several questions in the House of Commons on Friday evening last, it was stated that the promoters of this scheme had agreed to work by cable instead of by electricity, owing to the objections raised by the Science and Art Department. It was also stated that the objections raised by the Normal School of Science and the City of London Guilds Institute had been overcome by the promoters.

**The Croydon County Council and the Board of Trade.**—At a recent meeting of the Croydon County Council, the General Purposes Committee reported that the Board of Trade proposed to insert a clause in the Council's Provisional Order, to the effect that overhead wires were not to be erected without the permission of the Board of Trade. The report concluded by announcing that it was proposed to remonstrate with the Board of Trade on this point.

**Hours of Lighting in Milan.**—Profs. Colombo and Ferrini, of the Royal Technical Institute, Milan, have published, as the result of the working of the electric lighting station in Milan, certain data which show the relative number of hours during which various classes of consumers keep the light in use. The theatres and cafés in Milan run each lamp on an average 1,800 hours per annum; clubs, 1,300 hours; hotels, 950 hours; shops, 750 hours; offices, banks, &c., 400 hours; private consumers only 320 hours; average over all, 750 lamp hours per annum.

**The Subway Railway Bills.**—Steps are being taken to ensure the insertion of clauses in the Central London Railway Bill, the City and South London Railway Bill, and the South Kensington and Paddington Subway Bill, providing either (1) for payment to the local authority of a royalty or share of earnings after interest on capital and working expenses; or (2) for specially reduced fares on certain trains before nine o'clock in the forenoon and after six o'clock in the afternoon, the railway company being required to run a specified number of such trains daily.

**Train Lighting.**—Prof. Kohlrausch, says *Industries*, has reported on the experiments which have been carried out in the electric lighting of railway trains between Cannstadt and Stuttgart, and his conclusions are that such lighting must be independent of the locomotive, and that it must be on the accumulator system. He disapproves of carrying a dynamo, owing to the consequent increase in the number of couplings in the train, and advocates charging the accumulators by means of fixed engines at various stations, and changing the batteries when approaching exhaustion.

**Magnetic Rocks.**—At the Royal Academy of Lyncei on December 18th, Signors Sella and Oddone gave an account of some researches on the distribution of magnetism in certain regions on the Alps. They have found a number of magnetic foci, and record that the rocks which present distinct magnetic properties are magnetite, serpentine, diorite, melaphyre, and syenite. A magnetic rock was observed by Signor Sella on Punta Giufetti, in the Monte Rosa group, and, as it presented traces of fusion on its surface, as if it had been struck by lightning, it is suggested that this circumstance has endowed the rock with its magnetic properties.

**Cheltenham.**—At the last meeting of the Town Council, the Electric Lighting Committee reported that a circular letter had been received from the Board of Trade calling attention to the necessity of obtaining the approval of the Board of Trade to any system of electric supply proposed to be adopted. The Committee passed the resolution "That it is desirable to proceed, with as little delay as possible, in the exercise of the powers conferred by the Electric Lighting Order, and that the borough surveyor be directed, with such assistance as he might find to be necessary, to report as to the best system to be adopted." The Committee's report was adopted.

**High Speed Steam Engines.**—At a recent meeting of the Society of Engineers a Paper was read by Mr. Arthur Rigg on "The Balancing of High Speed Steam Engines." The author said that the present Paper was intended to take note of the external effect of the strains caused by reciprocation, and the modes by which their vibratory influence might be counteracted. A comparison was made between the effects of a compression of exhaust and an independent air buffer, showing how the former entailed a permanent loss of useful effect, which in some measure aided in producing the economy desired by an independent method for bringing these reciprocating parts to a state of rest.

**The London-Paris Telephone Cable.**—The vessel with the cable on board has been lying off Calais waiting for favourable weather, but the wind has been too high to allow the shore end to be properly laid. It has been impossible to make any experiments while the cable is disposed in coils, but it is confidently expected that communication will be satisfactory with ordinary Gower-Bell instruments. The report published in the daily papers that the London and Paris stockbrokers are strongly opposed to the telephonic communication is, we learn on good authority, entirely without foundation.

**The Distinction between Patents and Monopolies.**—If a patent, says the *Electrical Engineer* of New York, be in a proper sense a monopoly, "it is not," as a distinguished judge once said, "an odious monopoly." The distiction between patents and monopolies has never, perhaps, been better presented than in the following words, from the opinion of Justice Giles, in the sewing machine case, Singer *v.* Walmesley: "Patents are not monopolies, because a monopoly is that which segregates what was common before, and gives it to one person or class for use or profit. A patent is that which brings out from the realm of mind something that never existed before, and gives it to the country."

**An Armature Reaction.**—An American technical contemporary contains the following:—A professor of the Ricker Classical Institute took 50 of his pupils to the electric light station in Houlton one evening, to give them some practical instruction in the science of electric lighting. The professor took his place close to the armature, and, to better explain its workings to the class, he held a common door-key in his hand. At a certain stage of the exercises the key came in contact with the armature, the magnetic power was too great to break the connection, and in a few moments the insulation was torn off and the electric generator burned out. As a result of the experiment Houlton was in darkness until a new armature arrived from Connecticut.

**A Useful Application of the Chlorochromic Acid Battery.**—An interesting application of the chlorochromic acid ($CrCl_2O_2$) battery to portable incandescent lamp lighting was made last autumn in France by the underground explorers, MM. A. Martel and G. Gaupillat, who employed a battery of the Renard type (zinc platinised-silver) containing six cells, and capable of supplying current during five hours to a 12 or 15 candle-power lamp. Candles and magnesium lights were out of the question owing to the exhalations from the stagnant subterranean waters. The whole apparatus was 12in. high 8½in. in diameter, and weighed 17½lbs., which was not excessive for the purpose, since the lamp was carried on a small boat. The composition of the solution was approximately as follows:—Chromic acid, 1⅓lb.; hydrochloric acid, 1 pint; sulphuric acid, ⅓ pint; water, 3 pints.

**Aberdeen.**—The gas superintendent has prepared a report on the question of electric lighting, and submitted it to a sub-committee of the Gas Committee of the Aberdeen Town Council. The report estimates that some 150,000 units of electricity would probably have to be generated yearly within the compulsory area on the assumption that one in four of the present gas consumers took the electric light. After communication with Mr. W. B. Esson, the superintendent recommends that two machines of 1,000 lights each should be obtained, and estimates the total cost of the installation and mains at £21,300, the annual expenditure at £4,556, and the annual income at £5,875. In consequence of this report, the sub-committee have decided to issue circulars to all gas consumers within the compulsory area whose annual bill is over £5, asking them whether they would be likely to adopt the electric light.

**Electrolysis in Water Softening.**—For softening water by means of hydrated oxide of lead cheaply, it is necessary to obtain the oxide, and the following method has been devised by M. Villon. A solution of sodium nitrate is placed in a vat divided into two compartments by a diaphragm; lead electrodes of large surface are placed in the solution and the current from

Digitized by Google

a dynamo then passed through. The sodium nitrate is decomposed, caustic soda being formed in the negative compartment and nitric acid at the positive pole from which it dissolves a certain quantity of lead, forming lead nitrate. When the current has passed through the liquid for a certain time, the solutions are run from the two compartments into a second vat and there mixed by means of an agitator. The soda precipitates hydrated oxide of lead and itself forms sodium nitrate; the solution is then filtered and the nitrate solution again submitted to electrolysis.

**Granville's Electric Log.**—One of these logs, which are made by Elliott Brothers, has been fixed on board the "Orontes," and it is also in use in the Argentine Navy. Although essentially an electric log it contains no battery, the log, the iron hull of the ship and the ocean together forming the battery. It is of very simple construction and has only two moving parts, a revolving head and a small internal worm-wheel. The head is connected with the worm-wheel gearing, and every sixth revolution of the former is communicated, by means of a spring contact, through the tow-line to an indicator placed on the ship. The tow-line is insulated with braided tanned netting twine. The indicator consists of a small metal circular box with the necessary internal mechanism and external dials and pointers. The apparatus has shown itself to be an efficient means of accurately indicating, at any part of the ship where an indicator is fixed, the total distance run and the speed.

**St. Pancras Vestry Electrical Exhibition.**—At the last meeting of the St. Pancras Vestry the Electricity Committee Report stated that the Stanhope-street station was approaching completion. The vestry clerk reported with respect to the Electrical Exhibition to be opened at the Vestry Hall, Camden Town, on Monday, the 16th proximo, that there would be 35 exhibitors. The exhibition would be open for a week, a small charge being made for admission. The following firms are among the intending exhibitors:—Willans and Robinson, the Electrical Construction Corporation, Edison-Swan United, Benham and Froud, Strode and Co., Rashleigh, Phipps and Dawson; Clark, Muirhead, and Co., Johnson and Phillips, Woodhouse and Rawson United. A further report of the Electricity Committee stated that the Vestry were allowed to charge 8d. per unit. They recommended that the charge should be 6d. per unit, but that for the present no minimum charge be fixed. The reports were unanimously adopted.

**The Elihu-Thomson Motor Meter.**—At a recent meeting of the Société Internationale des Electriciens, M. René Arnoux, referring to the Elihu-Thomson motor meter (see *The Electrician*, January 16th, p. 332), pointed out that its speed must be very small if its indications are to be accurate. We have $E = c\,r + e$, where E is the potential difference at the shunt-wire terminals, $c$ the current in the shunt wire, $r$ its resistance, and $e$ the back E.M.F. of the motor meter. Now $c$ is equal to $K\,E\,\frac{\omega}{C}$, where $\omega$ is the angular velocity, and C the main current, and $e = K'\,\omega\,C$. Hence we have $E\,C = K\,E\,\omega + K'\,\omega\,C^2$, or $\omega \propto E\,C - K'\,\omega\,C^2$. Hence if the revolutions of the meter are to be proportional to E C, or the power consumed in the lamps, $\omega$ must be very small so that the term $K'\,\omega\,C^2$ may be neglected. Motor meters, it will be seen, are advantageous to consumers since this last term can never be entirely eliminated, and their indications are therefore always against the company.

**University Education.**—On Friday afternoon last a deputation waited on Mr. Goschen and presented a memorial in favour of the annual grant of £15,000 being increased. Amongst the speakers were Mr. Chamberlain, Mr. Erichsen of University College, Prof. Garnett, Sir Henry Roscoe, and Mr. Mundella. Before coming to any decision, Mr. Goschen said he should like to receive a statement from each of the colleges showing the number of students now as compared with the number of students before the grant was made, and the amount of subscriptions now as compared with the amount previously. A point which he appreciated the immense importance of was seeing that in these days, when technical education was being pushed in every direction, there was no falling off in the direction of other studies which were not bread-winning studies, but which rather appertained to the domain of general culture. He was anxious that the colleges that were engaged in the promotion of culture as well as the teaching of bread-winning studies should not be placed at too great a disadvantage by the help which was now given to technical education.

**Chelsea Vestry.**—At a meeting of this vestry last week the Electric Lighting Committee reported that they had considered a letter from Mr. R. Chamberlain, dated February 3rd, asking the Vestry to take into consideration the question of appointing an inspector under the Electric Lighting Acts, and suggesting that the duties might be performed by one of the existing officers. The Committee stated that they were unable to make a recommendation in the sense indicated by Mr. Chamberlain. The Committee also reported that they had considered a letter from the Cadogan Electric Light Company, dated February 4th, stating that they were at the present time working under an agreement with the Vestry, and being about to transfer their business to a newly-formed company, viz., the New Cadogan and Belgrave Electric Supply Company, they asked the Vestry to consent to the transfer of the agreement to the new company. On this the Committee recommended that the Cadogan Electric Light Company should be informed that the Vestry prefer that the company should obtain a Provisional Order. The reports were approved, and the recommendation adopted.

**The Counting of Press Messages.**—On Friday last, in reply to Mr. J. Maclean, who complained that figures in Press messages were counted each as a word, whereas in ordinary telegrams five figures were treated as one word, the Postmaster-General explained that before the introduction of the rate of a halfpenny a word for ordinary telegrams the regulations governing the charge for figures in those telegrams and in Press telegrams were the same, every figure being counted and charged for as a separate word. At the same time all addresses were sent free. When the halfpenny rate came into operation the addresses of ordinary telegrams were no longer sent free, and, chiefly as a concession to those who had to send telegrams to houses bearing numbers composed of several figures, it was decided to charge for five figures as a single word. But in the case of Press telegrams the addresses were still sent free, and as many as 75 words of text during the day and 100 words during the night could still be sent for 1s., whilst a copy of a telegram of the same number of words was telegraphed to any separate town for a charge of 2d. No change, then, having here been made, there appeared to be no ground for a concession in the case of Press telegrams, which were already the subject of such enormous privileges.

**The Mutual Telephone Company in Manchester.**—The first exchange of the Mutual Telephone Company was inaugurated in Manchester on Saturday last. The Mutual Telephone Company have determined to try the effect of low rates, metallic circuits and improved switching arrangements. Every subscriber is provided with a metallic circuit, so that overhearing between his line and those of others cannot take place; he also has a special wire for communicating his instructions to the operator according to the Mann system. It will no doubt be a surprise to many that an efficient exchange can be established before the use of carbon for transmitters has become free, but it must not be forgotten that the Bell telephone, specially constructed to act as a transmitter, was used for many years by the German Government on their Berlin Exchange, which is a single-wire one. This is sufficient to prove the possibility of employing it for exchange purposes. The magneto transmitters employed by the Mutual Telephone Company have been specially manufactured for them by Messrs. Siemens Brothers and Co. They are also employing an improved receiver. The result of the combination is stated to be satisfactory. The Mutual Company have no less than 2,000 lines on order in Manchester. The General Manager and Engineer of the Company is, it will be remembered, Mr. A. R. Bennett.

**Magnetic Rotation.**—At a recent meeting of the Chemical Society a brief Paper on this subject, by Prof. Ostwald, was read. The magnetic rotation of organic compounds, according to Perkin, was, he said, an additive function of their composition, and equal to the sum of the rotations of the components, but this was not the case with the rotation of inorganic com-

Digitized by Google

pounds, which was usually found greater than that calculated on such an assumption. In the case of hydrogen chloride, for instance, the calculated value was about 2·18, and as a matter of fact the value obtained for hydrogen chloride dissolved in an organic solvent, isoamyl oxide was 2·24, but when dissolved in water the value found was from 4·05 to 4·42, increasing with the dilution. The author pointed out that these exceptional values were only obtained in the case of electrolytes, and that they must therefore be referred to a fundamental difference existing between the constitution of electrolytes and that of non-conductors. That such a difference existed had been already deduced from other considerations, and had led Arrhenius to the formulation of the theory of electrolytic dissociation. The author claimed that the facts established with regard to magnetic rotation were in perfect accordance with this theory, and that any exceptional values in the magnetic rotations of electrolytes were due to the occurrence of electrolytic dissociation.

**A Simple Electrical Saw.**—In a recent issue of the *Chemical News*, Mr. H. N. Warren says, whenever a powerful electrical circuit is closed by a platinum wire of suitable dimensions, the well-known heating effect of the same is at once manifested; yet no one seems to have been struck with the idea that the simple heated wire may be employed as a most effective disintegrator of the hardest organic compounds. A similar but more convenient article may be constructed as follows:—It consists of two upright pieces of very stout brass or copper wire, connected at the lower extremities by a non-conducting medium, while across the top is secured a piece of moderately thin platinum wire. On thus connecting the apparatus by means of side binding screws to the terminals of about four Bunsen batteries, the platinum wire at once becomes heated to bright redness, and will be found to cleave the hardest wood with great facility, insomuch that a large number of useful appliances may be thus manufactured in a short space of time. Owing, however, to the platinum wire frequently breaking, probably on account of its intimate contact with the carbon whilst at an elevated temperature, the author has devised and used with advantage a modified wire, formed by depositing metallic platinum upon fine steel wire, by exposing that substance to the action of the electric current in contact with an ethereal solution of platinic chloride.

**Efficiency of Transformers.**—The following data, taken from tests made by Mr. William Stanley, Jun., and published in a recent number of the *Electrical World*, may be of interest. Mr. Blakesley's split dynamometer method was adopted for obtaining the hysteresis and Foucault current losses. It should be borne in mind, says Mr. Stanley, that the column marked "maximum efficiency" represents in reality lower values than actually are obtained in practice, because the total loss in a transformer is not the sum of the loss by hysteresis and the $C^2R$ losses, measured when the transformer is doing no work, but is less than the sum of these losses, because the hysteresis loss falls off as the load is increased upon the secondary. All transformers tested converted from 1,000 to 50 volts. In all tested, save the Thomson-Houston transformer, the current was taken from a Westinghouse alternator having a frequency of 138 ∿. In the case of the Thomson-Houston transformer, it was tested with the current from a Thomson-Houston machine having a frequency of 125 ∿.

| Type of transformer | Total weight in lbs. without case. | Capacity. Lights | Magnetising current, open circuit. | Watts expended in core. | $C^2R$ loss full load. | Maximum efficiency | Drop in volts on secondary at full load. |

**The Electrical Purification of Wine.**—For some time past, says *La Lumière Electrique*, M. de Meritens has been experimenting on the electrification of wine, and M. Martinotti on the application of electricity to vine diseases; and now F. Mengarini has just published a brochure extracted from the *Giornale delle Stagioni Sperimentali Agrari*, Vol. XVIII., entitled "The Reduction of Acetic Acid Present in Wine by Means of Nascent Hydrogen Generated by Electrolysis." If we take two jars filled with wine, connect them by a U tube filled with alcohol and divided at the middle by a parchment diaphragm, place platinum electrodes in the jars and pass a current, the acidity of the wine in the jar containing the kathode is diminished. It is this diminution of acidity due to hydrogenation that it has been sought to turn to practical account. The following are the results of some of the experiments. A 20·19 per cent. solution of acetic acid was converted into a 19·75 per cent. solution after four hours, and into a 16·72 per cent. solution after 28 hours electrolysis. Some sound red wine containing 7·208 per cent. of acid was exposed to the air for 24 hours, and turned sour when it contained 8·228 per cent. of acid. After eight hours of electrolysis the proportion of acid was reduced to 6·53 per cent. The current usually employed varied from 120 to 260 milliamperes, although currents of only 35 or 40 milliamperes were found to produce a beneficial effect. The apparatus intended for operations on a large scale is as follows:—A cylindrical vessel of 1 hectolitre (22 gallons) capacity, of enamelled earthenware, at the bottom of which rests a disc of compressed carbon 12in. in diameter, which communicates with the negative pole by means of a carbon rod about ½in. in diameter, encased in a glass tube containing paraffin. In the neck of the vessel slides a small earthenware cylinder, closed at the bottom by a sheet of parchment, on which rests a slab of carbon. The wine to be treated is poured into the larger vessel, the upper small cylinder containing alcohol and water.

**The Galvanic Action of Tidal Streams on Metals.**—In a Paper recently read before the Midland Institute of Mining and Civil Engineers, Mr. Thomas Andrews, F.R.S., gives a long account of experiments carried out by him on the subject of the galvanic action of tidal streams on metal structures. The general tendency in a tidal stream is to arrange the waters into layers, the lower containing denser salt water and the upper fresh water. It will, therefore, be readily understood that the upper and lower portions of a metal structure or vessel, although composed throughout of the same metal, is exposed to electrolytic disintegration from the galvanic action of two solutions of different composition. An analytical examination of the composition of the waters throughout the length of a tidal stream during diffusion of salt and fresh water, consequent on tidal action, reveals a very considerable difference in the proportion of saline constituents, between the water at the surface and that at the bottom, during certain times of tide. This difference amounts sometimes to near 100 per cent., and it may frequently be either much greater or less according to tidal fluctuations. This fact constitutes the basis of the investigation which the author undertook to obtain some approximate quantitative measurement of the resultant electromotive force. The experiments were made on large cylindrical bars of various brands of iron, of known chemical composition and specific gravity. Every bar was $2\frac{31}{32}$in. diameter, carefully turned and polished quite bright. In every instance the greatest electromotive force observed was due to hard steels, while the soft steels afforded, on the average, less electromotive force than the rolled wrought iron. The experimental results obtained afford an indication of the extent of similar action on structural ironwork in tidal rivers during diffusion between the surface and lower waters. The electromotive force observed was not only appreciable, but was in many instances very considerable, reaching not unfrequently 0·1 to $\frac{1}{7}$ volt. As similar conditions of galvanic action obtain in all our iron structures in tidal estuaries or rivers, the action of the salt and fresh water in course of diffusion constitutes a source of galvanic disintegration independent of any difference in composition of the metals. It should also be observed that in circumstances where the electromotive force arising from causes here pointed out acts in concert with any electromotive force, from differences of composition of the metals employed in structures, a very considerable total electrolytic disintegration is likely to ensue.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 510.*)

§ **23.** It will be noticed that although the $C^2R$ loss due to the exciting current is absolutely negligible in every case we have so far discussed, yet it has been inserted in all the efficiency tables. This was purposely done in order to draw attention to the enormons disparity between the two constant losses, viz., waste in the core and waste in the coils. Such a disparity might suggest that if we could reduce the core waste at the expense of the coil waste we should get greater all day efficiency, and in fact that is precisely what is done in an open transformer; with what results we shall now show.

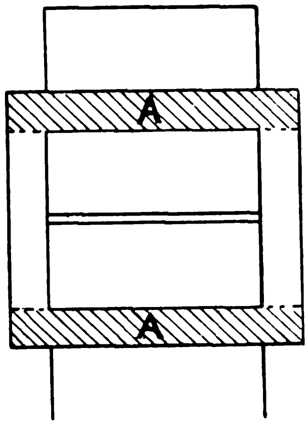

Fig. 5.—Closed Transformer No. 3.

We will first convert No. 3 into an open transformer. Take the two portions of the core AA (Fig. 5), and without removing the coils place them in one line, so as to form a transformer of Rhumkorff coil fashion, the arrangement being shown in Fig. 6. The total length of the core is now 76 cms., and

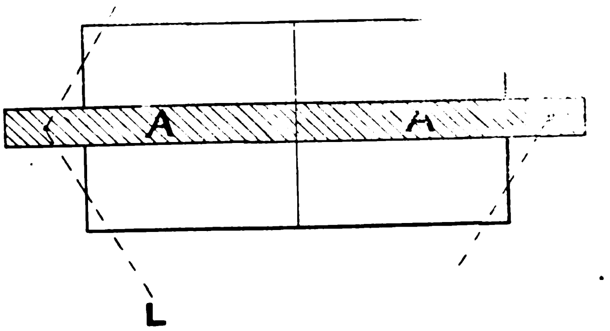

Fig. 6.—No. 3 as an Open Transformer.

of the coil 56, leaving 10 cms. of core projecting outside the coil at each end. The total volume of iron used is only 2,230 cub. cms., and if we were still able to ignore the waste due to the exciting current, we should be certain of obtaining a higher efficiency. But the exciting current will obviously be very large, and it becomes necessary to ascertain approximately what its value will be. This involves a calculation of what we are told ought not to be called the magnetic resistance of the air path from pole to pole. Imagine a long and very thin bar magnet with a sphere of iron fixed at each end, and assume that the whole of the induction through the magnet passes into the air at the surface of each sphere and so radially into space. In short, assume the old polar theory, only look at it from a modern point of view. It is clear that the magnetic resistance of an elementary spherical shell of air concentric with one of the magnet poles is $\frac{dr}{4\pi r^2}$, where $r$ is the radius of the shell. The resistance from the surface of the iron sphere to infinity will be $\int_a^\infty \frac{dr}{4\pi r^2} = \frac{1}{4\pi a}$, where $a$ is the radius of the iron sphere. The resistance from infinity back to the other pole being of course an equal amount, the resistance from pole to pole is $\frac{1}{2\pi a}$

§ **24.** So much for the imaginary magnet. When we try to apply the same theory to our open transformer we find, in the first place, that it has no convenient iron sphere fixed on each end of the core; but a little consideration shows that the resistance largely depends on the total surface of the poles, and that it makes little difference in the result whether we start from a sphere or a cylinder, or a cube, provided they expose the same surface. The surface on each projecting end of the core in Fig. 6 is 313 square cms., and a sphere of this surface would have a radius of 5cms., so we will suppose spheres of this radius have replaced the actual ends. The next difficulty lies in the fact that a considerable portion of the whole induction passing from pole to pole passes backwards through the coils, so that it will be safe to integrate over only three-fourths of the whole surface of the spherical poles, so as to include only that induction which threads both coils once. This limit, beyond which the induction is left out of account, is indicated in Fig. 6 by the dotted lines L, L. Finally, then we get $MR = \frac{4}{3}\,\frac{1}{2\pi a} = \frac{4}{30\pi}$, or $\frac{4}{90}$ roughly.

§ **25.** The maximum [H]* required for the air path is then $\frac{4}{90}$ B A; A being the area of the core = 29cms.; so that [H] = 12,900 for the air, and 6 × 76 = 460 nearly in the iron, a total [H] = 13,400 nearly enough, which, divided by 1·26 $N_p$, gives us the exciting current maximum, namely, 4·8 amperes, which is equivalent to an effective current of 3·4 amperes. In fact, the exciting current is nearly as large as the useful current at full load. However, bad as it looks, let the transformer be tried on the same load as the others, for it must not be supposed that this large exciting current implies large waste of power in the transformer; the primary E.M.F. wave, and the exciting current, differ in phase by very nearly a quarter of a period, so that practically the only loss is from $C^2R$. There is sometimes a confusion of ideas in calculating the $C^2R$ loss due to two alternating currents differing in phase. The true loss is

$$\frac{R}{T}\int_0^T \left(C_1 + C_2\right)^2 dt, \text{ that is to say,}$$

$$\frac{R}{T}\left\{ \int_0^T C_1^2 dt + \int_0^T C_2^2\, dt + 2\int_0^T C_1 C_2 dt \right\}$$

and as is well understood the integral of the last term is nothing when $C_1$ and $C_2$ differ by exactly one quarter of a period, so that we can, in the case under consideration, safely take the $C^2R$ loss from the exciting current quite separately from that due to the useful current.

§ **26.** The dimensions and other particulars of the open transformer are collected in Table X, from which we can determine the efficiency on the usual load. This is worked out in Table XI.

**Table X.**—*No. 3 as an Open Transformer.*

| | | | |
|---|---|---|---|
| Full-load output ........................ | = | 22·4 | kilowatts |
| Frequency = F ........................ | = | 70 | |
| Total volume of iron in core ......... | = | 2,230 | c.c. |
| Sectional area of iron in core ......... | = | 29 | sq. cms. |
| Mean length of iron in core ............ | = | 76 | cms. |
| Width of core plates ...................... | = | 5·1 | cms. |
| Thickness of core plates ................ | = | ·048 | cms. |

* [H] is used here to signify the integral of H taken throughout the air path and iron path; in the latter it is equal to H × (length of core).

$$\text{Efficiency} = \frac{24}{29·8} = 81 \text{ per cent. (nearly enough).}$$

Full load drop 2·8 per cent.

Astounding as it may seem, the removal of about one-third of the core and re-arrangement of the coils and remainder of the core as an old-fashioned induction coil has made practically no difference whatever in the efficiency. But although considered merely by itself, this transformer is in every way as efficient and would be somewhat cheaper to build than the closed transformer from which it has been formed. The large exciting current required is sufficient to condemn it when we recollect that a transformer is only one item in a system of distribution, for in a central station running transformers like No. 3 (open), although the light load during the day would be small in *power*, yet large machines must be kept running at practically no load simply to provide the enormous exciting current, so that the plant efficiency of the generating machines would be very seriously reduced.

§ 27. Leaving the discussion of this question until we have explained the method of drawing transformer indicator diagrams, we will now describe the ingenious device adopted by Mr. Swinburne for reducing the exciting current in an open transformer to more reasonable, or, let us say, less unreasonable, dimensions.

Reverting for a moment to the result arrived at (by a process resembling guesswork, it must be confessed) for the value of the magnetic resistance of the air path, it is easily seen that the most obvious improvement consists in increasing the radius of the "equivalent" sphere. If we do this by putting a solid lump of laminated iron on each end of the core, we soon find we are using sufficient iron to make a closed circuit. Suppose we slit the core plates up at each end into very narrow ribbons, and spread these out radially in all directions, so that their ends lie approximately on the surface of a hemisphere. The outline of the transformer will now be something like Fig. 7 ; the radius of the spherical surface is roughly equal to the length of the slit portion of the core (that is to say, to the length of the core projecting outside the coils), plus the average distance from the axis of the core to its surface. In estimating the surface of the equivalent sphere we meet a new difficulty : the ends of the ribbons not forming a continuous surface it is impossible to say exactly what their effective surface really is. We shall probably err on the safe side if we count the hemispherical surface formed by the ribbon ends as being continuous, and leave the flat surface of each hemisphere next the coil cheeks entirely out of account. It is as well to mention here that although this apparently loose and utterly unjustifiable reasoning was used by the writer in the absence of any experimental evidence of its even approximate accuracy, yet the actual exciting current required by Hedgehog transformers agrees very closely with that calculated on such a slender basis of fact. The radius of the hemisphere of ribbon ends (Fig. 7) is about 13cms., so that its surface is 106 square cm., and the radius of the "equivalent" sphere will be 9·2cms., as against 5cms. in No. 3 (open), so that [H] spent on the air-path will be reduced in the ratio $\frac{5}{9}$, and becomes 7,200, to which [H] required for the core, viz., 500 roughly, must be added, making the total 7,700 as compared with 13,400 for No. 3 (open). The exciting current will, of course, be reduced in the same proportion, and will now be 1·95 amperes. This is better, and leads to a higher all-day efficiency, as will be seen from Table XII. :—

**Table XII.**—*No. 3 as an Open Transformer with "Hedgehog" ends.*

Maximum B = 10,000 F = 70.

Load as in Table V.

| | | |
|---|---|---|
| Total output | 24,000 | watt hours |
| 24 hours' waste in core at 137 | 3,280 | ,, |
| 24 hours' waste $C_p^2 R_p$ at $(7·5 \times 1·95^2)$ | 700 | ,, |
| 6 hours' waste $C_p^2 R_p \times C_s^2 R_s$ at 62 | 372 | ,, |
| | 28,352 | |

$$\text{Efficiency} \frac{24}{28·4} = 85 \text{ per cent.}$$

Full load drop = 2·8 per cent.

§ 28. The efficiency of No. 3 as a "Hedgehog" is, in fact, as high as that of the best of the three closed transformers (No. 2), and examination of the losses in Table XII. suggests that the core waste can be reduced by lowering the induction just as in the case of No. 2. In short, if we convert No. 2 into an open transformer by precisely the same modifications as we adopted in producing Fig. 7, we get the open transformer shown in Fig. 8. The width of the plates being 10·2cms., the projecting ends of the core are, of course, 20·4cms., so that when slit into ribbons and spread radially they form hemispheres twice the radius of those

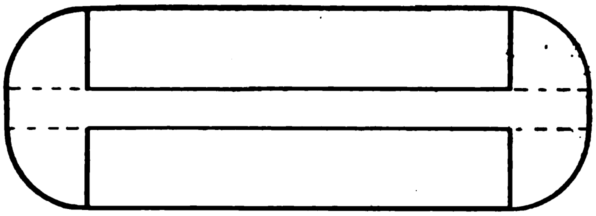

Fig. 7.—No. 3 Transformer ; open ; Hedgehog ends. One-tenth full size.

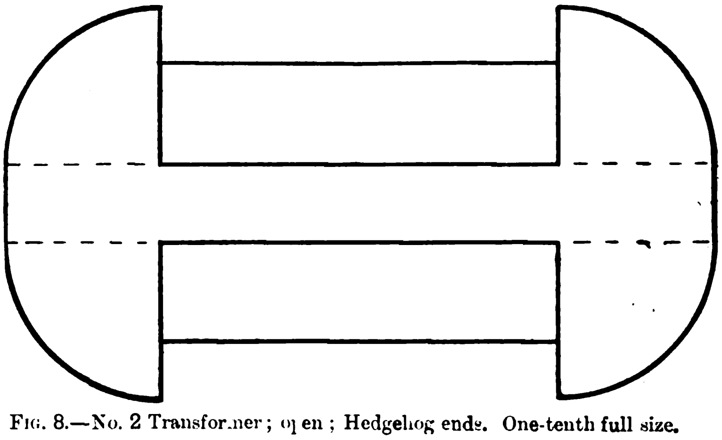

Fig. 8.—No. 2 Transformer ; open ; Hedgehog ends. One-tenth full size.

in Fig. 7, and the exciting current is reduced in nearly the same proportion, being actually 1 ampere. It will be remembered that when the original closed transformer, having 6,600 cub. cms. of iron in its core, was modified into No. 2, we were obliged to increase the volume in the core by 30 per cent., to make room for the new coils, so that it had 8,580 cub. cms. of iron in the core. Of this amount only 5,450 cub. cms. are required when it is converted into a "Hedgehog" so that the core waste is reduced in the ratio $\frac{545}{848}$, and becomes 103 watts. Its efficiency is given in the following table :—

**Table XIII.**—*No. 2 as an Open Transformer with "Hedgehog" ends.*

Maximum B = 5,000 F = 70.

Load as in Table V.

| | |
|---|---|
| Total output | 24,000 |
| 24 hours' waste in core at 103 | 2,470 |
| 24 hours' waste $C_p^2 R_p$ at $(7·6 \times 1^2)$ | 182 |
| 6 hours' waste $C_p^2 R_p + C_s^2 R_s$ at 62 | 372 |
| | 27,024 |

$$\text{Efficiency} = \frac{24}{27} = 89 \text{ per cent.}$$

Full load drop = 2·8 per cent.

Digitized by Google

§ 29. The full load efficiency of this transformer is very high, being just 96 per cent., so that by opening the magnetic circuit of No. 2, we have greatly improved it in efficiency at all loads, lessened the cost of materials, and probably also cost of construction. The one disadvantage introduced is the larger exciting current.

It will be noticed that when once the bold step is taken of reverting to an open magnetic circuit, Mr. Swinburne's "Hedgehog" suggests itself very naturally as an easy way of reducing the exciting current without increasing the volume of iron required for the core; only no one ever took that step.

§ 30. There are a few points that require notice, which we have hitherto neglected entirely in order to keep the comparison between open and closed transformers as free as possible from confusing details. In estimating the drop in volts at full load, an allowance must always be made in practice for the drop due to an independent back E.M.F. acting in the primary or secondary coil, or in both. In every practical transformer the primary and secondary coils are separately wound, and there is often a considerable space left between the coils. Each coil will then be threaded by induction due to its own current, only a portion of such induction threading both coils. The latter portion may be conveniently called "useful induction," the former being "stray induction." It is the stray induction which causes the independent back E.M.F. in each coil, and the quantity of stray induction being proportional to the currents in the primary and secondary coils (that is to say, proportional to the load), the back E.M.F. simply produces an extra drop in volts over the coils beyond that due to resistance. The amount of this extra drop being dependent on the shape and position of the coils is capable of being reduced to practically nothing; if the primary and secondary wires could with safety be wound side by side, the only stray induction would be that round and in each individual wire. Even in practice the effective stray induction may be made extremely small by a judicious arrangement of the two coils; but as we are not here concerned with transformer design, we need not discuss the matter. Any extra drop in the closed transformers we have described will be very nearly the same in all, and so does not affect the comparisons made. With the open transformers the case is rather different; the stray induction may easily bear a far larger proportion to the useful induction, and its direction varies slightly with the varying induction density in the core. It may be greatly reduced, however, by suitable windings.

§ 31. Another small detail in the case of open transformers has not yet been mentioned. We used exactly the same coils on the closed and open types. In practice, a few extra turns will have to be put on the secondary to keep the secondary E.M.F. at the proper value. It is readily seen that the whole induction due to the exciting current cannot be made to thread the secondary coil, so that its E.M.F. will be less than that calculated on the assumption that it is equal to the primary E.M.F. multiplied into the ratio of the turns on the two coils. As a matter of fact, the assumption is by no means necessarily true in the case of closed transformers. If the space occupied by the two coils is large compared with the area of the iron core, the secondary will require a few more turns than the calculated number. This is a point by no means generally understood by manufacturers, and the writer, by a curious accident, discovered that in the case of a well-known and largely used transformer the secondary and primary E.M.F.'s had been assumed to be proportional to the number of turns on the respective coils, with the result that the actual secondary E.M.F. was 10 per cent. below the calculated.

It will be remembered that in estimating the losses in closed circuit transformers, eddy current losses in the coils themselves were neglected as too insignificant to have any appreciable effect. In an open transformer a considerable fraction of the useful induction, in passing from pole to pole, traverses some of the windings near each end of the core, so that coils of copper tape, which are extremely convenient and perfectly admissible in a closed transformer, would probably lead to some energy waste in an open transformer.

§ 32. It will be convenient to pause at this point, and review the results arrived at so far, in this more or less theoretical investigation. For the sake of easy reference, the chief features of the six best modifications of the original transformer are collected in Table XIV.

**Table XIV.**—*Six Ten Horse-power Transformers. Full load drop = 2·8 per cent. in each.*

| Description of transformer. | Frequency (v per sec) | Maximum induction (gausses) | Exciting current (amperes) | Percentage efficiency | | Weight of materials. | |
|---|---|---|---|---|---|---|---|
| | | | | All day | Full load. | Iron. | Copper |
| CLOSED. | | | | | | | |
| No. 1 low frequency. | 35 | 10,000 | ·22 | 80 | 94·0 | 143 | 240 |
| No. 2 low induction. | 70 | 5,000 | ·11 | 85 | 95·0 | 143 | 240 |
| No. 3 small core ... | 70 | 10,000 | ·18 | 81 | 94·5 | 60 | 173 |
| OPEN. | | | | | | | |
| No. 3 small core (plain ends) ...... | 70 | 10,000 | 3·4 | 81 | 94·5 | 37 | 173 |
| No. 3 small core (hedgehog ends).. | 70 | 10,000 | 1·95 | 85 | 95·0 | 37 | 173 |
| No. 2 low induction (hedgehog ends).. | 70 | 5,000 | 1·00 | 89 | 96·0 | 91 | 240 |

The exciting currents are, of course, only approximate; the two last columns give the approximate weights of iron and copper used in pounds. Nos. 1 and Nos. 2, it should be remembered are identical so far as dimensions and disposition of core and coils are concerned, and No. 1 is not therefore inserted in the table as an open transformer at a low frequency. It is easily seen that its efficiency under these conditions would be raised by 4 or 5 per cent., but it would still compare unfavourably with No. 3 and No. 2.

§ 33. According, then, to the results condensed in Table XIV., the efficiency of any closed transformer, good, bad, or indifferent, is raised (both at full load and on a time load) when converted without any change in the windings into an open transformer with Hedgehog ends. The increased efficiency is due to diminution in the volume of the core, and is purchased at the expense of a largely increased exciting current, the total magnetising force for a 10-H.P. Hedgehog being roughly ten times that required by the same transformer with a closed magnetic circuit. We have just stated that these results apply to *any* transformer, and made no restriction as to size or output. It is not necessary to work out examples of larger or small transformers, in order to realise that this is true in a general sense; in fact, we can predict that the larger the transformer the greater the increase in efficiency when its magnetic circuit is opened. For removal of a large part of the core must raise the efficiency, even if the $C^2 R$ loss due to the exciting current increases at the same rate in large as in small transformers; but actually the ratio of extra loss in $C^2 R$, due to the large exciting current required by an open transformer, to the total waste becomes less and less as the transformer is increased in size, since the magnetic resistance of the air path practically depends only on the radius of the hedgehog ends, and only to a very minute extent on the distance from pole to pole. The same considerations apply with equal force (but in an opposite sense) to transformers of less than 10-H.P., so that if a 2-H.P. closed transformer, for example, were converted into a Hedgehog, we should find the $C^2 R$ loss for exciting current increased in a much larger ratio to the total waste than was the case in the 10-H.P. transformers. But a glance at Tables XII. and XIII. clearly shows that this loss might be very largely increased, indeed, before it balanced and neutralised the saving effected by throwing away a large portion of the iron core, so that there will still be a clear gain in efficiency on converting a small closed into an open transformer, although the smaller it is the less the gain on any given time load. However, a small diminution in the total daily waste is worth having in little transformers suitable for running single houses and therefore working for a very short time on anything like full load. A larger transformer, running a few hundred lights, would, in all probability, have one or two shops or offices in addition to houses on its secondary circuit and would feel the benefit of a more evenly distributed load.

## ON THE DETERMINATION OF THE CAPACITY OF LONG SUBMARINE CABLES.

BY ARTHUR DEARLOVE.

At the British Association meeting of last year Mr. Glazebrook presented a Paper, entitled, "On the Air Condensers of the British Association," with a Note by Dr. A. Muirhead, which dealt with a method of correcting the capacity of condensers for absorption and leakage. Dr. Muirhead also published in *The Electrician* (Vol. XXV., September 5, 1890, p. 487) some results obtained when determining the capacity of a short length of core by this method, using a formula to which the following is equivalent:—

$$C = K \frac{10000 - (R \mp P)}{R \mp P}.$$

where C is the total capacity of the cable,
K is the total capacity of the condenser used as standard,
R is the slide reading observed at balance,
and P is the correction found, and which is either substractive or additive as explained hereafter.

I have lately had an opportunity of applying this test and correction to a cable of over 1,300 miles in length, laid by the Telegraph Construction and Maintenance Company, for the Eastern Telegraph Company, while testing on behalf of Messrs. Clark, Forde and Taylor, engineers to the latter company.

The method of finding the capacity, long known as "Gott's method," was, I believe, first suggested by Sir William Thomson, in Vol. I. of the *Journal* of Society of Telegraph Engineers, pages 397 and 398. This test has been for some time employed by electricians, and possesses fewer disadvantages than any other of the well known methods of taking the capacity of long cables, and good results have been frequently obtained by it. The test, however, has had objections, in that the value obtained by it differed largely for various times of charge. The corrections suggested obviate to a large extent this difficulty, and moreover the necessary time of charge, in order to obtain a fairly correct value for the capacity of the cables, is easily determinable.

The following sketches (Figs. 1, 2, 3) show diagrammatically the varied conditions of things produced by the movements of the key when making the test. The key employed was the one specially designed by Mr. H. A. C. Saunders, of the Eastern Telegraph Company, and is described in *The Electrician*, Vol. XXV., June 20, 1890, p. 170.

The mode of procedure is as follows:—Join up the battery, slides, standard condenser, and cable as for an ordinary "Gott's test," charge the condenser with cable in "cascade" from the 10,000 end of the slides, and obtain by depressing the galvanometer or index key I. as good a balance as is possible; this is done by adjusting the slides until a point is found where the galvanometer deflection is *nil*, or at which the potential equals the potential of the junction of the standard condenser and the cable.

The galvanometer key should not be kept down for any considerable length of time, but very short contacts of the key should be made until an approximate balance is obtained; when near the balance, a longer contact is not objectionable. The balance having been obtained, the point K in Figure 1 is disconnected from the battery and slides, and is put direct to earth; the position of affairs is then represented by Figure 2, no circuit being made through the galvanometer. After the point K has been to earth for a period of, say, three to four seconds, for cables of from 1,000 to 1,500 knots length, the point J is discharged through the galvanometer to earth; the deflection so produced is noted in scale divisions, and called hereafter *d*. This diagram shows merely what is actually done to obtain the correction deflection, *i.e.*, *d*.

To ascertain the value of *d* in terms of the slide reading, or of potential difference, the index of the slides is run back towards zero, and the point J is charged from a position on the slides that gives approximately the same deflection as noted in the preceding operation (Fig. 3). Call this deflection *d'* and its equivalent in slide reading *p'*, then the value in slide readings of *d* is $p = p' \frac{d}{d'}$, and is either subtractive or additive, according to direction of throw.

If *d* and *d'* are in *opposite* directions the value *p* (in slide readings) must be *subtracted* from the original slide reading obtained on balance in the "Gott's test" (Fig. 1); if *d* and *d'* are in the *same* direction, *p* becomes *additive*.

The following series of tests was taken on laid cables of 1,331 knots and 100 knots in length, whose respective mean capacities were 0·352 microfarads and 0·354 microfarads per knot when tested at 75°f. in lengths of two knots. The absolute resistance of the 1,300 knots length was approximately one megohm, and that of the 100 knots length 6 megohms. The condensers used were compared step by step with a standard ⅓ microfarad, and had an insulation resistance of over 450 megohms per microfarad, or the 60 microfarads had an absolute resistance of over 7 megohms at 75°F.

A series of tests was taken with conditions as explained, using as a standard condenser 59·20 microfarads *versus* 1331·4

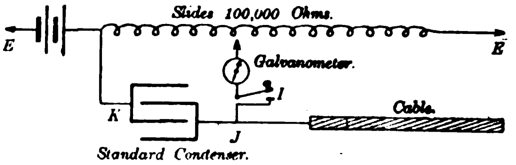

FIG. 1.

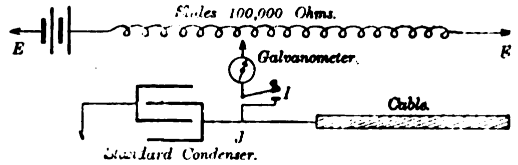

FIG 2.

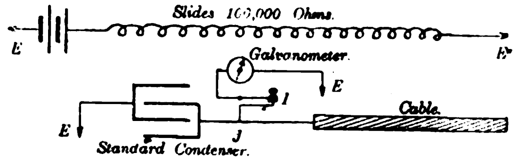

FIG. 3.

knots of cable and 10 Leclanché cells as a battery. The standard condensers, it may be understood throughout, were short circuited for a short time between each test.

*Series No 1.*

| Time of charge in seconds. | S.R. when balance obtained. | Earthing period. Seconds. | Discharge in scale divisions. | Equivalent value of scale, divs. in S. R.'s. | Corrected slide reading. |
|---|---|---|---|---|---|
| | | | *d* | *p* | |
| 6 | 1,148 | 2½ to 3 | 68 right | – 35 | 1,113 |
| 8 | 1,149 | " | 66 " | – 34 | 1,124 |
| 10 | 1,175 | " | 100 " | – 52 | 1,123 |
| 15 | 1,175 | " | 110 " | – 57 | 1,118 |
| 30 | 1,229 | " | 200 " | –117 | 1,112 |
| 30 | 1,224 | " | 185 " | –107 | 1,122 |
| 40 | 1,192 | " | 135 " | – 74 | 1,118 |
| 50 | 1,224 | " | 200 " | –117 | 1,107 |
| 60 | 1,243 | " | 225 " | –138 | 1,105 |
| Mean of ob. S. R.'s | 1,195.4 | | | Mean of cor S. R.'s | 1,115·8 |

Worked out, these results give the following values for capacity of cable.

Uncorrected S. R. = 1,195·4 = total capacity 436·4 = ·3,275 per knot.
Corrected " = 1,115·8 = " 471·35 = ·354 "
The capacity when tested in 2 knot lengths, which is here taken as the *true* capacity............ ............ 468·65 = ·352 "

Digitized by Google

In one case we have an error of 7·5 per cent., and in the other of about 0·5 per cent.

Some tests not included in the above series showed quite conclusively that the period allowed to elapse between the point K being put to earth and the deflection $d$ being noted had an important influence upon the accuracy of the correction. If the time allowed to earth is insufficient, the cable is not properly discharged, and the correction will be too large, the capacity, therefore, of the cable will apparently be much higher than it actually is.

To illustrate this, three or four tests are given below, in which the "earthing period" was about half that allowed previously, or about $1\frac{1}{4}$ to $1\frac{3}{4}$ seconds.

| Time of charge in seconds. | R. S. when balance obtained. | Discharge in scale divisions. | Equivalent value of scale divs. in S. R.'s | Corrected slide reading. |
|---|---|---|---|---|
| | | $d$ | $p$ | |
| 20 | 1,197 | 50 left, 250 right | - 117 | 1,080 |
| 30 | 1,200 | 250 „ | - 135 | 1,065 |
| 30 | 1,202 | 260 „ | - 158 | 1,044 |
| | | | Mean slide reading...... | 1,063 |

This corrected S. R. 1,063 gives a total capacity for the cable of 499 microfarads, or 0·375 per knot, which is 5·5 per cent. too high a value.

No. 2 Series was taken under the following conditions :—

*19·782 Microfarads versus Cable 1331·4 Knots.*

| Time of charge in seconds. | S. R. when balance obtained. | Earthing period. Seconds. | Discharge in scale. Divisions. | Equivalent value of scale divs. in S. R.'s. | Corrected slide reading. |
|---|---|---|---|---|---|
| | | | $d$ | $p$ | |
| 5 | 412 | $2\frac{1}{4}$ to $2\frac{1}{2}$ | 30 right | - 8 | 404 |
| 5 | 415 | „ | 38 „ | - 10 | 405 |
| 10 | 416 | „ | 45 „ | - 13 | 403 |
| 10 | 414 | „ | 38 „ | - 10 | 404 |
| 17 | 422 | „ | 70 „ | - 18 | 404 |
| 22 | 434 | „ | 112 „ | - 32 | 402 |
| 30 | 441 | „ | 133 „ | - 39 | 402 |
| 40 | 457 | „ | 200 „ | - 60 | 397 |
| 50 | 463 | „ | 220 „ | - 67 | 396 |
| 60 | 478 | „ | 280 „ | - 87 | 391 |
| Mean of ob. S. R's | 435·2 | | | Mean of cor. S. R.'s | 400·8 |

Mean S. R. for all times of charge up to 30 seconds equals 403·4 = 470·6 microfarads for cable, 0·353 microfarads per knot.

It will be observed that in the above test the "earthing period" is the same for all times of charge. The correction applied appears to answer perfectly up to 30 seconds charge, beyond this time it becomes too powerful. It is quite possible that when the cable is charged for so long a period as 60 seconds, a slight increase in the "earthing period" is required.

The following series of tests was made *varying* both the time of charge and the "earthing period" before noting the correction discharge from the point J, and the observations are entered exactly as taken. The cable current during operations was fairly steady, and about 10 divisions right.

The mean of the whole of these slide readings is 1,114·5, which gives a total capacity of 472· microfarads or 0·355 microfarads per knot for the cable, or assuming the 75° value per knot to be correct the result is 0·8% in excess.

An examination of the above figures shows that a less time to earth than three seconds complicates matters, as on discharging a throw is obtained first in one direction and then in the other; this, I think, may be used as a means of finding the proper amount of time necessary for the "earthing period" of any length of cable. The correction made above when these two throws occur is applied only to the *difference* of these readings.

*59·20 Microfarads versus Cable 1331·4 Knots.*

| Time of charge in seconds. | S. R. when balance obtained. | Earthing period. Seconds. | Discharge in scale divisions. | Equivalent value of scale divs. in S. R.'s | Corrected slide readings. |
|---|---|---|---|---|---|
| | | | $d$ | $p$ | |

| 25 | 1,124 | 5 | 5 left | - 3 | 1,121 |
| 25 | 1,128 | $2\frac{1}{2}$ | { 7 right then 20 left } | - 4 | 1,124 |
| 30 | 1,145 | 3 | 78 left | - 24 | 1,121 |
| 30 | 1,152 | 5 | 130 „ | - 40 | 1,112 |
| 40 | 1,149 | 3 | 90 „ | - 28 | 1,121 |
| 40 | 1,150 | 5 | 115 „ | - 35 | 1,115 |
| 50 | 1,148 | 3 | 100 „ | - 30 | 1,118 |
| 50 | 1,149 | 5 | 108 „ | - 33 | 1,116 |
| 60 | 1,158 | 3 | 127 „ | - 39 | 1,119 |
| 60 | 1,171 | 5 | 204 „ | - 66 | 1,105 |
| 60 | 1,179 | 10 | 250 „ | - 81 | 1,098 |
| 120 | 1,194 | 8 | 127 „ | - 93 | 1,101 |
| Mean of observed S. R.'s | 1,139·0 | | | Mean cor. S. R.'s. | 1,114·5 |

The foregoing series of tests was taken upon the 1,331 knots length, whose mean temperature was 72°F. The *following* tests were taken on the 100 knots length of cable, whose mean temperature was 80°F. In the case of the long cable, the correction to be applied to the original slide reading observed was invariably substractive; this was reversed on the 100 knots length, and it becomes always additive. These tests are inserted to show with what accuracy the capacity of such lengths can be found.

*19·782 Microfarads versus 100 Knots of Cable.*

| Time of charge in seconds. | S.R. when balance obtained. | Earthing period. Seconds. | Discharge in scale divisions. | Equivalent value of scale, divs. in S. R.'s. | Corrected slide reading. |
|---|---|---|---|---|---|
| | | | $d$ | $p$ | |
| 5 | 3,557 | 2 to 3 | 20 left | + 9 | 3,566 |
| 7 | 3,530 | „ | 85 „ | + 36 | 3,566 |
| 10 | 3,558 | „ | 40 „ | + 16 | 3,568 |
| 18 | 3,547 | „ | 53 „ | + 22 | 3,569 |
| 20 | 3,531 | „ | 92 „ | + 38 | 3,567 |
| 30 | 3,539 | „ | 62 „ | + 29 | 3,568 |
| 40 | 3,526 | „ | 97 „ | + 42 | 3,568 |
| 50 | 3,528 | „ | 93 „ | + 38 | 3,565 |
| 60 | 3,517 | „ | 120 „ | + 52 | 3,569 |
| Mean of ob. S. R.'s | 3,537 | | | Mean of cor. S. R.'s | 3,568 |

Observed S.R. = 3537 = 36·15 mfds. total capacity, or 0·361 per knot.
Corrected „ = 3568 = 35·66 „ „ or 0·356 „
Mean capacity when tested in two-knot lengths = ... 0·354 „

By the use of the correction it is evident that a nearer value to the actual capacity is obtained.

As a further illustration of the usefulness of this method, I give the values of tests on the same length of cable (100 knots), using 59·20 microfarads as a standard capacity.

*59·20 Microfarads versus 100·14 Knots of Cable.*

| Time of charge in seconds. | S. R. when balance obtained. | Earthing period. Seconds. | Discharge in scale divisions. | Equivalent value of scale, divs. in S. R.'s. | Corrected slide reading. |
|---|---|---|---|---|---|
| | | | $d$ | $p$ | |

| 30 | 6,144 | „ „ | 154 „ | + 114 | 6,258 |
| 40 | 6,129 | „ „ | 170 „ | + 126 | 6,255 |
| 52 | 6,045 | „ „ | 275 „ | + 207 | 6,252 |
| 60 | 6,070 | „ „ | 250 „ | + 187 | 6,257 |
| Mean of ob. S. R.'s | 6,139 | | | Mean of cor. S. R.'s | 6,256·3 |

Digitized by Google

These slide readings give the following results:—

Observed S. R.'s ... 6,136 = 37·23 mfds. total, or 0·372 mfds. per knot.
Corrected S. R.'s ... 6,256·3 = 35·425 mfds. total, or 0·354 „ „
Value of cable taken by
75° tests ............ = 35·460 total, or 0·354 „ „

The *corrected* S. R. when worked out gives for the cable identically the same capacity per knot as that *observed* in the factory tests on short lengths, the uncorrected S. R. giving too high a result by 5 per cent.

The values on long cables are of course affected by the earth currents existing at the time of observation, but the new correction adds nothing to the usual difficulties associated with strong earth-currents, and any error arising from them would be lessened, if not altogether eliminated, by a few readings taken with the poles of the charging battery reversed. It may be objected that there are few advantages in this test, and that it is of no practical use, but I consider that it gives an opportunity of verification of results afforded by no other method. Thus, whether the length of the circuit be known or unknown, and either the capacity of the cable, or the distance of a rupture in the conductor is required, the result may be considerably far from the truth, if the calculations are made from the uncorrected observations, whereas by employing this test and its correction intelligently, the capacity of the cable or the distance of the break can be obtained to within 0·5% of its true value.

The large number of tests taken and given here were made to get an idea of the capabilities of the method suggested.

The insulation resistance of the condensers and cable tested, has no doubt an influence upon the magnitude of the correction, but does not appear to seriously diminish its accuracy. Other things being alike, the magnitude of the correction no doubt depends on the relative rates of electrification of the dielectrics of the condenser and of the cable. Dr. Alexander Muirhead has lately shown me a curve of the electrification of a paraffin condenser at a temperature of about 78°F. This was plotted on the same sheet as the electrification curves of a cable whose mean temperature was 36°F. when tested, and they show a nearly identical electrification at their respective temperatures.

It should follow from this that when comparing condensers at say 75 deg. with a cable at a temperature of say 40°F. the correction would be found to be small. This is true only, I believe, when the insulation resistance of the two capacities compared are about the same per microfarad.

## REVIEWS.

**Electricity:** A Sketch for General Readers. E. M. CAILLARD. (London: John Murray, 1891.)

Of elementary books on electricity it would seem that we have far too many, and no subject seems so to tempt an author to display his ignorance, and sometimes his conceit. Yet the veriest trash runs into second and third editions, and the same old woodcuts are made to do duty again and again. Though it was not to be expected that the present publisher would bring out a book of this class, we turned over the pages with some doubts, and lighted on the words "by the term power engineers understand the rate of doing work." This was very reassuring, since most writers on popularised electricity do not appear to see any need for defining such a term, which would, as a rule, be used by them as a synonym for energy, force, and work. A glance at the preface revealed that the writer is a lady, and that the volume was therefore one of peculiar interest and meriting special attention. Having read it with care, we have great pleasure in coming to the conclusion that it is the only book of the kind (as far as we know) that can be thoroughly recommended, and one that may be safely relied upon for explaining the present state of electrical science and its applications, to the general reader. The writer does not give the applications a prominent position, as is done in "Electricity in Modern Life," and "Electricity in the Service of Man," and the pages are not, therefore, elaborately illustrated. The style is excellent, and the space devoted to the different branches of the subject are well proportioned, with the exception perhaps of the two chapters devoted to atmospheric electricity, but these are so interesting that little could be spared from them.

The book reveals a good many indications of the influence of the teaching of Profs. Ayrton and Perry, whose names and inventions are frequently alluded to. The authoress expresses her obligations to the former for his assistance in the revision of the proofs, and this being so we have less hesitation in pointing out a few slips which have escaped his notice. On p. 122 the favourite concept of the mathematician—a magnetic shell—is spoken of and described as though "a thin sheet of metal may be so magnetised that the whole of one face of it will possess north-seeking, and the whole of the opposite face south-seeking magnetism," although permanent magnetisation of thin steel plates at right angles to their planes has been shown, by Duole and others, to be impossible in practice. On p. 139 the two-fluid hypothesis of electricity is put forward under the guise of a two-current theory. "It must not be forgotten that there is always a negative current as well, whose course is exactly opposite." "No satisfactory theory can be propounded which does not take into account the double current." We do not count this as a slip, but as a rather rash assertion. The centimetre is said, on p. 198, to be "considerably less than two-thirds of an inch." Probably two-fifths is intended. "The main cause of the light" of an arc "appears to be the incandescence of minute particles of carbon, which are carried in two incessant streams between the carbon pencils." This is a careless, unverified statement, which has been common for years past in text-books and in the lecture room, and is the only one of its kind that we have found in the book. It is the surface of the carbons which emits the light, and the arc does not consist of particles of carbon but of carbon vapour, which emits a very small fraction of the light. Once only does the authoress get out of her depth. The proof reviser must have been nodding when he came to the foot of page 214, where there is a strange jumble about the self-induction in the core of a Gramme ring. The book is in a way unique, since on the one hand it is utterly unconnected with examination cram, and on the other hand is not a mere schoolboy's book, written up to a set of pretty illustrations, nor has it to do with advertising, like so many other popular publications on electric light.

**A Dictionary of Metric and other Useful Measures.** By LATIMER CLARK, F.R.S. (London: E. & F. N. Spon. 1891.)

Tables of weights and measures are among those matters which schoolboys are supposed to commit to memory. Many industrious schoolboys believe that their elders and betters carry about, at all events, the British measures firmly and clearly fixed in their minds, and that any well-educated person ought to be able to reckon in his head the number of firkins of water which would flood a field of 75 perches to the depth of three-seventeenths of a yard. But as he grows older, and becomes a second-year student at a technical college, he finds out that many well-educated persons, who have often to deal with weights and measures, carry about with them note-books or pocket-books, or slips pasted on the back of a slide rule; and as by that time he has to deal not only with our national system but with metric quantities and a host of electrical and physical units, he falls back on Molesworth or Munro and Jamieson, or Kempe, and if he needs to refer frequently to them, he must burden his pocket with information as to the minimum rounded projection of Prussian railway buffers, sundry tests of submarine cables, lists of jointers' tools, &c.

A reaction is taking place in this class of literature, and the whole body of tables are condensed into a few square inches or elaborated into a comprehensive form. Of the latter class, no more complete and handy a volume has ever appeared than the one before us. It is arranged in four columns. The first gives the name and definition of the unit or measure or the names of two measures, *e.g.*, "*Centimetres into feet.*" The second gives the multiplier for conversion; the third gives the reciprocal of the second for dividing; and the fourth contains the logarithms of the multipliers. The names are arranged in alphabetical order, and the system is manifestly much better than any attempt at classification. Such a collection of thoroughly practical and modern

Digitized by Google

weights and measures has surely never before been made. Obsolete and foreign terms are ranged with the latest and crudest suggestions. Thus we find *Barad* next to *Barley-corn*, and *Coulomb* next to a *Cran of herrings*, which is stated to consist of 37½ gallons. Imperial gallons are converted in some 20 different measurements, and as many more sundry gallons, such as the gallon of the United States and of Queen Anne, are enumerated and defined. Further on, we find together the *Kapp line*, *Kilderkin* and *Kilodyne*, the standard *Candle* and the *Carat*, besides numerous foreign measures and conversions, such as *Roubles per pood* into *Shillings per cwt.* The accuracy of the work is sufficiently guaranteed by the author's reputation. He has adopted the latest determination of the weight of a cubic inch of water (see *Electrician*, Vol. XXV., p. 633).

Since the author has given so large a number of different measures, we would venture to suggest that the ampere should be given in the weight of silver and copper deposited per minute and per second. We referred to this work for the purpose of checking the definition of ·000329 gramme of copper per second given in E. M. Caillard's "Electricity," and did not find it. Since the very object of the book is to save labour in conversion of measures, it might be well to give the weights also in pounds, to check statements about the commercial deposition of copper.

The abbreviated title on the cover, "Metric Measures," does not adequately describe the contents, since, as may be gathered from the items to which we have alluded, the whole ground is covered, including the metric system, which, though occupying but a portion, is dealt with in a more thorough, practical and convenient way than in any other work that we have seen.

**Histoire d'un Inventeur.** By G. Barral. (Paris: 1891.)

There is probably no man in this hemisphere who has produced so many electrical inventions as M. Gustave Trouvé. Whether Edison has outnumbered him by occasional attention to mechanical matters, or by concocting neuralgia cures, or whether M. Trouvé has occasionally designed a flying machine or two in which compressed air replaced the battery, they have made a profession of electrical invention, and these two men stand alone as the most prolific inventors of the century. The book before us, a large and copiously illustrated volume, consists of no less than 610 pages, on each of which M. Trouvé's name occurs at least once. M. Trouvé does not appear to strive after epoch-making discoveries. He devoted a great deal of attention to the making of small motors, and to supply current for these he experimented largely with bichromate batteries, which were also used for electric light. Unlike Edison, the subject of this volume appears to have done little towards the establishment of works on a large scale, but applied his motors in a diminutive form to the working of mechanical rabbits on scarf-pins, and provided batteries and glow lamps for the adornment of *danseuses de ballet*, of whom some nine or ten are portrayed with all the vigour of French wood engraving. Perhaps the most useful of the hundreds of ingenious inventions of M. Trouvé are the laryngoscopes, opthalmoscopes, and "polyscopes," with which a surgeon may examine the interior of the natural cavities of the human body, or may explore wounds and facilitate difficult operations. Telephones, electric launches, gyroscopes, and innumberable other devices are described and illustrated in this remarkable book.

**Laxton's Price Book, 1891.** (London: Kelly and Co. 1891.)

It is customary for members of any one particular trade to think lightly of any publication which purports to set forth particulars of the cost of the work with which they are familiar. If electrical engineers find, as usual, that this excellent annual may be relied on for information about the building trade generally, while they think that the short electrical section might be improved, it is certain that many other readers will appreciate the prices and other informatiom given. The chapter dealing with electrical engineering may be taken as substantially correct although the estimates for wiring are considerably lower than are generally to be found in practice.

## PHYSICAL SOCIETY.

At the meeting of this society, on February 27, 1891, the following Paper, by Prof. W. E. Ayrton and Mr. J. F. Taylor was read:—

**"Proof of the Generality of certain Formulæ, published for a Special Case, by Mr. Blakesley. Tests of a Transformer."**

In 1888 Mr. Blakesley published a number of formulæ relating to the measurement of power, &c., in alternating-current circuits by means of electro-dynamometers, one of which had its two coils independent, and placed in different circuits. These formulæ were deduced on certain assumptions, the chief ones being that the currents and magnetisations varied harmonically, and that the magnetic stress in the iron was proportional to the ampere-turns. The present Paper shows that the above assumptions are not necessary to the truth of the resu ting formulæ. To take the case of a transformer, let alternating current ammeters be placed in the primary and secondary circuits, and a direct reading, "split dynameter," have a coil in each circuit. Let $D_p$, $D_s$, and $D_{ps}$ be the respective readings, of these instruments, then whatever be the law of variation of the currents,

$$D_p = \sqrt{\frac{1}{T}\int_0^T A_p^2\,dt}, \qquad D_s = \sqrt{\frac{1}{T}\int_0^T A_s^2\,dt},$$

and

$$D_{ps} = \sqrt{\frac{1}{T}\int_0^T A_p\,A_s\,dt},$$

Where $A_p$ and $A_s$ are the values of the primary and secondary currents at any instant, and T the time of one complete alternation. If $i$ be the total induction in the core, P and S the numbers of turns of wire on the primary and secondary respectively, $V_p$ and $V_s$ the terminal pressures, $p$ the resistance of the primary coil, and $s$ the resistance of the whole secondary circuit, then the following equations hold at any instant:—

$$V_p = p\,A_p + P\frac{di}{dt}. \qquad \frac{di}{dt} = \frac{s}{S}A_s$$

Therefore,

$$V_p = p\,A_p + \frac{P}{S}\,s\,A_s.$$

Multiplying both sides by $A_p$ we get $A_p V_p = p\,A_p^2 + \frac{P}{S}s\,A_p\,A_s$ and integrating from $t = o$ to $t = T$ and taking the mean

$$\frac{1}{T}\int_0^T A_p\,V_p\,dt = \frac{p}{T}\int_0^T A_p^2\,dt + \frac{P}{S}\,\frac{s}{T}\int_0^T A_p\,A_s\,dt$$

or watts in primary $= p\,D_p^2 + \frac{P}{S}\,s\,D_{ps}$ quite independent of the laws of variation of A and V.

The power lost in heating the iron core was also shown to be

$$s\left(\frac{P}{S}D_{ps} - D_p^2\right).$$

Other formulæ, such as that given by Mr. Blakesley, expressing the primary volts in terms of the dynamometer readings, are shown to be true generally.

On the subject of transformer magnetisations, the authors state that it is desirable not to speak merely of the ampere-turns, but also of the self-induction, for they have reason to believe that the magnetising value of an ampere-turn varies. Defining the self-induction of the secondary by the equation $L_s = -\frac{dN}{dA_s}$, N being the total flux through the secondary, they show geometrically (assuming harmonic variations) that if $L_s$ diminishes the efficiency increases, and at the same time the phase angle $\theta$ between the primary and secondary currents and the magnetic lag $\phi$ decreases. On comparing this theoretical deduction with the results of experiment, they find a good agreement as will be seen from the following table:—

| Frequency. | Efficiency. | $L_s$ | $\theta$ | $\phi$ |
|---|---|---|---|---|
| 160 | 96·3% | ·0017 | 113° | 0° 24′ |
| 160 | 92·0 | ·0368 | 169 | 18° 24′ |
| 160 | 85·4 | ·1241 | 174·6 | 45° 36′ |

Similar results were obtained in different sets of experiments. It was also noticed that as the secondary current is increased the efficiency rises to a maximum and then diminishes, whilst $L_s$, $\theta$, and $\phi$ diminish and then rise again; the current which gives the maximum efficiency coinciding almost exactly with that which gives minimum values to $L_s$, $\theta$, and $\phi$.

Digitized by Google

The methods employed in making the tests are described in the Paper, and the formulæ used in working out the results are there demonstrated. Amongst the facts deducible from the experiments are the following :—

1. With constant frequency, the ratios $\frac{V_s}{V_p}$ and $\frac{D_s}{D_p}$ increases as the primary volts rise.

2. With frequency constant, and primary volts constant, $\frac{V_s}{V_p}$ decreases and $\frac{D_s}{D_p}$ increases as the secondary current increases.

3. With constant secondary current, $L_s$ decreases as the primary volts are increased.

4. With small constant secondary currents the efficiency diminishes as the frequency increases.

5. For large secondary currents the efficiency is approximately independent of the frequency.

6. Shunting the secondary with a condenser increases the efficiency.

---

Mr. T. H. BLAKESLEY then read a Paper :—

### "On Further Contributions to Dynamometry."

The object of Mr. Blakesley's Paper was, in the first place, to show what sort of physical quantities could be advantageously evaluated by using electro-dynamomoters of two coils of low resistance in circuits conveying electric currents. The meaning of a dynamometer reading was explained to be the mean value of the product of two currents, either steady or alternating, or one steady and the other alternating, undergoing any periodic variations with sufficient rapidity. In mathematical language such an instrument measured $\frac{1}{T}\int_0^T C_1 C_2 \, dt$, where $C_1$ and $C_2$ were the instantaneous values of the currents in the two coils, including, of course, the common case where these currents are identical.

Any physical quantity whose value was such a product, $C_1 C_2$, multiplied into something which was independent of the time, and which, therefore, on integration came outside the integrator, was well adapted to have its mean value given by such instruments. Power was such a quantity, being merely $(\text{current})^2 \times$ resistance. The square of an E.M.F. was another such quantity, but he did not wish to restrict the method to such evaluations.

It follows that any quantity whose instantaneous value can be expressed by terms each quadratic in current, and whose other factor was independent of time, could have its mean value expressed in dynamometer readings. In addition, the particular place and mode of coupling of the dynamometers was indicated by the instantaneous equation, as well as the factor to be applied to each reading. *Thus the equations are made to indicate the practical arrangements to be adopted, and the use to be made of the observations in each case.*

Examples were given for the cases of transformers in series and parallel, and special applications of the method were suggested in the measurement of the power employed in such diverse apparatus as, voltameters subject to direct or variable currents of any sort, welding machines, parallel generators, tuning-fork circuits, vacuum discharges and imperfect condensers. For parallel generators, the power of each could be separately estimated, and in the case of electric welders, the power employed in the welding circuit was shown to be measurable without introducing any resistance whatever into that circuit.

---

DISCUSSION.

Mr. J. SWINBURNE said that it had been impossible to follow the mathematical reasoning from hearing the paper read, and it would be necessary to see the calculations which had succeeded each other on the black-board in print, before discussion would be possible. The author's assumption that there is no back or forward E.M.F. in the primary and secondary circuits of tranformers except that due to $\frac{di}{dt}$, where $i$ is the total induction in the core, was unwarrantable, for in all real transformers there was a "drop" due to waste field, and this made the split dynamometer method useless. It makes the full load efficiencies too high, and this, he thought, accounted for the extraordinary results obtained by Prof. Ayrton and Mr. Taylor. If a dynamometer be used at all, it should, he said, be used as a wattmeter, the moving coil of one turn being joined in series with a non-inductive resistance, and put as a shunt to the primary. The power absorbed by the instrument itself should be then determined, and the power given out by the secondary measured by the same instrument, if the secondary be not non-inductive. Any errors due to self-induction in a wattmeter are, he said, equally present when it is called a split dynamometer; and, in addition to this, the wattmeter as a split dynamometer precludes the possibility of measuring power.

Mr. MORDEY said the results obtained by Prof. Ayrton and Mr. Taylor confirmed experiments he had made himself by an entirely different method, for he found that the losses in the iron decreased considerably as the secondary current increased, and this gave increased efficiency. In his experiments he kept the load constant until the transformer attained a steady temperature, and then substituted a direct current for the alternating one, varying its strength until the same steady temperature was maintained. The power thus supplied is a measure of the loss in the transformer under the working condition. A 6-kilowatt transformer, tested by this method gave a loss of 110 watts at no load, and at full load 205. Of this 205, 176 was accounted for by the loss in the copper coils, leaving only 29 watts as the iron losses at full load. Figures which he quoted from Prof. Ayrton and Mr. Taylor's Paper showed the same general result.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, March 6th.**

SOCIETY OF ARTS.

*4.30 p.m.* Popular Afternoon Lecture: "The Science of Colour," by Capt. ABNEY, F.R.S.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse: "Electro-Magnetic Repulsion," by Prof. J. A. FLEMING, D.Sc.

PHYSICAL SOCIETY.

*5 p.m.* Ordinary Meeting. Papers to be read: (1) "Note on Electrostatic Wattmeters," by Mr. J. SWINBURNE. (2) "Interference with Alternating Currents," by Prof. W. E. AYRTON, F.R.S., and Dr. W. E. SUMPNER. (3) "The Theory of Dissociation into Ions and its Consequences," by Mr. S. N. PICKERING, F.R.S. (4) "Some Points in Electrolysis," by M. J. SWINBURNE.

**SATURDAY, March 7th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "The Forces of Cohesion," by Lord RAYLEIGH, F.R.S.

CITY AND GUILDS OLD STUDENTS' ASSOCIATION.

*8 p.m.* Smoking Concert at the Mason's Hall Tavern.

**MONDAY, March 9th.**

SOCIETY OF ARTS.

*8 p.m.* Cantor Lecture IV. 1. "Photographic Chemistry." by Prof. R. MELDOLA, F.R.S.

**TUESDAY, March 10th.**

INSTITUTION OF CIVIL ENGINEERS.

Ordinary Meeting. Paper to be discussed: "On the Subterranean Water in the Chalk Formation of the Upper Thames, and its Relation to the Supply of London," by JOHN THORNHILL HARRISON, M.I.C.E.

**WEDNESDAY, March 11th.**

SOCIETY OF ARTS.

*8 p.m.* Ordinary General Meeting. "Electricity in Relation to the Human Body," by H. NEWMAN LAWRENCE and ARTHUR HARRIES, M.D.

**THURSDAY, March 12th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "Modern Chemistry in Relation to Sanitation," by Prof. C. MEYMOTT TIDY.

INSTITUTION OF ELECTRICAL ENGINEERS.

*8. p.m.* Ordinary General Meeting. "Transformer Distribution," by J. SWINBURNE. Adjourned discussion.

**FRIDAY, March 13th.**

SOCIETY OF ARTS.

*4.30 p.m.* Popular Afternoon Lecture: "The Science of Colour," by Captain ABNEY, C.B., F.R.S.

INSTITUTION OF CIVIL ENGINEERS.

*7.30 p.m.* Students' Meeting. Paper to be read: "The Lanarkshire and Ayrshire Railways," by A. P. TAIT, B.Sc., Stud. Inst.C.E.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse: "The Culture of the Singing Voice," by FELIX SIMON, M.D.

**SATURDAY, March 14th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "The Forces of Cohesion," by LORD RAYLEIGH, F.R.S.

# The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher,* "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "*Coutts and Co.*" *All other letters to be addressed to the Editor.*

*All letters intended for insertion in* "THE ELECTRICIAN," *or containing questions, must be accompanied by the address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of* "THE ELECTRICIAN" *commence in May and November.*

## SUBSCRIPTION RATES

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.*
**It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## STEEL-PLATE PORTRAITS

*Of W. H. Preece, F.R.S.; Michael Faraday; Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S., and Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers), have been issued as Supplements to* "THE ELECTRICIAN." *A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, post free, 4s. 6d.*

## THE SUPPLY OF ELECTRICITY.

It is a good thing that some quarter of a million glow lamps are now connected to upwards of 120 miles of mains laid under the streets of London, and that on an average several hundred thousand of these lamps are burning steadily and satisfactorily every night. It is a good thing that supply companies are beginning to hold their meetings, and to show their balance sheets. It is also a good thing that honestly-earned dividends are being paid, for in some quarters one is asked to believe that the whole thing is still tentative and experimental, that those who are making and using electrical machinery are quite mistaken as to the principles involved in its action, and wrong in their application of it to the supply of electrical energy. Fortunately, the public—the good public who pay the piper—are fairly content with the tunes, and will not give much attention to those who dispute about the definition of musical terms, object to the construction of the instrument, and throw doubts on the accuracy of the counterpoint. Some consumers of electric light mi hail with satisfaction the theory that the electrical energy purveyed to them by the supply company passes through general space to their lamps, and not through the wires, since they might imagine that they were getting something which did not necessarily pass through the meter; but other hesitating individuals, who cannot settle whether they shall admit the new light to their dwellings, may perchance hear that it is

Digitized by Google

averred by the leading authorities that the conductor does not conduct electricity as a pipe conveys water, and may imagine that streams of electric fluid are liable to trickle out and cause mischief. Then again, the advocates of low pressure distribution boldly accuse the users of alternating currents of burning half their coal and of incurring half the wear and tear of their machinery in magnetising their transformers throughout the day, and that these transformers are as costly to maintain as batteries, owing to frequent breakdowns. Well might an intending investor wait until some reply is offered, and some defence and refutation given. But it takes more than this to shake the confidence of the public when it has at length been won. This is a day of pessimism. Progress has been made at such a rate during the closing years of this century that there is a temptation to put oneself on the safe side and belittle the boldness of pioneers; for it is not difficult to follow if they succeed in opening up a new path, while yet more easy is it to jeer at them if they are impeded by difficulties, and to offer them advice if they go astray. But while pessimism is the fashion of a few, the public are not fooled by it; and while it is said that you may give a dog a bad name and hang him, it would need an exhaustive vocabulary of expletives to kill him with criticism.

We were once assured that the sides of Mr. CROMPTON'S conduits would give way, that they "would probably leak extensively," "insects would overrun the insulators," "the insulation would disappear," and "that these nice little roads under the footway would become a sort of Rotten Row for a large population of rats." It did not occur to the critic that the rats might eat the insects, and die in consequence, which we suppose accounts for the fact that no specimens of either species are to be found among the mains. In spite of all this prophecy we have heard of no trouble whatever, and the best proof is the fact that fresh conduits are being made to-day. But to all these forebodings about low pressure distribution it was retorted that transformers were hopelessly inefficient, and that the system of alternate currents demanded an extensive plant, and with no reserve there was liability to break down and extinction of the light; there would be great waste from continued running on light loads; that each electrical horsepower in the lamps would take about 18lb. of coal, and so on. But since that time several alternate-current supply stations have started, and no break-down at a London generating station at any rate has yet been heard of. We have recently been informed, in spite of the announcement that the critic does not think it well "to offer any criticisms lightly," that this system is all wrong, that the method of distribution is hardly likely to be permanent anywhere, that it has many disadvantages, that it is dangerous, and that the greatest drawback lies in the waste of power in the transformers themselves.

The latest panacea is the sub-station system. There is nothing very new about it. It has been discussed repeatedly. It is excellent on paper, and presents admirable features to any engineer who sits down to design the complete lighting of a town. But how often has he the chance of sallying forth with his plans under his arm and getting to work on the job? Until the contracts were given for the lighting of the City, all electric supply in this country, with the exception of some enterprising but small towns where series working sufficed, depended entirely on the supply to houses, shops, clubs and theatres. Street lighting is a very poor business compared with house work, even if the same price be paid for the current, on account of the comparatively great first cost of fittings and the length of conductors per lamp. The City of London schemes and that of Dublin are to provide primarily for street lighting, and the house follows as a matter of course. The street lighting settles the area over which the supply is to take place in a far more systematic manner than a schedule of compulsory streets. But even when street lighting is to form the skeleton of the system and to define the extent of the district, it indicates very slightly, if at all, how and where the bulk of the house lighting will come on. The engineer who is fond of calculating generally assumes that nearly everybody who wants the supply will take it as soon as he can get it, and neglects the period which must elapse before it is possible to tell where the heaviest demand will come from. The present system of distribution by transformers is eminently fitted for feeling one's way about a district, and permits of rapid extension. The choice of the size of a pipe for drawing in mains is a much less serious matter than the estimating of the dimensions of a conduit, while more difficult than either would be the selection of the sites of sub-stations. But after a district has arrived at an established condition, when all the streets of any importance have been served, and the rush of new consumers is over, an alternating supply company may consider the question of sub-stations. But in doing so, no brand new system is suggested, and there is not any reason whatever for supposing that the introduction of such a measure implies that the previous work was on wrong lines and was provisional, that electrical engineers do not know their own minds, and that the public should stand aside and wait for more perfected methods.

## THE ELECTRIC CURRENT AND ITS LAWS.

BY JOHN T. SPRAGUE.

(*Continued from p. 514.*)

§ 13. There are people so constituted that they flourish on a mental diet of $\frac{1}{2}$ V D ($L_1$ $N^2$) + $\sqrt{\mu}$ − $R^2$, and so on, and to whom scalars and vector potential act like hock or champagne; others find them useful as occasional stimulants only, while mortals of weaker digestion regard them as dangerous and apt to act emetically. Alas, I am one of them, and am compelled to use a simple diet easily cooked. I prefer to form concrete pictures of what I suppose really to occur in nature, or of the actions which a theory involves.

I have, therefore, endeavoured to put into a diagram the conception I can form of the theory described (p, 513), &c., so far as it is possible to represent motion, which I do by arrows.

§ 14. Fig. 1 represents an electric current by the middle arrow. S is the source which, in order to correspond with

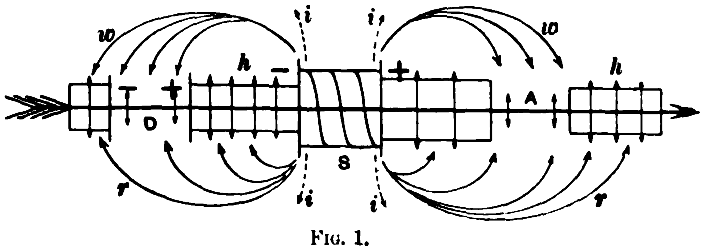

FIG. 1.

ideas to be developed later on, I show as a turbine, instead of as the usual pair of battery plates. The circuit consists of wires of different sections or conductance, in order to bring out the varying rates at which the heat which corresponds to $C^2$ R is radiated away, and which is shown by the cross-bars *h*; D is a decomposition cell, *i.e.*, a voltameter; and A is an arc lamp. These two are not often put in series practically, but for present purposes we can do what we like, as the horsepower expended is supplied gratis.

Digitized by Google

The upper arrows $w$ indicate the asserted energy streams in the outer medium, doing work; the lower lines $p$ show the similar streams, carrying the energy which overcomes the resistance and appears as heat in $h$.

I can in no way manage to include the actions which we know as the electric charge of the circuit, though I make a feeble attempt to do so in the arrows $i\ i$ issuing from the source S. Neither can I indicate the magnetic lines formed around the conductor; all this would make the diagram too confused, even if I could see my way to present them on this theory. I should be very glad if some one else would do so. No doubt, as suggested in p. 520, it may be better for my opponents not to attack my points in detail till I have stated my case, but in such matters as this it will save time if they supply information which I do not possess, or cannot give clearly.

§ **15.** I find it very much more easy to draw a picture of the other theory, the one which is unorthodox now, but was generally held until quite lately. I suspect it is still held by all electricians who belong to the ranks of the practical appliers of science. These men know that they must be careful to use enough iron and copper, and so much gutta percha as is necessary to insulate their conductors, and only regard its "medium" quality as an element of cheapness. They know they must provide a current conductor, but do not care how the energy travels, or make any provision for it.

§ **16.** Fig. 2 presents this, which for simplicity I will call my theory. It is just the same as Fig 1, as regards the current and the heat; but the energy is shown as a current inside the

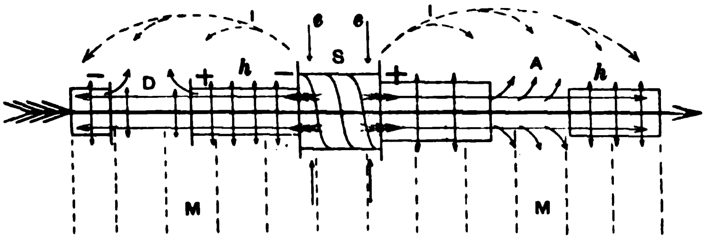

Fig. 2.

conductor, by arrows issuing from the poles of the source S. From these arrows or current (which is an integral part of the electric current, as will be shown by-and-bye) proceed the supplies of energy to carry on all the electrical actions—the heat of resistance $h$, the heat and light of the arc A, the chemical energy to give off, say, oxygen and hydrogen at the plates of the voltameter D, in fact all the accompaniments of the electric current. This internal stream also supplies the energy necessary for the actions which occur in the "variable period" on closing the circuit and previous to the forming of the true current. These are shown in dotted lines; I the static charge or lines of stress existing along the whole circuit and shown in what used to be called the "tension" between the various parts, now called slope of potential, &c. This is what is called also the self-induction, inductance, &c. The lines M M show the magnetic functions of the circuit, equal at every part, source, arc, voltmeter, as well as in the wires, but varying with the external conditions—that is, with the "permeance" or magnetic capacity of the substances near the conductor. These lines of energy then represent the magnetance of the circuit, and M and I are both storages of energy, which reappear in the circuit, and constitute the E.M.F. of the later "variable period," when the circuit is broken.

(*To be continued.*)

## THE FERRANTI METER.

This well-known meter has lately received considerable attention at the hands of the makers, who have introduced several improvements and have laid down special plant for turning them out in large numbers. The instrument, as is well known, depends upon the rotation of mercury in a magnetic field. The poles of the magnet are shown in Fig. 1, N S S. The current to be measured passes from the outside to the centre at right angles to the lines of force of the magnet, which are approximately axial. The rotation of the mercury sets in motion a fan, and this operates a counting train. To overcome the initial friction an auxiliary shunt coil is provided, and is shown in the figure over the letter

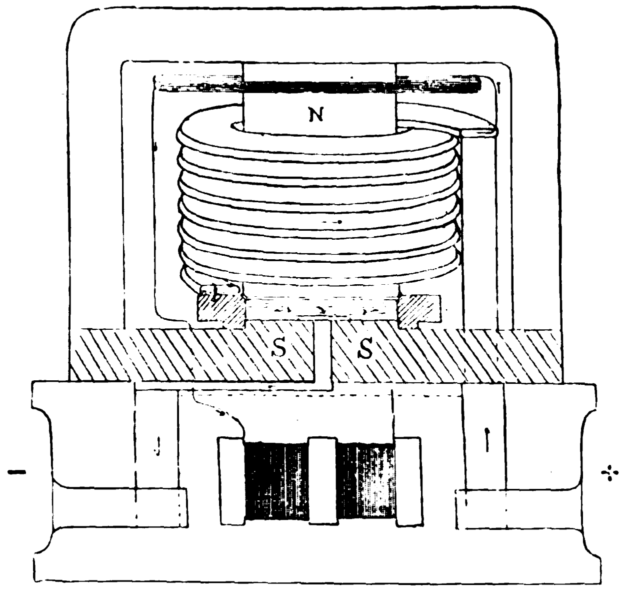

Fig. 1.—Section of Ferranti Meter, showing Direction of Current.

N. A resistance placed at the bottom of the case is in series with this. If the shunt current were strong enough, the meter would of course slowly revolve, but it is arranged so as to be just too weak to do this. A very small current through the main coils will therefore start the meter, whose readings are then proportional to the current. Figs. 2 and 3 are diagrams showing the method of ascertaining the constant of each instrument.

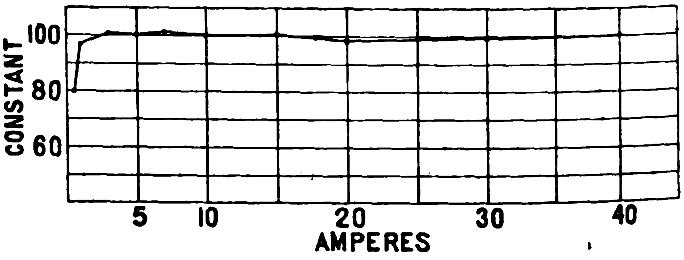

Fig 2.—Curve showing Performance of 40-ampere Meter.

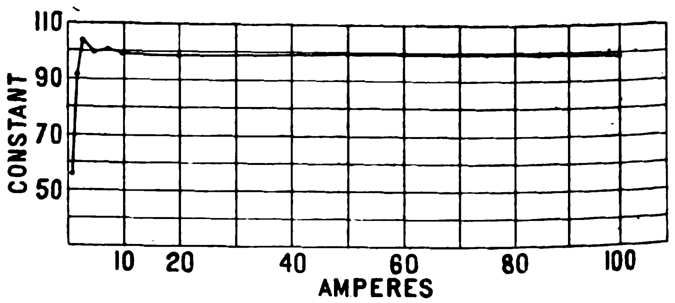

Fig. 3.—Curve showing Performance of 100 ampere Meter.

The following particulars give an idea of the performance of these meters:—Forty ampere alternate current mercury meter, shunted; started with three ampere; mean constant 7·56 over twenty-fold range; variation—above 1·85 per cent., below 2·12 per cent. 100 ampere direct current meter; starts with five amperes; mean constant 2·838 over fifty-range; variation—above 1·3 per cent., below ·99 per cent. Ten ampere continuous current mercury meter, unshunted; started with two amperes; mean constant 23·56 over twenty-fold range; variation—above 3·98 per cent., below 2·37 per cent.

## TRANSFORMER DISTRIBUTION.*

BY J. SWINBURNE.

*(Concluded from page 518.)*

It is thus possible by altering the field excitation of such dynamos to make them work well as generators or motors on supply circuits. Instead of depending on the reaction of the armature to strengthen or weaken the field, the field excitation may be automatically regulated, so that the current and electromotive force of the machine are always in step, or very nearly so.

Take first the case of a separately excited motor. The field magnets may have an additional set of coils, and these are put in series with the main armature current, which is redressed or rectified by a commutator. These coils are arranged so as to demagnetise or weaken the field as the current increases, so that it is not necessary for the machine to lag in order to take a large load.

The machine may be made to excite itself. In that case, special exciting coils on the main armature are provided. These are connected with the circuit for exciting the field-magnet. If a machine made in this way is used as a motor without a series demagnetising circuit round the field-magnets, it begins to lag as soon as load is put on, and the armature current then reacts on the fields and weakens them. As the exciting coils now pass through the same field, this will also lessen the field excitation directly; and as soon as the field is weakened by the armature reaction, the ampere-turns round are also reduced, because the electromotive force in the exciting circuit is lessened. A very small lag will thus weaken the field considerably, so that a large load may be put on without the lag being great enough to make the machine inefficient. A series demagnetising circuit may be used in addition. If the ampere-turns of the field magnet are not adjusted to the load with perfect accuracy, the machine adjusts itself by lagging or leading very slightly.

Machines with fields excited chiefly by special exciting circuits on the main armatures, and partly by series circuits, may be specially useful for working in parallel as generators. The series circuits are then arranged to magnetise instead of demagnetise. If power is applied to a motor instead of taken from it, it becomes a generator, and the direction of its main current is reversed, both in the armature and the series coils on the fields; so that a motor with a backward series circuit becomes a generator with a forward series-circuit. If one machine when used as a generator begins to lead because too much power is supplied to it by its engine, its field is strengthened by the series circuits, and this increases the armature electromotive force enough to make it give a large output corresponding to the power supplied to it. If machines excited from special armature circuits, without series circuits, are run in parallel, they will keep in step, because the least leading or lagging alters the field excitation.

The compound form is best, because the whole station will then supply the mains at constant pressure, if all the engines are mechanically governed for constant speed of one of them—that is to say, if the whole steam supply is regulated to keep the speed of all the engines constant, the engines taking the steam in proportion to their size. Instead of keeping the speed constant, an electric governor can keep the electromotive force of the whole station constant. With alternate machines as at present commonly used, it is necessary to alter the field excitation by hand or by automatic gear. Such machines as those described have advantages corresponding to those of compound direct-current dynamos, compared with shunt or separately excited machines. The analogy between these machines and compound or shunt direct-current machines must not be used too far. In direct-current machines, the electromotive force adapts itself by slight alterations of speed, and the armature reaction depends on the position of the brushes; in alternate machines, the speed is unalterable, and the armature reaction depends on lead and lag.

Prof. E. Thomson tells me that he has been accustomed to send out separate and series excited machines for working in parallel, and that they will work either with or without "equalising connections" such as are needed with direct compound machines. They also work well as motors, and so do the self-exciting machines with separate exciting armature circuits. He also finds the ordinary Thomson-Houston machines works efficiently as a motor.

In discussing such questions, however, we must always remember that the size of the machine is most important. A small dynamo has high resistance, small cross induction, and small armature reaction. A large machine has a small resistance and great armature reaction. Large machines may therefore easily run well in parallel or as motors, without automatically varied field excitations. A very small lagging current will reduce the field of a large machine 3 or 4 per cent., and the extra loss of power in the armature is small; for if C is the component of the current that is in step, and $c$ the lagging component, the power wasted in the armature is not $r\,(C+c)^2$, but $r\,C^2+r\,c^2$—a very different matter.

The case of motors, however, is not the same. A two-horse or one-horse motor is about the size that is most needed. There is no opening for 100-kilowatt motors on supply circuits just now. In these small sizes $c$ will be very large compared with C, so automatic regulation of the field may be of the highest consequence.

The subject of motors is of enormous importance, and is most interesting. I fear it cannot be pursued here, for want of time. It is to be hoped one of my hearers may be induced to write a Paper on this subject at an early date, unless, as is probable, it is exhausted in Mr. Kapp's Cantor Lectures.

According to the armature reaction theory, then, whether a machine will run in parallel with others depends on its armature resistance and armature reactions. It must be borne in mind that most machines have cast-iron fields, and though that may make no difference according to the orthodox theory, it does from the armature reaction point of view. If the field-magnets do not quickly respond to the armature reactions, it may be difficult or impossible to run machines in parallel.

Another important consideration is the government of the engines. If two engines are working two machines in parallel at 200 revolutions, and one governor is set for 200 and the other for 195 revolutions, if the governors are truly isochronous, one engine and dynamo will supply the whole of the power, and the other will be dragged round idle. The whole question of the government of central stations requires the most careful consideration. I have dealt with the matter at some length elsewhere,* but the subject should be very fully thought out in designing stations.

### *Arrangement of Station.*

Whatever system of distribution be used outside the station, the power leaves by high-pressure leads. In this country 2,000 volts is the pressure commonly employed; in America, 1,000. I cannot help thinking that the Americans are right. The use of 2,000 volts does not decrease the cost of copper so very much, and it increases the cost of insulation enormously. In addition to this,

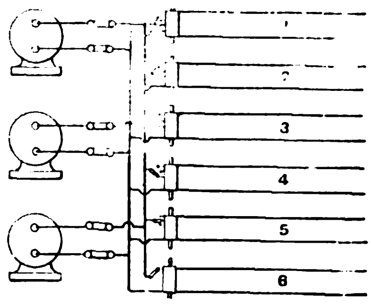

Fig. 8.

it increases the dangers of breakdowns, and the chance of danger to life. 2,000 volts seems to have been chosen in the early days, when people had very little idea of the commercial difficulties of high-pressure insulation. In addition to this, high pressure increases the cost of transformers as well as dynamos, and also lessens the output for a given size.

If the machines are employed in parallel, they may feed into common bars, as in the case of direct currents. If each district must have its own circuit—which seems to be generally assumed necessary—each circuit may be led away from the common bars with a transformer regulator in it. One objection that has been raised against parallel working is that, if each district has its own system, it may have an earth on one lead without disaster, while, if the station is in parallel, two leaks in the whole system cause a breakdown. This objection comes from America, where they have had a great deal of experience, but it seems to assume the leads to be in a very bad state. There is no need for such danger, however, for each district may be fed through a transformer, so that it has no metallic connection with the system of any other district. It is most difficult to understand why central station machines are made to give high pressures to begin with. In most forms of dynamos 2,000-volt insulation adds very materially to the cost of the machine, and lessens the output for a given size in addition. The difference of cost would more than cover the extra cost of transformers, as large converters can be made for considerably under £1 per 1,000 watts; and the efficiency, when very large, is very high, being above 99 per cent. at full load. So that the efficiency of a low-pressure dynamo and transformer is higher than that of a high-pressure dynamo working direct. It is also a great advantage to have all the switches, connections, and measuring instruments on the low-pressure side. The high-pressure circuits may then be arranged to have no metal exposed any-

* Paper read before the Institution of Electrical Engineers, February 19, 1891.

* *Industries*, September, 1890.

Digitized by Google

where. If each district must have its separate circuit, it has its own step-up transformer, with its regulator. If feeders are used on any system, each feeder has its step-up transformer, which is made adjustable; or it may have an unadjustable transformer and a feeder regu'ator, such as that designed by Mr. Kapp. If the district is large, it may have large transformers. Several feeders may then come off in parallel, each feeder having its own regulator. The regulators may have the adjustable parts connected with the low-pressure supply, so as to avoid high-pressure switches or other gear.

One arrangement is shown in Fig. 8. The dynamos are all in parallel, and wound for 100 volts, the immediate neighbourhood of the station being fed direct. Each feeder circuit has a transformer with a variable number of primary turns. A compensated voltmeter is placed on each, and all the attendant has to do is to alter the switches a little occasionally, so as to keep all the instruments' pointers vertical.

*Transformers.*

It is not my intention to go into the question of leads, as I am informed that a Paper specially devoted to that important subject is to be read here very shortly; I am therefore most happy to leave the very special question of high-pressure alternate-current mains in far abler hands.

Before discussing the relative merits of house transformers, low-pressure direct from the station, and various sub-station arrangements for distribution, it will be best to consider the vexed question of the transformers themselves.

In 1884 electrical engineers were surprised to learn from Dr. Hopkinson that the Gaulard and Gibbs transformers gave something like 90 per cent. full-load efficiency. Since then alternating work has developed enormously; but a complete change has come over the transformers: they are almost always made with the iron circuit closed on itself. The closed iron circuit has been regarded as an enormous advance on the old form; but it is difficult to find any definite statement as to where the advantage comes in. It was for a long time assumed that almost any closed-circuit transformer would give an efficiency of something like 98 per cent.—in fact, that the loss in transformers might be neglected.

In a discussion on the relative merits of direct and alternate current distribution, Mr. Crompton said that the efficiency of the ordinary commercial transformer in a station was about 50 per cent.; and I need hardly say he was not believed. He laid particular stress on the small proportion of the total number of lamps installed really used. The loss in the iron in transformers has till lately been very much overlooked; if it is even a small percentage of the full load of the transformer, it mounts up very seriously in station work when the transformers are in circuit all day and all night.

I had the honour of reading a Paper before the British Association in 1889, in which the question of design for all-day loads was, as far as I know, discussed fully for the first time; and the relative proportions of iron and copper for closed-circuit transformers which gave the best results were given. At the same time I pointed out that the loss in iron was really such a serious matter that by a special design not only can a very much higher efficiency be obtained at light loads, but that even at full load a new form is better in every way.

The principle of the "Hedgehog" transformer is this: By using an open circuit the iron can be reduced in volume with a given induction. The mean length of the iron part of the magnetic circuit is considerably less, and more copper turns can be wound on without increasing this length much. The additional turns admit of a smaller cross section of core, so that the iron is enormously reduced. The loss in copper is somewhat increased; but as the loss in copper is only serious at full load, this does not matter.

The old Gaulard and Gibbs form of transformer had the disadvantage of requiring a very large exciting current. Increased number of turns of copper reduces the exciting current; but, in addition, the ends of the core are spread out in a peculiar way, which again reduces the exciting current. The result is that the exciting current, though larger than in the case of closed-circuit transformers, is not a serious matter. The loss in copper is considerably smaller than the loss in iron in most closed-circuit transformers, and, as it varies as the square of the current, it is inappreciable except at full load, which very seldom occurs. The loss in iron is very small, so that the loss per day in ordinary working is very much smaller than in the case of closed-circuit transformers. Since my Paper at the British Association, many makers have altered the proportion of their transformers considerably; but still it is impossible to get as good results with closed circuits.

Perhaps the best way I can make this clear is by a comparison of actual transformers. I am here confronted by a difficulty. If I select any particular closed-circuit transformer of a particular maker, all the other makers of closed-circuit transformers would say that I had closen a bad example; while the maker himself would say that it was an old form, or that he now uses a quality of iron which wastes no power by hysteresis.

A great deal of unnecessary mystery has been made about the efficiency of transformers, and all sorts of roundabout ways of measuring or calculating it have been proposed, and sometimes tried. The matter is simple, however. The loss in the copper can be calculated if the resistance and current are known. The loss in iron in a given type of transformer depends on the quality of the sample used just as much as the loss in the copper depends on the quality of the copper used. I will therefore assume the ordinary "96 per cent." quality of copper, and I will assume that the iron is as good as the soft iron tested by Prof. Ewing. I have the best reasons for knowing that the iron used is generally much below this standard, so this assumption is considerably in favour of the closed circuits. Moreover, I am giving away the loss by Foucault currents, which is often considerable. Of course, anyone is at liberty to assume that he has some particularly good iron; but in discussing the relative value of the two types of transformer, he must allow me the same quality of iron. In fact, I might assume a special quality of copper equally unknown to the trade in mine.

As an average size of transformer, one taking 2,000 volts and a frequency of 100, and giving 15 amperes at 100 volts, may be taken, and the working compared.

Though the theory of the "Hedgehog" transformer was fully discussed in the British Association Paper referred to, it may not be out of place to describe the construction of the commercial article.

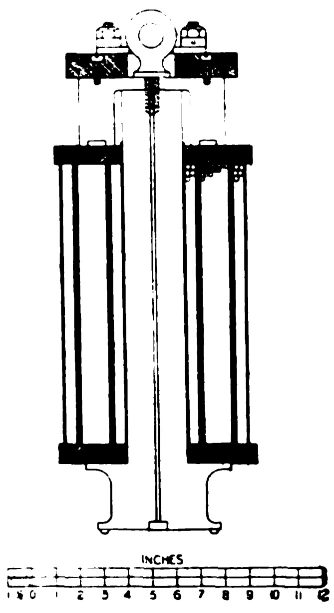

FIG. 9.

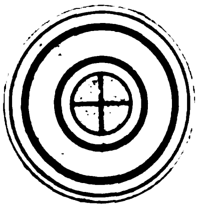

FIG. 10.

A gun-metal casting forms the backbone of the transformer. It is cross shape in section, and at one end is spread out to form four legs. It also supports the lower flange, or cheek, of the winding. The four spaces have bundles of soft iron wire put in, so that the core is practically cylindrical. The cross-shaped core has been criticised on the ground that there are Foucault currents in it. The least consideration will show that there is no change of induction in it, and therefore no Foucault currents. The iron wire is bound tightly, and the two flanges are slipped into place. A gun-metal "spider" is then screwed to the top. It is finally held on by the eye-belt, but temporarily a set screw is used. The core is then wound in a special lathe in the usual way. Both the terminal board and the coil flanges gave us a great deal of trouble till we found suitable materials. There is a great need of good insulating materials that will not warp, that will insulate perfectly, and that can be worked.

The electrical particulars of a 50 8-candle-power lamp transformer are as follows:—

Core, 13·5in. long, 2·5in. diameter. In taking the area of the core, allowance must be made for the space occupied by the backbone, and for the loss of room in using round wires. Maximum induction, 4,800. Loss of power in iron, assuming it to be of good quality, 13·5 watts. Primary, 3,920 turns of copper wire, 0·042in. diameter; resistance, 37 ohms (warm). Secondary, 200 turns, 19/0·042in.; resistance, 0·098 ohm. Loss of power in primary at full load, due to the transformed current, 21 watts; loss due to the exciting current—0·3 ampere—which is always on, 3·6 watts; loss in secondary at full load, 22 watts. Efficiency at full load, 96·15.

This transformer is shown to scale in Figs. 9 and 10.

Digitized by Google

Fig. 11. is a scale drawing of a closed-circuit transformer I have taken as representative. The primary is 400 turns of 0·042in. wire, and the secondary 20 turns of 0·176in. The loss in copper at full load is 11·3 watts, and the loss in the iron 120 watts. At full load the efficiency is 91·95, or nearly 92 per cent. The diagram (Fig. 12) shows the percentage loss at various loads of the two transformers. The ordinates are percentage loss, and the abscissæ fractions of full load. Curve II. is the "Hedgehog," and IV. is the closed circuit. It will be noticed that the "Hedgehog's" efficiency increases slightly at first, and keeps above 95 per cent. till the load is reduced to one-fifth, and above 90 down to one-tenth load, and it then begins to fall more rapidly. The efficiency of the closed form, however, begins to fall at once, and falls rapidly. In house work the full-load efficiency is a matter of little or no consequence; the loss at very light loads is really important. A house that has a 50-light transformer is wired for 50 lamps, and that is a maximum load.

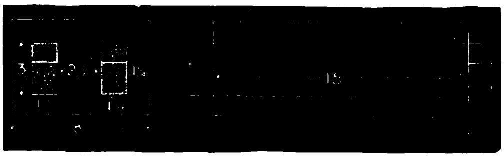

FIG. 11.

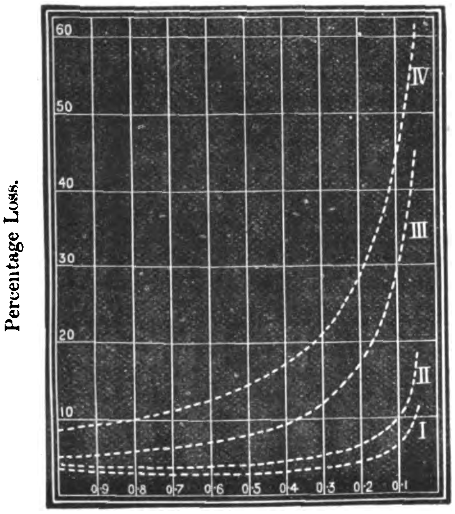
As a rule, there are seldom more than 25 lamps on at any one time, and these are on during the evening only. The average load varies with the time of year, and with the class of house. Shops, for instance, have full load for a short time each day; private houses have the lights in the hall and passages on the whole evening, with either the dining or drawing-room, and for some time both the dining and drawing-rooms are on. It will be a fair average if we take four hours of half-load per day as the output of house transformers. This means an efficiency of 83·3 per cent. for the "Hedgehog," and only 51 per cent. for the closed circuit. In other words, the waste in the closed circuit is between five and six times as great as in the open circuit.

It will, I have no doubt, be urged that various published tests have shown closed-circuit transformers to have efficiencies of, say, 95 per cent. I have elsewhere* examined some of these tests, and



Fractions of Full Load,

FIG. 12.

shown that, according to the figures given, the results can only be accounted for by the iron acting as freezing mixture, and supplying power to the transformer; the total loss given being in some cases less than the loss by copper resistance. In some other cases too few data are given, so that it is impossible to say how the figures are obtained. In order that an efficiency test can be taken as reliable it must contain full particulars of the transformer. It is then possible to see whether the supposed efficiency of 95 per cent. is due to the type of transformer, to inaccuracies in the measurements, or to phenomenal iron. Of course it is not impossible some one may discover phenomenal iron which will be the salvation of closed-circuit transformers, but it will have to be very good. In Fig. 12, Curve III. represents the loss in a closed-circuit transformer with phenomenal iron having a loss of only 60 watts, or half that taken in the example. The dotted curve (I.) belongs to the open-circuit transformer with the same quality of iron; for, of course, the phenomenal iron is available for both. It will be seen that the ratio of the percentage losses is sensibly the same, so that the open-circuit transformer is improved nearly as much as the closed. In the case taken of half-load for four hours a day, the loss in the closed circuit comes out more than four times that in the open, even without re-designing the "Hedgehog." There is thus no chance of iron being found good enough to allow the closed circuit-form to compete with the open. There is one objection to the "Hedgehog" which must not be passed over, and that is the exciting current. The exciting current in the 50-lighter is 0·31; in the closed circuit it is 0·2; so that it is quite half as much again. Moreover, if a better quality of iron is discovered it will lessen the exciting current in the closed circuit, but will make no perceptible difference in the open, unless it is re-designed. The exciting current does harm in two ways: it weakens the field of the dynamos at the central stations, and it gives rise to troubles in the station at light loads. For instance, if a station had 10 dynamos to run the full load, in the daytime three would be required to supply the exciting current, while in the closed circuit two would do. If the dynamos are direct-driven, this means three engines running light instead of two; and engines running light are very wasteful. These difficulties are, however, to a large extent imaginary. The weakening of the fields is, in ordinary working, counteracted by stronger excitation. Running three dynamos instead of two or one does not involve running three engines; the engine should be uncoupled and the dynamos run as idle motors, supplying the exciting current necessary for the transformers. In the future it is to be hoped that alternate motors will be used; and as they will be used chiefly during the times the load on the transformers is light, they will thus supply the exciting currents, and it will be unnecessary to run any idle dynamos. It must be remembered that the difference is only one of degree. Closed-circuit transformers have very considerable exciting currents; but it is most desirable to avoid any troubles, whichever kind is used. The solution of the difficulty lies in the employment of condensers. A condenser supplies the exciting current, so that the station dynamos supply a current sensibly proportional to the power used. Thus, in the daytime, with open-circuit transformers, a very small engine and dynamo will give all that is needed. More will be said about condensers presently.

*Distribution.*

Even with the most efficient transformers, the house system is a very poor method of distribution. Apart from the question of loss of power, consider the outlay involved in providing each consumer with a high-pressure double-pole fuse, a transformer, an automatic device for rendering the whole arrangement safe in case of insulation giving way, perhaps a double-pole main switch, a meter, and a fire-proof safe in which all these things have to be enclosed. In addition to this, it involves a complete high-pressure parallel system of distribution, and a network of 2,000-volt underground mains, involving a heavy outlay, and probably heavy depreciation. The adoption of sub-stations is generally regarded as the cure for all this. I believe no sub-station distribution is in use, or even in construction, in this country. The London Electric Supply Company are using sub-stations, but not in this way. These sub-stations merely transform from 10,000 to 2,500 volts, and the distribution itself is carried out by means of house transformers. The principle of sub-stations is that the town has a network of low-pressure mains, with low pressure feeders led to sub-stations. In each sub-station there are attendants who regulate the pressure in the network, as they have control of the feeders. The sub-station is supplied by high-pressure mains from the station, the power being transformed to low pressure at the sub-stations. There is, however, no need for sub-stations; the low-pressure network may be fed at various points by transformers and feeders coming direct from the station. These transformers need not be in houses or cellars; they can be placed conveniently in the ground in cases filled with insulating oil. The method of feeding into a low-pressure network was described in Mr. Kapp's Paper on transformers in 1888, and he referred to it as being in use on the Continent and in America. At the station each feeder can be regulated, and has a compound-wound voltmeter, so that an attendant can keep the pressure in the whole town constant. As Mr. Kapp pointed out, the advantage of such a system is enormous. In direct currents the low-pressure mains must be large. The great size needed for parallel distribution was pointed out at the time of the Electric Light Act of 1882, and Prof. Forbes afterwards went into the matter much more fully; but even now the enormous saving that can be effected by using small low-pressure mains fed at frequent intervals seems hardly to be realised.

In beginning in a new district it may be objected that the subscribers at first are so few that it does not pay to put down low-pressure mains. This would be true if alternate low-pressure had to be as large as direct-current mains. Without going into the cost of a particular case, it is probable that low-pressure mains large enough to supply any demand likely to arise for many years can be put down for little, if any, more than the high-pressure net

*"Induction, and other Things," *Electrical Review*, October, 1889.

Digitized by Google

work with its expensive insulation. Even in scattered districts it would generally pay to use small low-pressure mains and feeders. The alternate system has so many advantages over the direct in the matters of regulation and distribution, when worked on the low-pressure system, that it is astonishing that such arrangements are not utilised. For instance, with direct currents, it is most difficult to find a leak; and one leak on the positive at the west end, combined with one leak on the negative at the east, will cause serious trouble. With alternate currents, a number of small local networks may be used, each of them being complete in itself. It is not in metallic connection with any other part of the town, nor with the central station. Where it meets the network of the neighbouring district it is not metallically joined, as in the case of direct currents, but is connected through a one-to-one transformer sunk in the ground, in a case full of oil.

After the clear and able manner in which Mr. Kapp urged the advantages of low-pressure networks for alternating currents, it is most astonishing that engineers should go on with house transformers. With the low-pressure network system we have everything that can be wanted. Perfect regulation at every point throughout the town, small mains, inexpensive insulation, cheap and efficient plant, and—what is of importance in comparison with battery work—simple and inexpensive switch-boards. There is no trouble from general ground leak; and both arc and incandescent lighting can be done from same leads. The only thing wanting is storage; and to what extent is that really necessary, and what does it cost? It is significant that throughout America, where direct-current stations could have it for the asking, it is never used.

At present, however, we are using alternating currents in just about the worst way that could be possibly devised.

*Condensers.*

Condensers frequently figure in electric light literature, but they are only put forward as possible means for transforming currents. Direct currents and interrupters are generally discussed. Condensers may, however, have another very large opening in connection with ordinary alternate-current distribution. Take, for instance, the case of arc lamps. It is customary, whenever possible, to run arc lamps in long series with high pressures, generally with direct currents. In many cases such an arrangement is very convenient; but wherever there are incandescent lamps to be fed at the same places as the arcs, it is, of course, wasteful to run two sets of engines, dynamos, and leads. With direct currents this is sometimes necessary, for arc lamps in parallel do not burn well on 100-volt circuits, and must be used two at a time; and at 50 volts resistance is needed in series, which is wasteful. With alternate currents nothing is easier than to run lamps with choking coils. If the supply is high-pressure, each lamp can have its own transformer, and the transformer can be wound for nearly constant secondary current. Prof. E. Thomson has brought out several forms of constant-current transformer, and so has Mr. Tesla. The "Hedgehog" form, however, lends itself especially well; all that is necessary is winding the coils one at each end instead of one over the other. Whether the mains are high or low pressure, choking coils or constant-current transformers will give rise to large currents at the station, which will lower the output of the machines.

For instance, suppose a station supplies a 100-volt secondary circuit by means of transformers with 2,000 volts primary pressure; and suppose there are 200 arc lamps, each taking 33 volts and 10 amperes, arranged on the 100-volt circuit, with a choking coil in series with each. Suppose, for simplicity, that there are no incandescent lamps in use. The arc lamps then take 2,000 amperes and 100 volts; but this does not amount to more than 66,000 watts, as the current is not in step with the electromotive force. The dynamos thus have to supply 2,000 volts and 100 amperes; whereas the same power, if the current did not lag, would be supplied by 2,000 volts and 33 amperes. This gives rise to several troubles. Suppose each machine has an armature wound to give 2,000 volts and 33 amperes, or 66,000 watts, it takes three instead of one to work the lamps. In addition to this, the lagging of the current weakens the field of the dynamos, so that they need more excitation to give 2,000 volts than they would need even on full load on a non-inductive resistance. Moreover, running three engines and dynamos at a third load instead of one at full load is not economical. A condenser takes a current which leads relatively to the pressure, so that it counteracts the effect of the lagging current. The 100 amperes may be regarded as compounded of 33 amperes in step with the pressure, and 95 amperes lagging a quarter of a period. A condenser of about 85 microfarads will supply the 95-ampere component, while one dynamo supplies the 33 amperes really needed by the lamps. This reasoning holds good without the curve of sines assumption.

The use of condensers to overcome troubles arising from exciting or magnetising currents of closed or open circuit transformers has already been mentioned.

They may also be used to increase the output of dynamos. As already explained, even if a dynamo is worked on resistance, the cross induction causes the current to lag, and the back induction weakens the field. If a condenser is put in shunt to the terminals of the machine, its current strengthens the field again and increases the terminal pressure, and therefore the output. If the condenser is large enough, and if the armature actions are great enough, it might be possible to make a machine excite itself without any field winding at all. This action of a condenser on a dynamo may be equally easily explained on the self-induction theory. The difference between the two theories may be shown here, however. According to the self-induction theory, if the condenser is large enough to produce resonance—that is to say, when $(2\pi n)^2 LK = 1$ —the output increases till the current is as great as if the no-load pressure of the machine were short-circuited on the armature resistance. According to the armature reaction theory, the machine increases its field till the field-magnets become more saturated; in fact, the machine is like a direct-current shunt-wound dynamo which has a low-resistance shunt. I do not wish to go into this matter further here, for it might lead to a discussion of a rise in the Deptford mains—a subject which will be treated, I am informed, in a forthcoming Paper, and will certainly receive full justice at the hands of the authors.

The commercial manufacture of high-pressure condensers is not so easy as might be supposed. Knowing the difficulties there are in insulating leads and mains—in which thick insulation is permissible, and, in fact, advisable—it may be realised that to insulate many hundreds of square feet of metallic surface with the thinnest possible material is anything but an easy problem. In addition to being a good insulator, the dielectric must be free from "absorption." Some account of my work on condensers has lately been given.* Mr. W. F. Bourne, who has carried out all the experiments, has tried almost every conceivable kind of dielectric, and finds a kind of paper called "butter-skin," soaked in paraffin oil, the best material. It is curious that this particular kind of paper is specially made so as to be grease-proof. Some kinds of bank post paper worked nearly as well, but it is too expensive for commercial use. It seems as if the paper must be relied upon for insulation, not the paraffin. The condensers are simple cast-iron boxes containing numbers of sheets of paper and tinfoil. Lids are fitted on and made tight.

*Town Lighting.*

Alternate arc lamps have already been discussed to some extent. In some places, especially in small towns, it is usual to have special circuits for the town lighting, which are shut off during the day. It is needless to point out that if the low pressure network is used, condensers at the station allow arc lamps to be run with choking coils, and incandescent lamps can be run direct, and it is no more necessary to run special mains for the street lighting than it is needful to put down two sets of gas pipes in a town. Sometimes, however, high-pressure mains are used. Each arc lamp can then have its own constant-current transformer. If incandescent lamps are used, the plan generally adopted is using a transformer for every 10 or 20 lamps. If the wires are underground, this involves great expense; and if overhead, it means both expense and unsightliness. A small "Hedgehog" transformer has been designed to meet this particular want. It is so small that it can be worked into the design of the lamp-holder or shade, and one can be used for each lamp.

In America alternating arc lamps are run in series, with a series transformer for each. This arrangement is quite unnecessary for places where there is incandescent lighting too. It has the advantage of allowing series arcs without bringing high pressures into the lamps. It has no other advantage over direct series lighting. The dynamo used by the Westinghouse Company is made to give nearly constant current. This is a barbarous arrangement. It is a reversion to the old alternating machines of 10 years ago, which gave approximately constant current. All that is needed is great armature reaction, and hence a large machine for the output. The economical way of getting constant current is to use a good dynamo, and to take the governor off the engine, or to use it as a safeguard against racing only. If the Westinghouse machine has only quarter load on, it still goes at full speed, using nearly full steam, and wearing everything out. With a constant-pressure dynamo it would run at quarter speed, each cylinderful of steam being used economically and being expanded properly. To put a constant-speed governor on the engine, and then to design a special dynamo to get over the difficulties you have introduced, is a very common proceeding with direct-current arcs also.

Alternating constant currents have, however, one advantage over direct that I think is not realised. Synchronising motors will run perfectly on series constant-current circuits; and as they run at constant speed, there is no racing, or trouble about governing, as in the case of direct currents. Of course, constant speed of engine is here necessary to give constant frequency. Many people seem to have gathered from Dr. Hopkinson's Paper that series alternating motors will not run; but this is a false inference.

## PHENOMENA OF ALTERNATING CURRENTS OF VERY HIGH FREQUENCY.*

BY NIKOLA TESLA.

Among his many experiments Prof. Crookes shows some performed with tubes devoid of internal electrodes, and from his remarks it must be inferred that the results obtained with these tubes are rather unusual. If this be so, then the writer must regret that Prof. Crookes, whose admirable work has been the delight of every investigator, should not have availed himself in his experiments of a properly constructed alternate-current machine—viz., one capable of giving say, 10,000 to 20,000 alternations per second. His researches on this difficult but fascinating subject would then have been even more complete. It is true that when using such a machine in connection with an induction coil the distinctive character of the electrodes—which is desirable, if not essential, in many experiments is lost, in most cases both the electrodes behaving alike ; but, on the other hand, the advantage is gained that the effects may be exalted at will. It is possible to obtain excessively high electromotive forces in the secondary circuit with a comparatively small primary current ; moreover, the perfect regularity in the working of the apparatus may be relied upon.

The writer will incidentally mention that anyone who attempts for the first time to construct such a machine will have a tale of woe to tell. He will first start out, as a matter of course, by making an armature with the required number of polar projections. He will then get the satisfaction of having produced an apparatus which is fit to accompany a thoroughly Wagnerian opera. It may, besides, possess the virtue of converting mechanical energy into heat in a nearly perfect manner. If there is a reversal in the polarity of the projections, he will get heat out of the machine ; if there is no reversal, the heating will be less, but the output will be next to nothing. He will then abandon the iron in the armature, and he will get from the Scylla to the Charybdis. He will look for one difficulty and will find another, but, after a few trials, he may get nearly what he wanted.

Among the many experiments which may be performed with such a machine, of not the least interest are those performed with a high-tension induction coil. The character of the discharge is completely changed. The arc is established at much greater distances, and it is so easily affected by the slightest current of air that it often wriggles around in the most singular manner. It usually emits the rhythmical sound peculiar to the alternate current arcs, but the curious point is that the sound may be heard with a number of alternations far above 10,000 per second, which by many is considered to be about the limit of audition. In many respects the coil behaves like a static machine. Points impair considerably the sparking interval, electricity escaping from them freely, and from a wire attached to one of the terminals streams of light issue, as though it were connected to a pole of a powerful Toepler machine. All these phenomena are, of course, mostly due to the enormous differences of potential obtained. As a consequence of the self-induction of the coil and the high frequency, the current is minute, while there is a corresponding rise of pressure. A current impulse of some strength started in such a coil should persist to flow no less than four ten-thousandths of a second. As this time is greater than half the period it occurs that an opposing electromotive force begins to act while the current is still flowing. As a consequence, the pressure rises as in a tube filled with liquid and vibrated rapidly around its axis. The writer's experiences tend to show that the higher the frequency the greater the amount of electrical energy which may be passed through the body without serious discomfort ; whence it seems certain that human tissues act as condensers.

Experiments with Geissler tubes are of special interest. An exhausted tube, devoid of electrodes of any kind, will light up at some distance from the coil. If a tube from a vacuum pump is near the coil the whole of the pump is brilliantly lighted. An incandescent lamp approached to the coil lights up and gets perceptibly hot. If a lamp have the terminals connected to one of the binding posts of the coil and the hand is approached to the bulb, a very curious and rather unpleasant discharge from the glass to the hand takes place, and the filament may become incandescent. The discharge resembles to some extent the stream issuing from the plates of a powerful Toepler machine, but is of incomparably greater quantity. The lamp in this case acts as a condenser, the rarefied gas being one coating, the operator's hand the other. By taking the globe of a lamp in the hand, and by bringing the metallic terminals near to or in contact with a conductor connected to the coil, the carbon is brought to bright incandescence and the glass is rapidly heated. With a 100-volt 10 candle-power lamp one may without great discomfort stand as much current as will bring the lamp to a considerable brilliancy ; but it can be held in the hand only for a few minutes, as the glass is heated in an incredibly short time. When a tube is lighted by bringing it near to the coil, it may be made to go out by interposing a metal plate or the hand between the coil and tube ; but if the metal plate be fastened to a glass rod or otherwise insulated, the tube may remain lighted if the plate be interposed, or may even increase in luminosity. The effect depends on the position of the plate and tube relatively to the coil, and may be always easily foretold by *assuming* that conduction takes place from one terminal of the coil to the other. According to the position of the plate, it may either divert from or direct the current to the tube.

In another line of work the writer has in frequent experiments maintained incandescent lamps of 50 or 100 volts burning at any desired candle-power with both the terminals of each lamp connected to a stout copper wire of no more than a few feet in length. These experiments seem interesting enough, but they are not more so than the queer experiment of Faraday, which has been revived and made much of by recent investigators, and in which a discharge is made to jump between two points of a bent copper wire. An experiment may be cited here which may seem equally interesting. If a Geissler tube, the terminals of which are joined by a copper wire, be approached to the coil, certainly no one would be prepared to see the tube light up. Curiously enough it does light up, and, what is more, the wire does not seem to make much difference. Now one is apt to think in the first moment that the impedance of the wire might have something to do with the phenomenon. But this is of course immediately rejected, as for this an enormous frequency would be required. The result, however, seems puzzling only at first ; for upon reflection it is quite clear than the wire can make but little difference. It may be explained in more than one way, but it agrees perhaps best with observation to assume that conduction takes place from the terminals of the coil through the space. On this assumption, if the tube with the wire be held in any position, the wire can divert little more than the current which passes through the space occupied by the wire and the metallic terminals of the tube ; through the adjacent space the current passes practically undisturbed. For this reason, if the tube be held in any position at right angles to the line join the binding posts of the coil, the wire makes hardly any difference, but in a position more or less parallel with that line, it impairs to a certain extent the brilliancy of the tube and its facility to light up.

It is well to take certain precautions when operating a Ruhmkorff coil with very rapidly alternating currents. The primary current should not be turned on too long, else the core may get so hot as to melt the gutta-percha or paraffin, or otherwise injure the insulation, and this may occur in a surprisingly short time, the current's strength considered. The primary current being turned on, the fine wire terminals may be joined without great risk, the impedence being so great that it is difficult to force enough current through the fine wire so as to injure it, and in fact the coil may be on the whole much safer when the terminals of the fine wire are connected than when they are insulated ; but special care should be taken when the terminals are connected to the coating of a Leyden jar with anywhere near the critical capacity.

The limit of audition of an arc depends on its size. The greater the surface by a given heating effect in the arc the higher the limit of audition. The highest notes are emitted by the high tension discharges of an induction coil in which the arc is, so to speak, all surface. If R be the resistance of an arc, and C the current, and the linear dimensions be $n$ times increased, then the resistance is $\frac{R}{n}$, and with the same current density the current would be $n^2C$; hence the heating effect is $n^3$ times greater, while the surface is only $n^2$ times as great. For this reason very large arcs would not emit any rhythmical sound even with a very low frequency. It must be observed, however, that the sound emitted depends to some extent also on the composition of the carbon. If the carbon contain highly refractory material, this when heated tends to maintain the temperature of the arc uniform, and the sound is lessened ; for this reason it would seem that an alternating arc requires such carbons. With currents of such high frequencies it is possible to obtain noiseless arcs, but the regulation of the lamp is rendered extremely difficult on account of the excessively small attractions or repulsions between conductors conveying these currents. An interesting feature of the arc produced by these rapidly alternating currents is its persistency. There are two causes for it, one of which is always present, the other sometimes only. One is due to the character of the current, and the other to a property of the machine. The first cause is the more important one, and is due directly to the rapidity of the alternations. The heating effect is practically continuous and the arc behaves like one produced by a continual current, with the exception, however, that it may not be quite as easily started, and that the electrodes are equally consumed, though the writer has observed some irregularities in this respect.

The second cause alluded to, which possibly may not be present, is due to the tendency of a machine of such high frequency to maintain a practically constant current. When the arc is lengthened the electromotive force rises in proportion, and the arc appears

* Abstract from the *Electrical World* of New York.

Digitized by Google

to be more peristent. Such a machine is eminently adapted to maintain a constant current, but it is very unfit for a constant potential. As a matter of fact, in certain types of such machines a nearly constant current is an almost unavoidable result. As the number of poles or polar projections is greatly increased, the clearance becomes of great importance. One has really to do with a great number of very small machines. Then there is the impedence in the armature, enormously augmented by the high frequency. Then, again, the magnetic leakage is facilitated. If there are three or four hundred alternate poles the leakage is so great that it is virtually the same as connecting in a two-pole machine the poles by a piece of iron. This disadvantage, it is true, may be obviated more or less by using a field throughout of the same polarity, but then one encounters difficulties of a different nature. All these things tend to maintain a constant current in the armature circuit.

In this connection it is interesting to notice that even to-day engineers are astonished at the performance of a constant-current machine, just, as some years ago, they used to consider it an extraordinary performance if a machine was capable of maintaining a constant potential difference between the terminals. Yet one result is just as easily secured as the other. It must only be remembered that in an inductive apparatus of any kind, if constant potential isrequired, the inductive relation between the primary or exciting and secondary or armature circuit must be the closest possible; whereas, in an apparatus for constant current just the opposite is required. Furthermore, the opposition to the current's flow in the induced circuit must be as small as possible in the former and as great as possible in the latter case. But opposition to a current's flow may be caused in more than one way. It may be caused by ohmic resistance or self-induction. One may make the induced circuit of a dynamo machine or transformer of such high resistance than when operating devices of considerably smaller resistance within very wide limits a nearly constant current is maintained. But such high resistance involves a great loss in power, hence it is not practicable. Not so self-induction. Self-induction does not necessarily mean loss of power. The moral is, use self-induction instead of resistance. There is, however, a circumstance which favours the adoption of this plan, and this is, that a very high self-induction may be obtained cheaply by surrounding a comparatively small length of wire more or less completely with iron, and furthermore, the effect may be exalted at will by causing a rapid undulation of the current. To sum up, the requirements for constant current are:—Weak magnetic connection between the induced and inducing circuits, greatest possible self-induction with the least resistance, greatest practicable rate of change of the current. Constant potential, on the other hand, requires: Closest magnetic connection between the circuits, steady induced current, and, if possible, no reaction. If the latter conditions could be fully satisfied in a constant potential machine, its output would surpass many times that of a machine primarily designed to give constant current. Unfortunately, the type of machine in which these conditions may be satisfied is of little practical value, owing to the small electromotive force obtainable and the difficulties in taking off the current.

With their keen inventor's instinct, the now successful arc-light men have early recognised the desiderata of a constant current machine. Their arc-light machines have weak fields, large armatures, with a great length of copper wire and few commutator segments to produce great variations in the current's strength and to bring self-induction into play. Such machines may maintain within considerable limits of variation in the resistance of the circuit a practically constant current. Their output is of course correspondingly diminished, and, perhaps, with the object in view not to cut down the output too much, a simple device compensating exceptional variations is employed. The undulation of the current is almost essential to the commercial success of an arc-light system. It introduces in the circuit a steadying element taking the place of a large ohmic resistance, without involving a great loss in power, and, what is more important, it allows the use of simple clutch lamps, which, with a current of a certain number of impulses per second, best suitable for each particular lamp, will, if properly attended to, regulate even better than the finest clockwork lamps. This discovery has been made by the writer—several years too late.

It has been asserted by competent English electricians that in a constant-current machine or transformer the regulation is effected by varying the phase of the secondary current. That this view is erroneous may be easily proved by using, instead of lamps, devices each possessing self-induction and capacity or self-induction and resistance—that is, retarding and accelerating components—in such proportions as to not affect materially the phase of the secondary current. Any number of such devices may be inserted or cut out, still it will be found that the regulation occurs, a constant current being maintained, while the electromotive force is varied with the number of the devices. The change of phase of the secondary current is simply a result following from the changes in resistance, and, though secondary reaction is always of more or less importance, yet the real cause of the regulation lies in the existence of the conditions above enumerated. It should be stated, however, that in the case of a machine the above remarks are to be restricted to the cases in which the machine is independently excited. If the excitation be effected by commutating the armature current, then the fixed position of the brushes makes any shifting of the neutral line of the utmost importance, and it may not be thought immodest of the writer to mention that, as far as records go, he seems to have been the first who has successfully regulated machines in providing a bridge connection between a point in the external circuit and the commutator by means of a third brush. Tht armature and field being properly proportioned and the brushes placed in their determined positions, a constant current or constant potential resulted from the shifting of the diameter of commutation by the varying loads.

In connection with machines of such high frequencies, the condenser affords an especially interesting study. One experiment performed three or four months ago with such a machine and a condenser may serve as illustration. A machine was used giving about 20,000 alternations per second. Two bare wires of about 20ft. long and two millimetres diameter, in close proximity to each other, were connected to the terminals of the machine on the one end, and to a condenser on the other. A small transformer without an iron core, of course, was used to bring the reading within the range of a Cardew voltmeter by connecting the voltmeter to the secondary. On the terminals of the condenser the electromotive force was about 120 volts, and from there inch by inch it gradually fell until on the terminals of the machine it was about 65 volts. It was virtually as though the condenser were a generator, and the line and armature circuit simply a resistance connected to it. The writer looked for a case of resonance, but he was unable to augment the effect by varying the capacity very carefully and gradually or by changing the speed of the machine. A case of pure resonance he was unable to obtain. When a condenser was connected to the terminals of the machine—the self-induction of the armature being first determined in the maximum and minimum position and the mean value taken—the capacity which gave the highest electromotive force corresponded most nearly to that which just counteracted the self-induction with the existing frequency. If the capacity was increased or diminished the electromotive force fell as expected. With frequencies as high as the above-mentioned, the condenser effects are of enormous importance. The condenser becomes a highly efficient apparatus capable of transferring considerable energy.

The writer has thought that machines of high frequencies may find use at least in cases when transmission at great distances is not contemplated. The increase of the resistance may be reduced in the conductors and exalted in the devices when heating effects are wanted, transformers may be made of higher efficiency and greater outputs and valuable results may be secured by means of condensers. In using machines of high frequency, the writer has been able to observe condenser effects which would have otherwise escaped his notice. He has been very much interested in the phenomenon observed on the Ferranti main which has been so much spoken of. Opinions have been expressed by competent electricians, but up to the present all still seems to be conjecture. Undoubtedly in the views expressed the truth must be contained, but as the opinions differ some must be erroneous. Upon seeing the diagram of M. Ferranti in *The Electrician* of December 19th the writer has formed his opinion of the effect. In the absence of all the necessary data, he must content himself to express in words the process which, in his opinion, must undoubtedly occur. The condenser brings about two effects. (1) It changes the phases of the currents in the branches; (2) it changes the strength of the currents. As regards the change in phase, the effect of the condenser is to accelerate the current in the secondary at Deptford and to retard it in the primary at London. The former has the effect of diminishing the self-induction in the Deptford primary, and this means lower electromotive force on the dynamo. The retardation of the primary at London, as far as merely the phase is concerned, has little or no effect, since the phase of the current in the secondary in London is not arbitrarily kept. Now, the second effect of the condenser is to increase the current in both the branches. It is immaterial whether there is equality between the currents or not; but it is necessary to point out, in order to see the importance of the Deptford step-up transformer, that an increase of the current in both the branches produces opposite effects. At Deptford it means further lowering of the electromotive force at the primary, and at London it means increase of the electromotive force at the secondary. Therefore, all the things co-act to bring about the phenomenon observed. Such actions, at least, have been formed to take place under similar conditions. When the dynamo is connected directly to the main, one can see that no such action can happen.

The writer cannot believe in the armature-reaction theory as expressed in *Industries*, though undoubtedly there is some truth in it. Mr. Swinburne's interpretation, however, is so broad that it may mean anything. Mr. Swinburne seems to have been the first who has called attention to the heating of the condensers. In the

Digitized by Google

opinion of the writer, the heating of the condensers is due to three distinct causes: first, leakage or conduction; second, imperfect elasticity in the dielectric, and, third, surging of the charges in the conductor.

In many experiments he has been confronted with the problem of transferring the greatest possible amount of energy across a dielectric. For instance, he has made incandescent lamps, the ends of the filaments being completely sealed in glass, but attached to interior condenser coatings, so that all the energy required had to be transferred across the glass with a condenser surface of no more than a few centimetres square. Such lamps would be a practical success with sufficiently high frequencies. With alternations as high as 15,000 per second it was easy to bring the filaments to incandescence. With lower frequencies this could also be effected, but the potential difference had, of course, to be increased. The writer has then found that the glass gets, after a while, perforated and the vacuum is impaired. The higher the frequency the longer the lamp can withstand. Such a deterioration of the dielectric always takes place when the amount of energy transferred across a dielectric of definite dimensions and by a given frequency is too great. Glass withstands best, but even glass is deteriorated. In this case the potential difference on the plates is of course too great, and losses by conduction and imperfect elasticity result. If it is desirable to produce condensers capable to stand great differences of potential, then the only dielectric which will involve no losses is a gas under pressure. The writer has worked with air under enormous pressures, but there are a great many practical difficulties in that direction. He thinks that, in order to make the condensers of considerable practical utility, higher frequencies should be used, though such a plan has besides others the great disadvantage that the system would become very unfit for the operation of motors.

## PARLIAMENTARY INTELLIGENCE.

### Central London Railway Bill.

BILL BEFORE THE HOUSE OF COMMONS SELECT COMMITTEE.

On Tuesday the Central London Railway Bill, which provides for the construction of an electric railway from Shepherd's Bush to Cornhill, E.C., came before a Select Committee of the House of Commons, consisting of Mr. Hanbury (Chairman), Mr. Barran, Mr. Gane and Mr. F. Parker. There were 27 petitions against the Bill.

The counsel for the promoters were Mr. Pember, Q.C., Mr. Saunders, Q.C., Mr. Freeman and Mr. Munro. The leading opponents with their counsel were as follows:—The Corporation of London, Mr. Littler, Q.C., and Mr. Rigg; the Commissioners of Sewers for the City of London, Mr. Russell Griffiths; the Ecclesiastical Commissioners, the London County Council, Mr. Pope, Q.C.; owners, &c., in Cornhill and Cheapside, and various local authorities, lessees and occupiers on the line of the proposed railway.

Mr. PEMBER, in opening the case for the promoters, said this was a very important measure which now came before Parliament for a second time. Last year it passed the House of Commons, but was lost in the House of Lords, and it was no secret that the ground upon which it was thrown out was that their lordships thought it was a year too soon. At that time they had had no experimental working of the City and South London Railway, and their lordships thought that under all the circumstances the Bill might very well stand over for another year. The object of the Bill was to enable the construction of an electric railway from Shepherd's Bush via Lansdown-road, Notting Hill Gate, Queen's-road, Westbourne, Marble Arch, Davies-street, Oxford Circus, Tottenham Court-road, Bloomsbury, Chancery-lane, Newgate-street, to Cornhill. At the terminus at Shepherd's Bush the promoters proposed to purchase a piece of land for the erection thereon of what was known as the generating plant. Last year the Bill proposed that the line should stop at Queen's-road, and that the generating plant should be put up there. No doubt the generating station in that case would have been erected in the midst of some largely valuable property, and certain members of the Committee by which the Bill was considered were a little anxious as to the effect of the erection of the plant in such a neighbourhood. That difficulty was got rid of under the present Bill by the proposal to erect the plant at Shepherd's Bush. The line last year was 4½ miles in length, but now it was 6 miles. The line would be, on an average, about 50ft. below surface. It rose to a higher level at one or two places, while at others it would be between 70 and 80ft. down in the London clay. The capital of the Bill was £3,600,000, being £2,700,000 in shares and £900,000 by borrowing powers. The proposed railway did precisely that which neither of the underground railways did, it tapped a great business thoroughfares. In addition to that there would be no such nuisance as that which arose from the smoke and noise on the underground lines during working hours. The deep level of the line would avoid any disfigurement of the streets. The sites for the 13 different stations, which would be erected at intervals of something less than half a mile, would be excavated first. Then the boring operations would begin at all the 13 stations, and the soil removed by those operations would be brought to the surface and carried away. There would be no noise or vibration, and there would be no blow-holes, because the railway would be worked by electricity. There would be two tunnels, one containing the up and the other the down line. The tunnels would be perfectly distinct, and consequently each train, as it passed through, would make its ventilation. Each tunnel would be 11ft. 6in. in diameter internally. Access to the platforms would be obtained by means of stairs and hydraulic lifts. They would be able to attain a maximum speed of 25 miles an hour, but including stoppages they would be able to do the journey at the rate of 15 miles an hour, or about 25 per cent. quicker than the speed of the trains on the Inner Circle Railway. The journey from the Marble Arch to the Bank—the best portion of the distance—would be performed in about a quarter of an hour. There was no doubt that this Bill was needed. In 1867 the London General Omnibus Company carried 42,000,000 passengers and the Metropolitan Railway Company 11,000,000; but in 1889 the former carried 104,000,000 and the latter 82,000,000. In the same year the District Railway Company carried 34,000,000, the London Road Car Company 15,000,000, and the tramways 169,000,000, bringing up the total number of passengers carried in 1889 to no less than 407,000,000, as against 53,000,000 carried 25 years ago. Last year there were 37 petitions against the Bill, but this year that number has been reduced to 27. Amongst the petitioners were the Westminster Electric Supply Company, who alleged that their generating works would be injured by the operations of the promoters in the neighbourhood of Oxford-street. The railway was undoubtedly one for Londoners. It would be similar to that which was recently opened in South London—the motive power, the tunnels and the stations would be precisely similar. The City and South London Railway at present ran only from the City to Stockwell. It was three miles in length, and at present it had only a six minutes' service with three cars. It had no middle-day traffic worth the name, and yet from December 18th to about the same date in February it carried over 900,000 passengers. That showed, at all events, that the system of electrical traction was an undoubted success. While no doubt there had been small hitches, nothing had occurred to wreck the confidence which the promoters of the Bill had last year in the success of electrical traction. One of the results of the success was that the City and South London had found that their rolling stock was insufficient, and that they ought to have a three minutes' instead of a six minutes' service. People could not get in at intermediate stations because the trains from Stockwell to the City, and *vice versa*, were full when they arrived. There was no doubt that the City and South London Company would double their traffic as soon as they could get sufficient rolling stock. The promoters intended to construct larger tunnels and stations than those on the City and South London line, and to make their carriages more commodious, and they would probably have a two minutes' service. He (the learned counsel) intended to call evidence to show that the cost of electrical traction would be at least as cheap, if not cheaper, than steam, and that the promoters were financially able to carry out their scheme. With regard to the claim that the promoters ought to pay compensation for the subsoil, he maintained that they ought not to be called upon to pay more than a public authority whose duty it was to lay down sewers. If such a clause were introduced into the Bill, the scheme would not go on.

Mr. J. H. GREATHEAD, M.I.C.E., consulting engineer of the City and South London Railway Company, stated that jointly with Sir John Fowler and Sir Benjamin Baker he was engineer of the proposed railway. He had given great attention to a system of boring underground for many years. The main object of the Bill was to afford better facilities for travelling between the western portion of London and the City. The main line of railway was from Shepherd's Bush to Cornhill, but there was a short line from Shepherd's Bush down Caxton-street to the depôt. The short line consisted of a single tunnel, which would not be used by the public. The proposed line was nearly straight, and its worst curve was at the junction of Cheapside and Newgate-street. The worst gradient against the load was 1 in 100. Last year the worst gradient was 1 in 58, and that on the City and South London was 1 in 30. From Notting Hill Gate to Tottenham Court-road the line was absolutely level. Cornhill station was between Cornhill and Lombard-street, and access to that station would be obtained from Change Alley. He was confident that the depths shown on the plans would enable the tunnels to be fixed down in the London clay. He had made a number of borings from time to time along the route of the proposed line, and he had come to the conclusion that the line would be well down in the London clay. The witness then proceeded to explain to the Committee by means of a model how the clay would be cut out and the tunnels fixed. He said the method of boring would be the same as was adopted in constructing the tunnels from the City to Stockwell. After a piece of clay had been cut out an iron ring would be at once placed in the aperture, and in that way a continuous tube was formed.

Mr. BARRAN: What prevents corrosion?—The iron is dipped into a composition of tar while it is hot, and that forms a sort of black varnish over the top.

WITNESS, continuing, said the iron would be protected from any action of the atmosphere both inside and out. The experience he acquired during the construction of the City and South London Railway would be of great value to him in constructing the proposed new line. Some little damage had been done on the City and South London Railway near the stations, and therefore the promoters had resolved to construct their stations in tunnels. There was a great advantage in having two separate tunnels. They secured perfect ventilation by the mere movement of the train, the carriage acting as a kind of piston in a cylinder. The tunnels would be entirely free from soil evaporation, and, therefore, dry. That was his experience on the City and South London Railway. The carriages would be constructed in the same manner as those on the City and South London Railway, the doors being at the end instead of at the side of the carriage. It was estimated that a train would seat about 336 passengers, whilst on the City and South London line they only carried 96 passengers per train. On the proposed line it was intended to have two classes of passengers. The motive power was to be electricity,

Digitized by Google

which would be generated at the depôt at Shepherd's Bush, and carried by a main conductor throughout the entire length of the two tunnels.

The CHAIRMAN: Is the depôt above or under ground?—Above.

WITNESS, continuing, said that in addition to the main conductor there was what was called the working conductor, or naked conductor, from which the locomotives could obtain the current.

Have you any doubt whatever that electricity will prove at least as efficient a motive power on this line as it has on the City and South London line?—I have no doubt whatever that electricity will work very well indeed.

Are you satisfied with your experience in South London?—Yes, it has worked very satisfactorily.

WITNESS, continuing, said that access to the platforms would be obtained by means of stairs and by hydraulic lifts. The hydraulic power would be generated at Shepherd's Bush. On the City and South London line the lifts had worked extremely well. The total costs of the works, including the purchase of land, was estimated at £2,173,515. To that amount must be added £600,000 for equipment, such as carriages and electrical and hydraulic plant. It would be possible to run a two minutes' service on the proposed line. The average speed of the trains would be between 14 and 15 miles an hour, including stoppages. The rate of speed would be from 20 to 25 per cent. better than that on the Inner Circle Railway. The whole distance between Shepherd's Bush and the Exchange would be covered in 25 minutes. The figures given by Mr. Pember with reference to the traffic in London were correct. On the City and South London line there had been about twenty stoppages in two months, and the longest stoppage was for an hour and a half. As a rule, stoppages had been for a few minutes.

The CHAIRMAN: Have stoppages arisen through a defect in the system which can be got over? Yes, and they have been overcome. I am satisfied with the system, which is perfectly workable, and will go on working satisfactorily.—Were there more stoppages during the first month than in the second? There were. There is nothing in the system to prevent it from becoming a complete success.

By Mr. POPE: He had not heard that the main of the South Metropolitan Gas Company had sunk near Kennington Church. It was not intended to have any brick tunnels. The line was no doubt a purely metropolitan scheme. If this railway failed as an electric railway it would be useless for anything else. It could not be used by another railway company.

Mr. BARRAN: May it not be used as a rope railway if it failed as an electric railway?—Certainly.

Mr. POPE: Why did you abandon the rope railway in South London?—Because we thought that an electric railway would be better. I do not think the County Council ought to have the right to purchase the railway.

By Mr. BIDDER: The length of the proposed line was double that of the City and South London Railway, and therefore it would be necessary to have a more expensive conductor to convey the electricity. In two months 900,000 passengers were carried on the City and South London line. Does that number include those who went over the line to see the system?—I believe the number was made up from the amount received. Then the gross takings have been about £900 a week?—No; between £700 to £800. On the City and South London line they have the turnstile system without tickets. If you have two classes of passengers what becomes of that system?—There must be a modification of it.

By the CHAIRMAN: The estimate of £600,000 for equipment was for a three minutes' service.

By Mr. RUSSELL GRIFFITHS: On the City and South London line the hydraulic lifts were more than sufficient to take down the passengers; but the train service on that line was not sufficient to carry the traffic. On the proposed line there would be more accommodation for passengers.

Re-examined by Mr. SAUNDERS: You cannot tell us what portion of the cost of equipment is for electricity?—No; not without making an elaborate calculation. I am perfectly satisfied that we have ascertained the efficiency of the different machines. How much do you lose by leakage on the City and South London Railway?—One horse power. On that line have the original calculations been fulfilled as regards power?—The power is ample. The amount of power required is less than we reckoned for. Do you think that your calculations as to the amount of power required for the proposed line are also likely to be verified?—Yes. Is it a fact that in consequence of the crowd coming from Stockwell in the morning you cannot, on the South London Railway, take up passengers at the other stations?—Yes; and the same thing occurs in the evening when the people return from the City.

The CHAIRMAN: Why don't you run oftener?—We have not sufficient equipment yet. We desired to see how the experiment worked before we ordered more stock.

Mr. SAUNDERS: Have you ordered new carriages?—Yes, and new locomotives as well. The stoppages or hitches on the South London Railway have not been sufficient to deter people from using the railway?—No.

The further hearing was adjourned till the following day.

### WEDNESDAY, MARCH 4TH.

SIR BENJAMIN BAKER, one of the engineers of the proposed railway, and consulting engineer to the City and South London Railway Company, said that he had not the slightest doubt that the proposed railway would work advantageously. After a great deal of consideration the engineers decided that the only way of carrying an underground railway through the heart of London was to take it entirely clear of all the sewers, and to construct it without interfering with the road traffic. He was convinced that the proposed railway could be constructed without any damage to the surrounding buildings.

After a careful consideration of the line do you say it can be safely and well worked by electricity as proposed?—Yes. Last year it was said by our opponents that experience was adverse to us; therefore when I went to America last autumn I took care to satisfy myself as to what really was American experience. I found that experience in America was entirely in our favour, and I challenge our opponents to repeat what they said last year with regard to American experience.

Have you found that experience confirmed by the working of the City and South London line?—I have. After taking into consideration what the train service should be—a three minutes' service; what the speed should be—an average of 14 miles per hour; and what the traffic is likely to be, I calculated what electrical horse-power would be required to work the line satisfactorily. I came to the conclusion that to perform the journey from Shepherd's Bush to the City and back again in an hour, including stoppages, we should require one electrical horse-power for each ton weight of trains on the line. As we shall require 18 trains on the line to perform the three minutes' service, and each train will be 120 tons weight, we shall require 2,160 electrical horse-power. I find that Dr. Hopkinson has made a similar calculation on the basis of the actual results obtained on the City and South London Railway, and has arrived at the conclusion that 1,800 electrical horse-power only will be required. The fact is that the experience on the City and South London Railway showed that we are 10 per cent. better than the evidence we gave last year. The experience in America is confirmatory of that also.

Allowing for the extra weight of trains to be drawn on this line, the extra length of the line and other circumstances, have you the smallest doubt that electricity will work the system proposed by the Bill?—No one can entertain any doubt about it. At present there are nearly 2,000 miles of electrical railway in the United States, and I have often travelled upon some of the lines. I have travelled on some of the fastest lines, such as that on the outskirts of Boston, and on some of the steepest, such as that at Richmond, Virginia. The gradients on the proposed line are easy, and the curves are not so severe as they are on the City and South London. That is a reason why we can travel 25 per cent. quicker than the Inner Circle Railway.

Do you think there will be any difficulty in working a two-minutes' service if required?—No.

Have you any doubt that this line will not only be able to take the passengers, but to obtain them?—I have no doubt at all about that.

Have you considered the question whether this will be a remunerative line?—Yes, I have no doubt about that.

Mr. CRIPPS said the complaints of the Westminster Electric Light Company would probably be arranged, and therefore he did not propose to cross-examine the witness.

Mr. SAUNDERS, in reply to the Chairman, said that while the promoters would not be liable for damage arising from working the railway, they would be liable for any injury caused by the construction.

Dr. JOHN HOPKINSON stated he knew last year precisely what the results of the London Railway would be, and the working of the line has confirmed his then views.

Have you been using the full pressure on that line?—Occasionally. The pressure has varied from 400 to 500 volts. The average has been about 400.

There have been a certain number of hitches in working the line. Have they been due to the electrical portion of the system?—Some of them have.

Have the hitches been reduced in number?—Yes. The hitches in connection with the electrical plant have been small. One stoppage, for instance, was due to a nut of one of the motors becoming loose, and jamming the machine. We have had some hitches due to the inexperience of the drivers. We have had to educate nearly 40 drivers, who had never been on an electrical locomotive before.

Nothing has occurred to check your confidence in the practical use of electricity as a motive power?—Absolutely nothing.

Can you give us the total cost of working?—No.

Have you heard of anything to shake your confidence that the railway can be worked as cheaply as you supposed it could be?—No; everything confirms that view.

Are the circumstances of the proposed new railway in some respects more advantageous than those of the City and South London Railway for electrical work?—Yes. It is a longer line, the trains are more frequent, and the trains are heavier, the gradients are less severe, and the curves are not so sharp. All these points are in favour of the proposed line.

You propose to work the line at 500 volts as a maximum pressure?—Yes.

Have you made an estimate of the total cost of the plant, the generating engines, and other machinery?—Yes.

Have you also made an estimate of the cost of working the trains?—Yes.

What is your estimate?—According to my estimate the working will cost 8$\frac{1}{10}$ths of a penny per train mile. Ninepence per mile would be a superior limit of the cost of running these trains.

Cross-examined by Mr. POPE: How is it that you have not been able to apply electric power to locomotive engines?—Do you mean for ordinary traffic?

Yes.—There the case is not so advantageous as it is here. It could be done, but the costs in comparison with the ordinary locomotive would be considerable. The trains do not run so frequently.

Cross-examined by Mr. MOON: Mr. Mather proposed to guarantee the working of the City and South London Railway at ninepence per train mile?—Yes.

This line will be a little more expensive to work than that of last year because it is longer?—It will involve a little extra, but not a great deal.

Last year, if I remember rightly, you agreed with the estimate of ninepence per mile, for a line 4½ miles in length?—That was not an estimate but a guarantee offered by a contractor, and you may suppose he allowed himself a good margin.

Digitized by Google

You thought it was a fair time?—I thought it was a sum at which it could be done.

What would you say would be the additional cost of prolonging the circuit by a mile and a-half, assuming ninepence to be a fair sum for $4\frac{1}{2}$ miles? - I should think something like three halfpence.

Mr. R. E. FARRANTI and others gave evidence to the effect that the proposed railway would be of great advantage to the working classes.

Mr. HAMILTON, Managing-Director of the Exploration Company of London, said the shareholders of this Company were very influential men in London, New York, and Paris. He was a member of the syndicate for promoting the Bill, and he had no doubt that the necessary capital would be raised. If, however, a clause were inserted in the Bill giving the County Council the right to purchase, the capital would not be raised.

Sir J. FOWLER, Consulting-Engineer to the City and South London Railway, said he was one of the engineers responsible for the present scheme. He had carefully considered the route and details of the proposed scheme, and he agreed with the evidence of Mr. Greathead and Sir Benjamin Baker. The strong objection to the scheme of last year was that the generating station was at Queen's-road. That objection could not be raised now, as the generating station would be at Shepherd's Bush. The construction of the railway would do no harm to adjacent buildings, and in no way interfere with the use of the roads. The mode of construction would secure perfectly pure atmosphere to the passengers using the line.

Mr. PEMBER informed the Committee that the promoters had arrived at an understanding with the Gas Light and Coke Company and also with the owners and frontagers in Cheapside and Cornhill.

This concluded the case for the promoters, and the further consideration of the Bill was adjourned till Thursday.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 20, 1891.

**Meeting of the National Electric Light Association at Providence.**—The event of the past week was the meeting of the National Electric Light Association at Providence, R I. The semi-annual conventions of this Association are events in the electrical world; but the present one was, from the size of the attendance, and the enthusiasm displayed, more than usually interesting. About 400 delegates were present, representing not only central station managers and those directly connected with the production of electric light, but every department of electrical industry. The meeting extended over three days. By Monday, February 16th, the head-quarters of the Association were already crowded. The neighbouring hall, furnished with light and power circuits, was set apart for exhibition purposes, and a very large number of electrical devices of various sorts were there displayed in operation. The citizens of Providence proved most hospitable, and two large receptions were tendered to the delegates during the continuance of their stay, besides numerous less ostentatious courtesies. The Papers were of a very high order of merit, and prominent among them was a discussion on the electric arc by Prof. Elihu Thomson. Another very practical and valuable Paper was on the distribution and care of alternating currents, by Mr. T. C. Smith. This is a topic not often discussed, and hence was of very peculiar interest to members of the Association who have to do with alternating circuits. An occasional fault of Papers read at these conventions is a lack of useful detailed information. Mr. Smith, however, did not fall into this error, and his practical hints were of extreme value. Wednesday, February 18th, was set apart as pioneers' day to celebrate the close of the first decade of commercial electric lighting. The morning session of the convention was taken up by interesting reminiscences on the part of the early workers in the field of electric lighting and power. Among the number were Prof. Thomson, Mr. F. J. Sprague, Mr. E. W. Rice, and other well-known electricians. One interesting fact brought to light was that some of the original Thomson-Houston 10-light arc dynamos made under Prof. Thomson's personal direction were still in use and doing excellent service in a central station at Kansas City, Mo. On Wednesday evening Mr. M. J. Perry, the president of the Association, gave a large reception to the delegates, and on Thursday evening a most unique festival was held, on the invitation of Mr. E. F. Phillips, president of the American Electrical Company, in the just completed factory of that organisation decorated expressly for the occasion with a profusion of bunting and electric lights. The annual election of officers occurred on Thursday afternoon, and resulted in giving to the Association a progressive and active set of officers, who will make their enthusiasm felt in all work of the Association. The president elected was Mr. C. R. Huntley, a central station manager of long experience and high reputation, while the office of first president was filled by Mr. J. I. Ayre, the enterprising young engineer who is at the head of the largest arc light station in the world at St. Louis, Mo. The next meeting will be held, in response to a most cordial invitation, at Montreal, and the time will probably be late in the coming August.

## CORRESPONDENCE.

### ELECTROSTATIC FORCES *VERSUS* GRAVITATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Sprague might satisfy himself what chance electrostatic forces have of coping or interfering with gravitation by doing the following little sum:—Let the earth be charged till its potential is a million million volts, and suppose the sun to be charged with an equal quantity of electricity, what force will they exert on each other? If I make no mistake it comes out about 22 tons weight.

Now the gravitative pull between earth and sun exceeds the weight of seven trillion tons.

The force which the sun's *light* exerts upon the earth is, I reckon, something not far short of a hundred thousand tons weight, and even that is altogether too insignificant to appreciably affect gravitation.—Yours, &c.,

OLIVER J. LODGE.

### ELECTRIC THEORIES.—ETHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There are a few misconceptions in Mr. Sprague's article on p. 513. I do not, however, write to dilate upon them now, but merely to say that I shall endeavour to profit by Mr. Sprague's criticisms, and try to remove them in my present articles as occasion presents itself. Perhaps, in the meantime, other writers may be able to assist him; and this would, I think, be facilitated by a receptive state of mind. Some of his questions will be found to be already answered in §§ 15, 16 of "Electromagnetic Theory."—Yours, &c.,

March 1, 1889. OLIVER HEAVISIDE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Mr. Gray (p. 520), I did not say anything about Sir W. Thomson's use of a "massless fluid," and certainly I do not pretend to use it myself. All I meant to use was the statement that "massless" means devoid of inertia: mass being defined by gravitation force and resistance to motion of matter. There is a metaphysical meaning sometimes given to mass, to which Sir William alludes and ignores. I say, as he said, "in the strictest dynamical language 'mass' is taken as the measure of inertia." Therefore, I went on to say, no inertia, no momentum; no momentum, no basis for the application of dynamics. And I will ask Prof. S. P. Thompson how he can conceive a structure in a substance devoid of friction? Can parts hold together (when in motion) without adhesion, and is not adhesion a form of friction—at all events when exposed to shearing actions, as all moving parts must be?

I may as well add that I see a little uncertainty left in Prof. Thompson's fourth definition, "transfer of energy *through* the medium." I had not noticed this. I consider the lines of force of the magnet are formed in the medium. I do not consider that when a wire cuts those lines they transmit any energy with it; they oppose its passage. The energy comes from the motor which forces the wire into the lines, not from, or in any true sense by, the agency even of the medium, though indirectly by the agency of the magnet. But I shall meet this in my articles. I only need mention the point to avoid misunderstanding. I purpose showing that in every form of source, the energy is *in* the conductive form the first, as the source is a definite part of the conductor.—Yours, &c.

JOHN T. SPRAGUE.

## MAGNETICS AND NOMENCLATURE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Cannot something be done to check Mr. Oliver Heaviside's prolific invention of new words? I do not complain of "resistivity" or "permittivity." I do not even know what they mean. But to use the name of a well-known unit in a new sense is quite contrary to the permittivity of, and is likely to lead to considerable resistivity from, the general body of physicists. Mr. Heaviside proposes to call the unit magnetomotive force the gauss. Is he aware that the "powers that be" have already christened the unit of magnetic induction (unit B) the gauss? And although unit B and unit H are numerically equal in free ether, it is just as well to give them different names, because free ether is very rarely found outside text books.

There is one unfortunate unit which has never been christened, namely, "one line of force." I have been in the habit of calling this a Thom. Why not? Also why not call the whole flux *the* induction, and when we wish to speak of induction per unit area let us call it induction *density*. If Maxwell had been living now he would have agreed to this at once. It is a long time since he wrote his book, and the world has not stood still. Here is a list of my suggestions:—

| Physical quantity. | Unit: either C.G.S. or a convenient multiple. | Convenient symbol. |
|---|---|---|
| Electric current | Ampere | C |
| Current density | Amps per cm. | $\gamma$ |
| Electric resistance | Ohm | R |
| Specific resistance | Ohms per c.c. | $\rho$ |
| Magnetic induction | Thom. | B |
| Induction density | Gauss, or ohms per cm. | $\beta$ |

Of course, being only a practician, one has to use the orthodox B and B x area. Like Pooh-Bah, "It revolts me—but I do it."—Yours, &c., SYDNEY EVERSHED.

## THE CALLAN INDUCTION COIL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Allow me to supplement in a few points the admirable historical sketch of the induction coil from the pen of Dr. Fleming, which has recently appeared in *The Electrician* (pp. 396—416). It escaped my notice until a few days ago.

The large electro-magnet constructed by Dr. Callan in the year 1836, "with two separate insulated wires, one thick, the other thin, wound on the iron core," which was the immediate predecessor of his induction coil, is still preserved here. It is horse-shoe in shape, measures 13ft. in length, and weighs, with its armature, 210lb. A somewhat smaller one, constructed on the same principle, was presented to Mr. Sturgeon, and exhibited by him the following year at a meeting of the Electrical Society in London.

In Sturgeon's "Annals of Electricity" for April, 1837, there is described by Dr. Callan an instrument devised for producing a rapid succession of electrical currents in the coil by making and breaking connection with the battery. In some of his subsequent Papers he calls it a "repeater." This was the first form of contact breaker ever made (*Philosophical Magazine*, April, 1858). This simple piece of apparatus, forming, as it did, an essential element in the development of the induction coil, I have also carefully preserved.

But the most valuable relic I found here on succeeding Dr. Callan as Professor of Natural Philosophy was a large induction coil, which may be regarded as the completion of his labours. Although constructed by him nearly thirty years ago, it has still, for the same battery power, few rivals. A brief description of it may be of interest to some of your readers.

The core is a cylindrical bundle of annealed iron wires, 42in. in length and 3·5in. in thickness. The thickness of each wire is $\frac{3}{16}$in. The primary coil is a copper wire, ·25in. thick, covered with cotton thread and wound in three layers of spirals. For insulation the primary coil is covered with several layers of thin sheet gutta-percha, cemented together by a paste formed by dissolving gutta-percha, resin, and wax in boiling oil. The secondary coil, which is of iron wire ·01in. thick, consists of three separate rings. The inner diameter of each ring is 5·75in., the outer diameter is 21in. Two of the rings are 3in. in thickness, one is 4in. The rings are so arranged on the primary coil as to divide its entire length into four equal parts, the planes of the rings being perpendicular to the axis of the core. In each ring both ends of the wire are left projecting, so that the rings can be connected together either in series or in parallel. The contact breaker is an automatic mercurial one, which is worked by one extremity of the core. Two condensers of different dimensions, so arranged that they can be used together or separately, serve to reduce the spark at the break to a minimum with varying battery power. With six cells of the Maynooth or cast iron battery, I have frequently got sparks 15in. long in air, with the barometer at 30in., the rings being joined in series and the negative terminal connected with an insulated plate, the positive with a pointed wire placed opposite. Three cells of any of the nitric acid batteries are sufficient for all the ordinary experiments.

Let me add, in conclusion, that students of electricity owe a debt of gratitude to Dr. Fleming for the first true history of the induction coil that has appeared in our language. Most of our text-books would lead one to believe that we are indebted to our continental neighbours for this very useful invention. And considering the Frenchman's proclivity to appropriate the inventions and discoveries of other nationalities, such misstatements might be overlooked in books which are professedly translations. But text-books written by English authors for English-speaking students should be free from such blunders. Let us hope that Dr. Fleming's exhaustive narrative will prevent their recurrence.—Yours, &c.. FRANCIS LENNON.

Maynooth College, February 27, 1891.

## THE BARKING ROAD CARS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue, the Secretary of the General Electric Power and Traction Company (Limited), at the request of his managing director, publishes a correspondence in which it is stated that the Tables 4 and 5 of Cantor Lecture, given by Mr. Kapp at the Society of Arts on Monday, the 16th ult., are entirely misleading, &c. Now, Table 4 shows the cost of the equipment of the Barking-road line with half a-dozen 52-passenger accumulator tramcars carried out by the writer in the spring of 1889 for the Electric Traction Company (Limited), every item of which is accurate, and their details can be furnished, the amount being £6,191. 16s. (see *The Electrician*, February 20th). The cars proper are not included in the table, as only those items connected with the running expenses are dealt with. To include the cars would add £1,200 to the total, making it £7,391. 16s., which is perhaps not what is desired. Table 5 gives the running expenses for the full mileage of the line, *i.e.*, five cars in service running a total of 100,844 miles per annum, being 8·068d. per car mile. This corresponds to the year ended June 30, 1890. It is accurate. It must also be very nearly true, indeed, for the present time, since the five most important items, namely, batteries, wages at depôt, drivers, steam plant, remain unchanged, and these five items represent 88 per cent. of the total. The life of the batteries is 10 months or 300 discharges up to present time. The cars have now been on the road 21 months, and are working with their second renewals. It is to be hoped that the K type plates may prove more durable. The end of the present year will show their merits or demerits as compared with the ordinary type.

It is to be observed that the 8d. per car mile corresponds to the full mileage of 100,844 miles per annum, and that the wages at depôt are a fixed charge of £677. 6s. a year.

The mileage run during the first half-year of 1890, under the charge of the writer, was 44,047 car miles, the mileage run during the second half-year (the installation now becoming the property of the General Electric Power and Traction Company, Limited), was 33,794 car miles, or a decrease in miles run, period for period, of 10,252. Is this a measure of the improvement? This low mileage runs up the proportion of

Digitized by Google

shed wages from 1·612d. to 2·40d., and making the car mile run 8·361d., which is unpleasantly near to 9d.

I must remind Mr. Mackenzie that I left the Electric Traction Company (Limited) at the time of its liquidation, and was in no way connected with the company to which he is secretary.—Yours, &c., T. FRAZER.

114, Broadway, Plaistow, E.

## ELECTRIC LIGHTING STATISTICS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR :—As on a former occasion you were good enough to publish some correspondence of mine in reference to the hours of lighting that may be calculated on, exclusive of public lamps, I would wish to call your attention to the following figures, taken from Mr. Manville's estimate for the private supply in Dublin, the total number of lamps to be supplied being 3,000. Of these Mr. Manville assumes that 300 will be lighting *day and night*, and he estimates the hours of burning as 300 × 24, or 7,200 hours per annum for each lamp. By taking 300, instead of 365 days, I presume he excludes Sundays and holidays.

The remaining 2,700 lamps he calculates will burn each for 1,000 hours. We thus have—

300 lamps × 300 days × 24 hours = 2,160,000
2,700 lamps × 1,000 hours......... = 2,700,000

Total ..................... 4,860,000 hours.

It would therefore appear that about 45 per cent. of the whole consumption would be appropriated by these 300 "day-and-night" lamps. Again, this raises the average over all the lamps to 1,620 hours.

When I wrote to you on a former occasion you estimated, from some data before you, the hours of lighting at about 800 or 20 per cent under that of the 2,700 lamps given above. But what strikes me most is this. Where in Dublin could there be 45 per cent. of the whole consumption used by lights burning *night and day?* The only establishments there that work at night are flour mills, of which there are very few; distilleries and breweries, which would require very few lights at night, and bakeries. None of these require artificial light by day, with the exception of a few used in brewers' cellars. It may be remarked that as land is cheap in Dublin, the inhabitants are not driven to that system of burrowing under ground which becomes necessary where land is very valuable.

We have in Dublin only one railway tunnel, and that far distant from the proposed central station. I should like to know if any provider of gas or electric light has an "all round the clock" consumption, equal to 82 per cent. of the light supplied to ordinary consumers who go to bed at reasonable hours?

In the Paris notes of your correspondent, it is stated that the low-tension supply leaves a net profit of £1,720 in a rental of £11,840, being nine months' working. This equals 14½ per cent. of the rental, and is said to be 10 per cent. on the capital sunk in the undertaking. This last figure cannot be checked, as there is no statement given of the *portion* of capital allotted to the low-tension system. But what is a most important omission is this: No mention is made of the *price* which is charged to the consumer, which I have been informed is very high in Paris. It would be desirable that the number of units paid for should also be given. This would enable us to compare French with English rates.

The Taunton Electric Lighting Company was the model small central station, and for some time was unique in showing a profit. Captious critics averred that the profit was made by the sale of fittings, &c., and not by the supply of light. This seems to be confirmed by the last report, which shows a deficit of £438, or 3½ per cent. on a capital 12,780, without making any allowance for ordinary depreciation, or the necessary loss incurred in abandoning old for new works. I may have misread the report, but if I have done so, I will be glad to be corrected.
—Yours, &c., DENNY LANE.

72, South Mall, Cork, Feb. 28, 1891.

P.S.—Since writing the above, I find the following statement made by Profs. Colombo and Ferrini of the Technical Institute Milan, which may be interesting.

*Number of Lamp-hours of Electric Lights in Milan (per annum).*

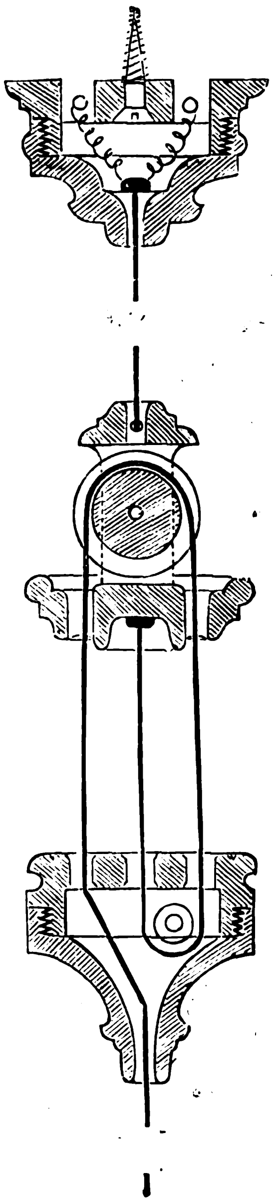
| | | | |
|---|---|---|---|
| Theatres, Cafés | 1,800 hours | Shops | 750 hours |
| Clubs | 1,300 „ | Offices, Banks, &c. | 400 „ |
| Hotels | 950 „ | Private consumers | 320 „ |

Average 750 hours. Gas jets: Average 650 hours.

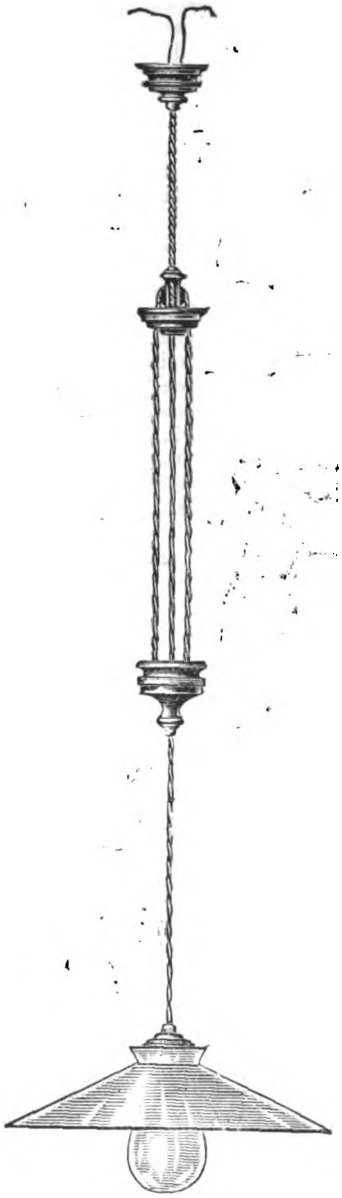
I take the statement from the *Gas World* of this date.—D. L.

## THE RENTSCH INCANDESCENT LAMP SUSPENSION.

The movable suspension device shown in the annexed figures is due to Mr. Rentsch, of Cölln-Meissen. Two collars are secured to the ceiling-rose by means of a twin flexible well-insulated conductor. This conductor is knotted at the top as shown, and long



Section.



General appearance, with Lamp fitted.

Rentsch Incandescent Lamp Suspension.

ends are carried to the terminals, so that the weight of the lamp, etc., shall come upon the knot instead of upon the separate wires attached to the terminals. Another knot prevents the upper collar from sliding further down. The wire passes round the little pulleys on its way to the lamp. When the lamp is pulled down the lower collar rises, (the lamp descending through three times the distance traversed by it.) Pulling the collar down causes the lamp to rise.

# TRADE NOTES AND NOTICES.

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891**

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

ELECTRICIANS', ENGINEERS', BUILDERS', AND IRONMONGERS' EXHIBITION.—This, the third annual exhibition of the kind, is announced to take place at the Agricultural Hall, Islington, N., from April the 23rd to May 2nd next. We are asked to state that the space is being taken up rapidly, and that the success of the Exhibition is assured.

REMOVAL.—We are asked to announce that Mr. E. M. Evans, electrical engineer, has removed from the Corn Exchange, Manchester, to 18B, Fountain-street, where more extensive and convenient premises are secured.

REGENERATIVE ELECTRIC LIGHT COMPANY (LIMITED) (IN LIQUIDATION).—A meeting is to be held at 13, Victoria-street, on April 2nd, at 2 o'clock, for an account of the winding-up.

NORTHERN DISTRICT TELEPHONE COMPANY (LIMITED) (IN LIQUIDATION).—A meeting is to be held at 5, Moorgate-street, on April 6th, at 3 o'clock, to receive the report as to the winding-up of the Company.

# PATENT RECORD.

## APPLICATIONS FOR PATENTS.

**NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.***

February 12, 1891.

2,518. W. GIBBINGS. Garston. An improved method of depositing copper or other metals by electrolysis with the object of refining it or them, or of recovering the precious and other metals contained in or alloyed with the metal under treatment.

2,522. W. R. LANE and J. HALL. Birmingham. Improvements in metallic bedsteads and other articles of a like manufacture.

February 13, 1891.

2,654. Sir C. S. FORBES, Bart. London. Improvements in primary batteries.

2,664. L. B. ATKINSON and C. W. ATKINSON. London. Improvements in machinery for cutting coal and other minerals driven by electricity.

February 14, 1891.

2,677. C. A. PARSONS. Birmingham. Improvements in meters for measuring, registering and recording electrical currents in part applicable to other measuring and recording instruments.

2,689. E. W. LANCASTER. Birmingham. An improved ceiling rose or connector for electrical circuits and for the suspension of electrical fittings and similar purposes.

2,706. A. W. HEAVISIDE and R. C. JACKSON. Whitley. Making joints and connections in concentric cables, or mains for conveying electric currents.

2,714. R. J. RAY. London. Improvements in electric lighting and for other like purposes.

2,732. W. WHITE. London. Improvements in flexible supports for electric lamps.

February 16, 1891.

2,798. H. J. ALTMAN. London. Improvements in solutions and salts for electro-deposition and other purposes.

20,425. VON DOLIVO (Doprowolsky and others). Alternating current motors. (Price 6d.)

# COMPANIES' MEETINGS & REPORTS.

## Telegraph Construction and Maintenance Company (Limited).

The twenty-seventh ordinary general meeting of the shareholders in this Company was held at the offices, 38, Old Broad-street, on the 3rd inst., under the presidency of Sir George Elliot, Bart., M.P.

Mr. SHUTER (Managing Director) read the notice calling the meeting and the minutes of the last ordinary meeting and of the half-yearly general meeting held last July. These minutes were approved by the present meeting and signed by the Chairman as correct.

The CHAIRMAN: Gentlemen, I have great pleasure in coming before you to make a very brief statement regarding the results of the working of the Company during the past year. I suppose that each of you will have read with much interest the report which has been placed in your hands, which I assume we may take as having been read. The past year has been, I must say, a very successful year for our Company. We have done a great deal of most interesting and useful work in every sense of the word, and more particularly useful and interesting to the Company, because it has been done so well. There has been an entire freedom from the slightest accident in the execution of the enormous amount of work which was done by the Company during the year 1890. The effect of this has been to yield us a fair and good profit. That our enterprise has not been in any degree impaired by any misadventure in all the precarious and interesting work which we have done in the past year is due to our staff. We have laid—I suppose nearly all of it in deep sea, or the great bulk of it—4,000 miles of submarine cable during the past year, and we have manufactured a considerably larger quantity, part of the contracts remaining unexecuted. That work is going on in the present year, for which it augurs well. I am glad to say, therefore, that our prospects for this year seem very encouraging. We are at the present moment laying a cable from Madras across the Bay of Bengal, and loading another cable at our works for the Indian Ocean. I have been here since the formation of the Company, and I was connected with this business, as you know, for many years before the formation of the Company, and we have never made boasts about anything that we have done. We have been a silent Company, doing our work quietly and well, and generally having plenty of work to do. I

Digitized by Google

hope you will continue to be satisfied with the 20 per cent. dividend which we are enabled to give you, leaving something as a nest-egg for next year. By this means I trust we shall always—at any rate for many years to come—provide a safe guarantee for carrying on the Company in the way we have hitherto done, not dividing everything you earn, and in the next year having little or nothing. We try and steady our dividend. When we have one bad year we have something in hand to equalise our dividend, and we trust that this way of transacting our business will have your approval. The resolution which I have now to propose is as follows :—

"RESOLVED,—*That the report and accounts of the Directors to the 31st December, 1890, submitted to this meeting be, and the same are hereby received and adopted, and that a dividend of 36s. per share (in addition to the 12s. per share interest or interim dividend paid to June 30th, 1890), be paid upon all shares of the Company for the year ending December 31st, 1890, and that such dividend be paid free of income-tax.*"

Mr. PHILIP RAWSON, J.P.: I have much pleasure in seconding that.

The CHAIRMAN: Before putting this resolution to the meeting, I shall be very glad to answer any questions which may be asked.

Mr. WHISH thought that the proprietors had every reason to be most thankful for the exceedingly prosperous year which the Company had had. Its prosperity was most remarkable in the amount carried forward. This was so very noticeable that he desired to ask why such a large amount should be carried forward instead of some of it being added to the reserve fund. He did not propose that a larger dividend should be paid, but that, instead of the entire sum of £61,500 being carried forward, a portion of the amount should be added to the reserve fund.

The CHAIRMAN: I thought the observations I had made would have sufficed to explain that. Our work is of a very precarious character, and if you had had that which you might have had more than once in the course of last year, you might have lost half of that £60,000. It is the excellent manner in which the business of the Company has been executed that has enabled us to make these large profits, as there has been absolutely no inconvenience or accident in all the work that we have done. Our business is large, and it is of a special character, and the way in which it is done by the Directors and the staff—and especially the staff—is security for your position. We are enabled by doing our work with so much precision and regularity, and in such a very short space of time, to secure you a large business; and our position is safer and better by our always being well supported by a good reserve. You must be good enough to let us judge of this matter.

Mr. WHISH observed that he had merely thought that part of the amount carried forward might be added to the reserve fund.

The CHAIRMAN: I hope that my answer is regarded as sufficient.

The motion was then put and carried unanimously.

Mr. GEORGE W. CAMPBELL next proposed the re-election of the retiring Directors, Sir George Elliot, Bart., and Mr. P. Rawson.

Admiral Sir GEORGE H. RICHARDS, K.C.B., F.R.S., seconded the motion, which was unanimously adopted.

Mr. HEWAT afterwards proposed :—

"RESOLVED.—*That Mr. John Gane, F.C.A., and Mr. Patrick A. Glegg be and are hereby re-elected Auditors of the Company for the year 1891 at the usual remuneration.*"

Mr. BRYDEN seconded the motion, which was carried unanimously.

The CHAIRMAN: That is the end of our business, gentlemen.

Mr. CROFT: We ought not to separate without passing a vote of thanks to the Chairman and the Directors for the very excellent way in which they have conducted the business of the Company.

Mr. WHISH seconded the resolution, which was carried unanimously.

The CHAIRMAN: On behalf of my colleagues and myself I have to thank you very much. So long as we have your confidence we shall do our best for you.

The proceedings then terminated.

## The St. James' and Pall Mall Electric Light Company (Limited).

An extraordinary meeting of the shareholders of this Company was held on Monday last, at Winchester House, Old Broad-street, E.C., under the presidency of Mr. Eustace J. A. Balfour.

The GENERAL MANAGER and SECRETARY (Mr. James Strick) read the notice convening the meeting.

The CHAIRMAN: Gentlemen, I have to propose the first resolution, which is as follows :—

"*That the capital of the Company be increased to £200,000 by the creation of 20,000 shares of £5 each, to be called Preference Shares, and to be entitled to a Preferential Dividend at the rate of 7 per cent. per annum on the amount for the time being paid up on such shares, payable out of the net profits of the Company for each year.*"

In moving this resolution, I need scarcely dwell on the necessity for the increase in our capital as the terms of the Provisional Order, under which the St. James' Company exists, oblige us to extend our operations over the whole area of the parish of St. James. The chief questions which the Directors had to consider were—firstly, the amount of the increase; and, secondly, the form in which that increase should be made. To state with any certainty the exact amount of money we shall ultimately require would involve a gift of prophecy which none of us pretend to possess, but as nearly as we can estimate we consider that the original capital ought to be doubled. There are on the face of this matter three ways in which the capital might have been raised, namely, by the creation of ordinary shares, or Preference shares bearing a lower rate of interest than 7 per cent., or 7 per cent. Preference shares. I will give you the reasons which weighed with the Board in recommending the last of these three. You are aware that the founders' shares of this Company receive half the net profits after a dividend of 7 per cent. has been paid on the capital to the ordinary shareholders. Thus, supposing that ordinary shares were created, the present shareholders instead of receiving half the net profits after 7 per cent. had been paid would only receive one-fourth of that sum. The Seven per Cent. Preference shares, on the other hand, would receive their complete moiety. In order to place the present shareholders in a still better position, the Directors have intimated that they intend, should the resolution be adopted, to offer 10,000 of these Preference shares to the holders of ordinary shares in the proportion of one to two. And here I must call your attention to an error in Clause 14 of the report, in the fourth line of which the word "now" should have been written "then." It will read thus :—"It is the intention of the Directors to offer 10,000 of such shares to shareholders then on the register," &c.

Sir JOHN H. MORRIS seconded the motion.

Mr. MUIRHEAD said he wished to ask whether the Board was unanimous in recommending these 7 per cent. shares. He had a reason for asking the question.

The CHAIRMAN: That is a question which no shareholder has any right to ask.

Mr. MUIRHEAD said he had always understood that 7 per cent. meant bad security, and he did not think that theirs was a bad security. On the contrary, it was very good; and, therefore, he did not see why such a high rate of interest should be offered. He could not see the advisability of raising money at 7 per cent. to pay off Debentures which bore 6 per cent.

The CHAIRMAN: The Debentures are practically paid off.

Mr. MUIRHEAD thought it would be perfectly possible to raise the money at 5 per cent.

The CHAIRMAN: We are not borrowing at all. We are only creating new shares, and, of course, the creation of these shares gives us fresh borrowing powers. It is a matter of policy.

A SHAREHOLDER asked if the Board had any estimate from the engineer as to the cost of the proposed works.

The CHAIRMAN: We have not yet.

The SHAREHOLDER asked whether they proposed to work by tender.

The CHAIRMAN: There are details which the Board will have to consider.

The resolution, which was seconded by Mr. LATIMER CLARK, was carried unanimously.

The CHAIRMAN then said: The next resolution is :—

"*That the Articles of Association before the meeting be adopted as the Articles of Association of the Company in lieu of those at present in use as such.*"

The primary object of our wish to alter the Articles of Association is to enable the shares of the Company to be quoted on the Stock Exchange, which under the present Articles would not be the case. There is one alteration which specially affects the Directors, and to which I wish to call your attention, and that is the remodelling of the £1,500 limit under the remuneration of the Directors. It is conceded that they are entitled to the 10 per cent. in respect of the profits, and there is no doubt that the shareholders wish the Directors to participate in an industrial business of this nature. It has not been brought to its present state of prosperity without an enormous amount of very anxious work, as you may well understand, and I think we may fairly claim that our labours, while they have met the reward of success, have not met with any very tangible reward in any other direction. In this matter, of course, we are in your hands.

Mr. LATIMER CLARK seconded the motion, which was agreed to *nem. con.*

The ordinary meeting of the Company was afterwards held.

The SECRETARY and MANAGER having read the notice,

The CHAIRMAN said, in moving the adoption of the report, there are a few matters which I am sure will be of interest to you, matters connected both with the past and the present condition of the Company. You may recollect that it was at one time the intention of the Directors to propose a scheme for the reconstruction of the Company. Owing to the enormous improvement in our position this has now become unnecessary. The original contract with Latimer, Clark, Muirhead, and Co., we practically completed, and as a result of placing our claim against them for decision by arbitration we have received an award of over £1,800. I wish to take this opportunity of placing the credit of this fact where it is due, namely, to Colonel Francis. At the same time even, arbitration is a risky and possibly expensive resource. And, although in this case we have been successful, I am still of opinion that to agree to a reasonable compromise would have been a sounder course to adopt. Owing to expressions of opinion at last year's General Meeting, the Directors offered £7,000 (the unissued debentures) to the shareholders. This course was against their better judgment, they considering that it would be better if these debentures could all be held in one hand. Experience has justified their view, for, had this been done, these £7,000 of debentures would have been converted with the remainder. The Directors hope that the three shareholders who hold these debentures will see their way to converting them into ordinary shares, and it is for the purpose of inducing them to do so that we wish to substitute the word "then" for the word "now" in the last clause of the report. With respect to the issue of shares in July last, the Directors found themselves, owing to the want of the support of the shareholders, in the position of guaranteeing to subscribe £2,000 each. I merely mention this as an interesting practical comment on a somewhat violent attack that was made on them last year by a small body of the shareholders. By a perusal of the accounts it will be seen that the whole of the profit last year was made in six months, the greater part of it during the last quarter, from October to December inclusive. The true profit for the last six months of last

Digitized by Google

year represents for that period a dividend at the rate of 10 per cent. on £100,000, which is an amount largely in excess of the capital at the disposal of the Directors at any time during that period. I do not wish to prophesy, but I can put before you some figures which will, I hope, satisfy you as to our prospects in the future. The output of current during the last two months is considerably in excess of half the output for the whole of last year. The number of lamps wired at this moment is nearly seven times as many as on January 1, 1890, and we have application for over 10,000. The average daily revenue during the last week is not far off six times as large as the average daily revenue during January 1890, and that although the days are longer. I think that if you will put these figures together in your minds, recollecting that this increase of business is on our original capital, and that it implies but a small increase of staff, that you will agree with us in thinking that you possess a most valuable property, and one likely to be remunerative; and the Directors feel that the results of the year's working have completely justified the course of this Company's business as foreshadowed by them. As negotiations for the purchase of a site on the northern part of the parish of St. James are proceeding, it is undesirable to enter into details on this subject. The experience gained in the erection of the present station places us in a position of great comparative advantage with respect to the erection of new works, both from the point of view of economy and efficiency. We shall continue to follow the principle of the sub-division of engine power, the adoption of which principle has been one of the causes of our steady success, and we shall further develop this principle by connecting the new station with the old in such a way that in case of necessity each can afford the other support. In conclusion, I shall again thank the members of our staff for the admirable and energetic way in which they have worked, and I wish specially to mention our Secretary and Manager, Mr. Strick, and our Chief Engineer, Mr. Dobson. If any of you had been acquainted with the details of the work that they had gone through, I am sure you would feel, as we do, that these gentlemen greatly deserve our thanks. I now move:—

"*That the report and accounts of the Directors for 1890 be and the same are received, approved and adopted, subject to the alteration that the word 'then' be substituted for the word 'now' in the fourth line of clause 14 of the report, and that a dividend of 5s. per share, free of income tax, be declared and paid forthwith on the 9,000 ordinary shares in existence on December 30, 1890.*"

Mr. LATIMER CLARK seconded the motion, which was carried unanimously.

On the motion of Mr. HODGSON, seconded by Mr. HOWARD, the retiring Directors were re-elected, as were also the auditors, Messrs. Deloitte, Devers, Griffiths, and Co., on the motion of Mr. HODGSON, seconded by Mr. MUIRHEAD.

A vote of thanks to the Chairman and Directors terminated the proceedings.

## Taunton Electric Lighting Company (Limited).

The fourth annual meeting of this Company was held at the Castle Hotel, Taunton, on Wednesday, the 25th ult., under the presidency of Mr. W. H. Fowler, J.P., the Chairman of the Company.

In moving the adoption of the Directors' report, which appeared in our last issue, the CHAIRMAN said the past year had not been so satisfactory as former ones, but the report fully set out the difficulties they had met with, and which to some extent had been unforeseen. He had made an estimate for next year of their probable income and expenditure, as it struck him that their whole position hung on this question. He then referred to the estimate in detail, and made the probable total expenditure £1,895, and the income as £100 less. This was allowing the sum of £300 for payment of five per cent. interest on £6,000 debentures. There were two things they might do. First, they might increase the rentals. The light was supplied at a loss at the present time. The price of coal had gone up, and consequently the price of gas had been raised in most places, and he thought the electric light ought to go up. Then they could easily pay 5 per cent. on the Debentures, and have something left in hand. A 10 per cent. rise would make all the difference between paying 3½ per cent. and 5 per cent. They were overloaded with capital at the present time. They in Taunton were pioneers, and pioneers always had great difficulties; gas companies experienced great difficulties in starting, but the longer the Electric Light Company could keep going with its own money, the more likely they were in the future to have a prosperous concern. At present they had to raise £5,000 on Debentures. He did not think the Directors themselves were prepared to finance the concern at the present time, but next year they would see how the concern was going on, and would be in a better position to consider what should be really done. If they could keep the whole of the machinery running at full power the thing would pay in itself, and what they had to face was the difficulty in getting people to come to the front and take the light. He hoped every shareholder would see the necessity of getting additional people to take the light. The light must be had: it was in Taunton, and it must stop there. Every shareholder who obtained new customers was doing the best possible thing for the interests of the Company. He begged to move the adoption of the report.

Mr. MASSINGHAM seconded the motion. He regretted that there was no dividend this year, but he was not disappointed, because all the working members of the Board had realised that they would be quite unable to pay anything. The past year has been an abnormal one. They had to work two concerns at the beginning of the year, and great delay was caused by the Board of Trade, who were bringing out new rules at the time. They had to pay a year's expenses, and only got returns for three months. Their expenses had thus been very abnormal. At the same time he took a more hopeful view than the Chairman did, for he thought there was a very bright future before the Company. There was a time when gas companies could not make things meet anyhow, and it took them a great number of years to attain to the prosperity they now enjoyed. He thought that in course of time the electric light would prove even more successful financially than gas. Their coal bill for the past year had been very large, and he hoped that this year it would be considerably smaller. He felt sure that additional customers would be forthcoming, and he hoped they would be forthcoming during the present year. The Company possessed a large and efficient plant, but at present they were only using it to about a quarter of its capacity. The Company had paid 16 per cent. in four years, and that was 4 per cent. on the whole of the shares and 5 per cent. on the debentures.

The report having been adopted, and the retiring Directors (Messrs. Alfred Lewis and H. G. Massingham) having been re-elected,

Mr. MASSINGHAM, in returning thanks, said it had been suggested that during the year, and probably in the month of August, an exhibition of the electric light industry should be held in Taunton. Taunton was the pioneer town in electric lighting, and the light was a success there before it was in any other place. It had been suggested that such an exhibition might assist the Company very materially in popularising the light. The exhibition might include electric light appliances and electricity in every form, such as the telephone, the telegraph, and electricity as a motive power. He did not know whether the expenses of the exhibition would be guaranteed, or whether the Great Western Railway Company would be disposed to assist by running excursions on the main line between Plymouth and Bristol, and also on the branches. If the railway company were willing to co-operate, and the expenses of the exhibition could be guaranteed, it was probable they might have the pleasure of carrying the suggestion into effect.

The auditor (Mr. A. Goodman) was re-elected, and the meeting terminated.

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.

## Keswick Electric Light Company (Limited).

The adjourned annual general meeting of this Company was held at the Court Buildings, Keswick, on Saturday afternoon. R. D. Marshall, Esq., J.P., presided.

The CHAIRMAN moved the adoption of the report and statement of accounts, which were taken as read. The Company, he said, was in a growing state; the Directors found that business was increasing, and to meet the increase they required additional power at the station. Already they had made some preparation, and an appeal had been made to the shareholders; but the response had only been partial, and, therefore, they were not in so good a position as he had hoped they would have been to supply even the present demand. It was very important that the work should be done, and he hoped the shareholders would think fit to put a little more money into the business to enable the Directors to carry out the intended enlargement. The works have been dependent chiefly on the water supply, which had been very precarious during the winter owing to exceptional frost, and there had been great difficulty in keeping the turbine clear and supplied with water. The engine had not been of the help expected, but their engineer assured them it would be in the future. The Directors were anxious to carry out the alterations as soon as possible. Referring to the profits, he said the balance was small, but the concern was young and could not jump into profits at once. New businesses had their ups and downs, yet, considering the bad weather and the delay that had occurred in some of the work, he thought the balance-sheet was satisfactory. Next year he hoped they would be able to show a much better result.

Colonel SPEDDING seconded the motion, and it was carried unanimously.

Mr. WILSON remarked that the position of the Company was better really than it appeared. Certain things had been paid for out of revenue which might have been charged to capital, and so have permitted a dividend.

The CHAIRMAN said that they might have paid 2 per cent.

Mr. THOMPSON said the balance would have been about £50. The whole period of the receipts extended only over eleven months, and some of them for only seven, eight or nine months. He estimated that the twelve months' takings of the company, as wired at present, and as their arrangements are made, would amount to about £460.

A resolution passed at a meeting on February 3, 1890, was rescinded, and it was now resolved that the accounts be made up to December 31st of each year, and that the Company meet annually in general meeting not later than the end of February.

Major CROSTHWAITE intimated his willingness to take another £100 worth of shares, and he said he thought there were plenty of people who would be glad to subscribe.

The SECRETARY said that now there remained but £1,545 worth of shares to dipose of.

Colonel SPEDDING suggested that immediate attention should be paid to the securing of way-leaves, so that the Company could be in a position to supply their customers.

The meeting closed with a vote of thanks to the Charman.

## NEW COMPANIES REGISTERED.

**JOSEPH RICHMOND AND CO. (LIMITED).**—Registered by Thomsons, Brooks and Danby, 63, Cornhill, E.C., with a capital of £25,000 in £10 shares. Object: To acquire the business carried on at 30, Kirby-street, Hatton-garden, and the New Sun Iron Works, Burdett-road, E., by Joseph Richmond and Walter Whiting, under the style of Joseph Richmond and Co., to carry on business as engineers, machinists, boiler makers, brass founders, metal workers, steel converters, &c.

**RUBBER TRUST SYNDICATE (LIMITED).**—Registered by Parker, Garrett and Parker, St. Michael's Rectory, Cornhill, with a capital of £10,000 in £100 shares. Object: To acquire the whole or any part of the founders' shares, or the other shares, of the New York Belting and Packing Company (Limited), or of any other company carrying on the business of indiarubber manufacturers.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended February 27th amounted to £5,998.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended February 28th amounted to £753.

**CUBA SUBMARINE TELEGRAPH COMPANY.**—The estimated traffic receipts of this Company for the month of February were £3,400, as compared with £3,391 in the corresponding month of last year.

**DIRECT SPANISH TELEGRAPH COMPANY (LIMITED).**—The Board of Directors of this Company decided on Tuesday to recommend the payment of the dividend at the rate of 10 per cent. on the Preference shares and a dividend at the rate of 6 per cent. per annum, together with a bonus of 1 per cent. (both free of income-tax) on the ordinary shares, making, with the previous half-year's dividend, a total distribution of 7 per cent. for the year on the ordinary shares. The traffic receipts of this Company for the month of February show a decrease of £272 as compared with the corresponding period.

**EASTERN EXTENSION TELEGRAPH COMPANY.**—The receipts of this Company for February amounted to £43,833, as against £38,466 in the corresponding period of last year, showing an increase of £5,367.

**EASTERN TELEGRAPH COMPANY (LIMITED).**—The traffic receipts for the month of February, 1891, amounted to £59,155, as against £53,347 in the corresponding period of 1890, or an increase of £5,808.

**ELECTRIC CONSTRUCTION CORPORATION (LIMITED).**—Provisional certificates for the Six per Cent. First Mortgage Debentures are now ready at the offices of the Corporation to be exchanged for bankers' receipts.

**NATIONAL TELEPHONE COMPANY (LIMITED).**—This Company have this week invited subscription for £350,000 Four and a-Half per Cent. Debenture Stock, forming part of a total amount of New Debenture Stock which is limited to one-half of the subscribed share capital of the Company for the time being. The payments are 5 per cent. on application, 20 per cent. on allotment, 25 per cent. on April 30, 1891, 25 per cent. on June 30, 1891, 25 per cent. on September 30, 1891. The present will make £3,044,920 issued out of a total authorised capital of £4,000,000. Notice has been given to pay off the existing Debenture Stock and Bonds. The new Debenture Stock will then be constituted a first charge on the entire undertaking and property of the Company. The net revenue of the Company for the year ending April 30th last was £185,754. The Debenture Stock is redeemable at the option of the Company on six months' notice at 110. The first payment of interest on the new stock will be made on July 1st next. The subscription lists were opened on Saturday, and closed on Tuesday.

**SANITAS COMPANY (LIMITED).**—At the fourteenth ordinary meeting held on Friday last a resolution was passed declaring a dividend of 5 per cent. for the half-year ended December 31, 1890, free of income-tax, making, with the interim dividend paid on June 30th, a distribution of 10 per cent. for the year. Mr. F. H. L. R. Moll, the chairman, and Mr. Kingzett, the managing-director, alluded to the disinclination of the Stock Exchange Committee to grant an official quotation of the shares of the Company, but they hoped that the Committee would favourably reconsider the application.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ending February 27, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,895.

**WEST INDIA AND PANAMA TELEGRAPH COMPANY.**—The traffic receipts of this Company for the half-month ended February 28th show a decrease of £625 as compared with the corresponding period.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/8 per lb.

FACTORY.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

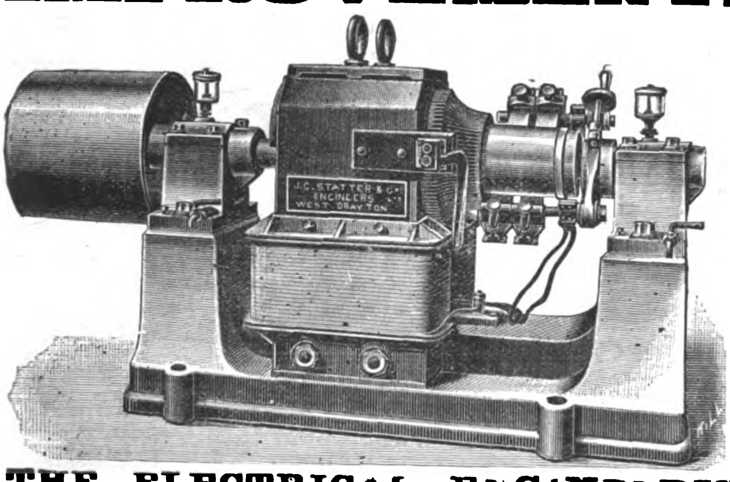
# IMPROVEMENTS IN DYNAMOS



## STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**

**MACHINES BUILT TO 500 KILOWATTS.**

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 669.—Vol. XXVI. FRIDAY, MARCH 13, 1891. Price Fourpence.

## NOTES.

The "Monarch" having been waiting at Calais for fair weather to lay the new telephone cable, as we informed our readers last week, we were rather surprised to find on Tuesday, when a considerable gale was blowing, that the greater part of the work had been accomplished. We learn, however, that Monday morning was clear at Calais, and the shore end was accordingly laid, and paying out began. But before half the distance had been covered, a very strong easterly gale and snowstorm swept down the Channel. The "Monarch" found herself in a very awkward position, and was obliged to pay out the whole of the cable, and to slip the end and buoy it. She was sighted from the English coast during a lull in the storm at about 5 o'clock, and then went into the Downs. About five miles will have to be relaid; of these two miles were picked up yesterday afternoon, and connection will probably be completed to-day.

We had an opportunity of testing the land line between London and Dover on Wednesday last. The circuit is of course looped, and ordinary Gower-Bell instruments are used. We conversed with an officer in the hut at St. Margaret's Bay, a distance of about 83 miles, and found the articulation to be of extraordinary clearness, while the volume of sound was, if anything, too loud for agreeable conversation.

The Central London Railway Bill, after having been five days under consideration by the Select Committee of the House of Commons, passed successfully through that ordeal on Wednesday. Last year twelve days were spent on the Committee stage. The attempt of the County Council to be allowed to purchase the line on favourable terms after 42 years, the determination of the Committee that workmen shall be carried six miles for a penny, and the persistent demand that the rates shall be relieved at the expense of the Company, all tend to show that its opponents do not really believe that the line will never be used and cannot possibly prove remunerative, as was so ably argued both last year and this.

At the last meeting of the Physical Society Mr. Swinburne gave a brief description of a method of using an electrometer for measuring power, and there are several advantages in this arrangement. It is to be hoped that electrometers will soon come into fashion for engineering purposes, for while they are most troublesome in the laboratory, they offer great advantages where large forces are to be dealt with, and if made throughout of one kind of metal they entirely dispense with any corrections, and have no errors due to temperature, self-induction, or magnetism. For the testing of transformers electrostatic methods seem to be peculiarly valuable.

In our last issue we alluded to the error which is introduced in Mr. Blakesley's method of measuring power, by the presence of magnetic leakage. Dr. Fleming's discourse at the Royal Institution contained many references to the peculiarities of the stray field of magnets when excited by alternating currents and throttled with coils of copper wire or "shaded" with copper plates. The majority of his brilliant experiments depended upon such a stray field. The effects were altogether different from those of continuously excited magnets, and as a transformer is essentially a magnet with a throttling coil, it would be worth considering to what extent the stray field is affected, and how the leakage differs from that of ordinary electromagnets.

The second Paper at the Physical Society's meeting was a record of a very great number of experimental results obtained at the Central Institution; and although some of them are not new, they were then published for the first time in a collected form. The thanks which the mathematician gets come, as a rule, long after his work has been published, since his readers have, for the most part, to study his arguments with care, and to realise his deductions with deliberation. But experimentalists who carry out researches and practical examinations of the phenomena which are of daily increasing interest, attract the immediate attention of those who, having no opportunities for laboratory investigations, can apply the results directly to their daily work. This is particularly true in electrical science, especially in its modern developments, and such work as is done at the Central Institution, is extremely valuable in explaining those facts which are essential to a proper understanding of alternating currents. The Paper is marked by an implicit reliance on experiment, and, as a bird in the hand is worth two in the bush, we venture to congratulate the authors on this characteristic, though in no sense under-estimating the future value of such Papers as those which were presented to the previous meeting.

The interference effects described in the Paper by Prof. Ayrton and Dr. Sumpner will possibly throw considerable light upon the vexed question about the so-called back-electromotive force in the electric arc, to which we alluded below. The investigation of the "Ferranti effect" by experiment

Digitized by Google

will probably put that question upon a more satisfactory basis than it was left by the discussion which recently took place in these columns. A very strange peculiarity about the "Ferranti effect" is that no two persons seem to have heard the same account. In the discussion Mr. SWINBURNE introduced contentions about a difference of pressure between the London and the Deptford end of the mains. It is true that as the mains gradually grew in length, as mile after mile was laid, the observed pressure at the end remote from Deptford increased. But we have always understood that had the mains been tapped at intervals, all the way back to the Deptford transformer, the pressure would have been found to rise slightly on account of the ohmic resistance of the copper. In his reply, Prof. Ayrton speaks of pilot transformers. They have no doubt been used on the Deptford mains, or we should not have heard about them on more than one occasion from him, but we have no reason to suppose that the information given in our leading article of December 19 (page 205) was inaccurate in any particular. The very sensible method of using five lamps in series was there described. They were used by the workmen "in order to be quite sure that the pressure was on the mains," and evidently no pilot transformer was used when the effect was first noticed. The "London transformer" mentioned in the discussion probably referred to some later experiments.

THE recent meeting of the Electric Light Convention at Providence is noteworthy chiefly for the interesting paper by Prof. ELIHU THOMSON on the electric arc. The communication, of which an abstract will be found in another column, deals with a subject that has received but little attention. Prof. SILVANUS THOMPSON, in his Society of Arts Paper two years ago, broke fresh ground, and in the first section of that communication he placed the physics of the arc upon a sound basis. He showed that the temperature of the light emitting surface was the temperature of volatilization of carbon, and was therefore constant. No rush of current can ever raise carbon above this temperature under ordinary pressure, precisely as water cannot be raised above boiling point by any amount of firing.

ANOTHER point in connection with the physics of the arc was emphasised by Dr. FLEMING in his Royal Society paper of January 9, 1889, namely, that "the rise of potential along the arc takes place very suddenly just in the neighbourhood of the crater," and he had arrived at this conclusion by experimenting with a third carbon. He attributed this phenomenon to the fact that "the molecules are loosened from the mass by heat, and then move away by electric repulsion from the surface in virtue of the electric charge which they retain." It is probable that all chemical actions are due to electric charges, and Prof. SILVANUS THOMPSON, in his Society of Arts paper gave an explanation from the chemical point of view, describing the effect as one of evaporation, and as that takes place at the positive pole it is here, in fact on the very glowing surface, that we should look for the great change of potential. Nor is this theory shaken in any way by the experiments of H. LUGGIN, described in our "Notes."

THESE and other matters are alluded to by Prof. ELIHU THOMSON, but in describing the mushroom growth on a short arc, he does not give the interesting scientific suggestion of his English namesake, for the great difference in the counter-electromotive force, viz., the condensation of the volatilised carbon on the negative pole. Prof. ELIHU THOMSON says that he is not aware that any others have experimented with three or more carbons. We cannot recall any great success in this direction, but Mr. KILLINGWORTH HEDGES certainly exhibited some triple carbon lamps at Paris in 1881, and RAPIEFF has used four carbons. Little or no advantage has as yet resulted, and the usual practice in search light work seems preferable to the plan suggested and illustrated in Prof. THOMSON'S paper.

THE information given by Mr. KING in our correspondence columns does not go far towards removing the reproach which has recently been cast upon the economy of traction by secondary batteries. We now learn that the positive plates will last for 400 discharges if they are handled with sufficient care, and the negative plates (750 discharges); he further informs us that he has not seen a plate actually broken down from fair wear and tear. But do the exigencies of tramway work allow a more merciful treatment for accumulators than for horses? Do not the lives of tramway horses vary "according to the degree of care in handling," and is not the wear and tear such that they frequently *do* break down? In short, is not tram work the most trying duty that either a battery or a horse can be called upon to perform? We fail to appreciate the value of the "crucial experiments" to which Mr. KING refers, since he fails to give the conditions under which they were made. If they were carried out under any other conditions than those of the daily working of tramcars for public service, they must partake of the character of laboratory experiments. From these we can deduce facts of scientific interest, but not arguments in support of statements as to the cost of maintenance under every-day commercial conditions, which the amended figures in connection with the Barking-road cars can alone supply.

FROM a *précis* which appeared in *The Times* of yesterday of some correspondence which has recently taken place between the Postmaster-General and the Boy Messengers' Company, we gather that the powerful department over which Mr. RAIKES presides is threatening the Boy Messengers' Company with all manner of pains and penalties. We do not question for one instant the correctness of the contention of the Postmaster-General that to carry messages and to use an electric call system without his licence is illegal; but if we read this correspondence aright he refuses to grant the necessary licence. Now, the Boy Messengers' Company performs a most useful function, and meets a decided public want, and we trust that in his dealings with the Company the Postmaster-General has borne in mind the fact that after all the Post Office is made for the public, and not the public for the Post Office.

IN making an abstract of the final report to the Electrical Committee of the Bristol Town Council, we have omitted the oft recurring expression "bot" which does not appear to

Digitized by Google

be very useful, and which is certainly anything but graceful. When the Board of Trade first took electric lighting under its protection, the "unit" was defined as equivalent to the energy contained in a current of one thousand amperes flowing under a pressure of one volt during one hour. The man in the street, for want of a better name, at once called this "a Board of Trade unit," and the rather cumbrous title has stuck to it. Were it not that this has been unfortunately shortened into "bot," the matter would hardly need any attention. We understand, however, that it is considered that there is a real need for some good name. We have found the expression "a supply unit," or even "a unit," is amply sufficient, but if any of our readers have a sensible name, not immortalising any distinguished electrician, or torturing the English or any other language, we shall be glad to hear of it.

**Trinidad-Demerara Cable.**—This cable is now repaired.

**The Old Students' Association.**—The concert given by the Old Students' Association last Saturday was of a very successful character, the programme being excellent.

**Royal Society.**—Amongst the Papers down for reading yesterday at the Royal Society was one by Prof. Roberts-Austen, "On the Mechanical Properties of Metals in Relation to the Periodic Law."

**The Ferranti Meter.**—In the description of this meter on p. 544 of our last issue, for starts with 3 amperes, read ·3 ampere; starts with 5 amperes read ·5 ampere, and starts with 2 amperes read ·2 ampere.

**Underground Telephone Wires.**—At the last meeting of the Commissioners of Sewers an application was received from the National Telephone Company for permission to lay cables beneath the public ways.

**The Reduction of the German Telegraph Tariff.**—The reduction in the German Telegraph Tariff, which came into force on February 1st, has resulted, during the first month, in an increase in the number of messages amounting to about 7 per cent.

**Reduced Cable Rates to Australia.**—The negotiations for the reduction, under a guarantee from the Australian Colonies, of the rate for telegrams to Australia to 4s. per word are almost completed, and the new rate will probably come into force on April 1st next.

**Leamington.**—An inquiry into the applications of the Corporation and the Midland Electric Light and Power Company for Provisional Orders for lighting Leamington by electricity was held in that town on Tuesday, by Major Marindin, of the Board of Trade.

**Accumulator Traction.**—According to the *Elektrotechnisches Echo*, Messrs. Hostmann and Co., who, with the Oerlikon Company, have been carrying on traction experiments in the neighbourhood of Hildburghausen, have decided to abandon the use of accumulators.

**Duty on an International Telephone Cable.**—The United States Treasury has decided that the American portion of the telephone cable passing through the St. Clair river tunnel, connecting Sarnia, in Canada, with Port Huron, in the United States, is subject to duty.

**The Mechanical Equivalent of Heat.**—At the ordinary meeting of the Manchester Association of Engineers, held on the 28th ult., Mr. John Angell delivered a Paper descriptive of the labours of the late Dr. Joule during his demonstration of the mechanical equivalent of heat.

**Triplicate Aden-Bombay Cable.**—The Telegraph Construction and Maintenance Company's ss. "Calabria" sailed last Saturday with the shore ends of the new Triplicate Aden-Bombay cable for the Eastern Telegraph Company. The ss. "Scotia," with the main cable on board, sails to-morrow.

**Stafford.**—At the last meeting of the Town Council the Electric Lighting Committee reported that to the 54 circulars issued only 27 replies had been received, and of these only two were favourable to the adoption of the electric light. The committee, therefore, did not feel justified in recommending the adoption of the light at present.

**Belgrade.**—The Town Council of Belgrade have decided to adopt electricity to light their streets. For this purpose 65 arcs of 1,000 c.p. and 1,000 glow lamps of 16 c.p. will be required, and it is estimated that from 2,500 to 3,000 additional glow lamps will have to be installed for public and private lighting. The concession is to last 41 years.

**Flexible Glass Tubes.**—The *Electrical Review* of New York reports that Mr. Alex. P. Wright, of Boston, has produced a flexible glass tube intended for indoor wiring purposes. The glass tube conduit is enclosed in a strong woven jacket, giving it high tensile strength and strong abrasion resistance. The whole conduit is then soaked in an insulating material.

**Matlock Bath.**—Mr. Geen, of Okehampton, has sent in a report to the Local Authority, in which he estimates the cost of the adoption of the electric light at from £1,300 to £2,500, providing the motive power is taken at a minimum expense from the river Derwent. A deputation has been appointed to approach Mr. F. C. Arkwright, of Willersley Castle, to get the necessary permission to fix the plant in the river.

**Electric Traction in New South Wales.**—An electric tramway, on the Thomson-Houston system, has been installed on a line between Waverley and Randwick, in New South Wales. The line is a little over two miles in length. There is scarcely a level stretch over the whole distance. Curves varying from half a chain radius to two chains, and all on heavy grades, are constantly met with, while the grades vary from 1 in 16 to 1 in 30.

**The Lighting of the City.**—At the last meeting of the Commissioners of Sewers the Streets Committee reported on the letter from the Board of Trade relative to the City of London (East District) Electric Lighting Order, 1890, and submitted a further letter from the Board, signifying that, after consideration of the further evidence furnished, they were satisfied that the undertakers were in a position to discharge the duties and obligations imposed upon them by the order.

**Electrical Standards Committee.** — This Committee met yesterday (Thursday) morning, when the following members were present:—Sir William Thomson, Lord Rayleigh, Dr. John Hopkinson, Professor Ayrton, Mr. Preece, Major Cardew, and Mr. Courtenay Boyle. Mr. Thomas Parker, Chief Electrician of the Electric Construction Corporation, and Mr. Hugh Erat Harrison, Principal of the Electrical Standardizing, Testing, and Training Institution, attended and gave evidence.

**Litigation in Connection with Transformer Sub-stations.**—In the Chancery Division of the High Court of Justice on Tuesday, last Mr. Justice Kekewich, on the application of Mr. C. M. Warmington, Q.C., and with the consent of all parties, appointed Tuesday April 14th, for the hearing of the motion Savory and Moore *v.* London Electric Supply Corporation. The object of this action is to obtain an injunction to restrain the defendants from so carrying on their business as to be an annoyance to the plaintiffs.

**Leicester.**—On Thursday last week the National Telephone Company opened their Leicester Exchange, and placed the town in communication with the 133 towns now connected together in this district. The Post Office have for many years been working an exchange in Leicester, but for some time past it has been felt that they did not give to the town the advantages possessed by other towns worked by the National Telephone Company. The opening ceremony was presided over by the Mayor. The exchange starts with 170 subscribers.

**Palladium Plating.**—Palladium, a whiter, lighter, and more fusible metal than platinum, has of recent years been much used to plate watch movements with. According to M. Pilet, four milligrammes (about one-seventeenth of a grain) of palladium are sufficient to coat the works of an ordinary sized watch. M. Pilet recommends the following bath:—Water, 2 litres; chloride

Digitized by Google

of palladium, 10 grammes; phosphate of ammonia, 100 grammes; phosphate of soda, 500 grammes; benzoic acid, 5 grammes. This bath is suitable for all metals except zinc.

**The London Electric Supply Corporation and the Marylebone Vestry.**—The Works Committee of this Vestry have presented a report with reference to the notice from the London Electric Supply Corporation of their intention to lay a distributing main along the south side of Oxford-street, from Marble-arch to Wardour-street, to which proposed works the Vestry had given the Corporation formal notice of disapproval. An intimation has been received from the Corporation of their intention to appeal to the Board of Trade.

**Electric Blasting.**—Speaking at the meeting last Monday, of the Roburite Explosives Company, the Chairman referred to the experiments which had been conducted by Mr. Hall, H.M. Inspector of Mines, to test the influence of coal dust on mining explosions. This gentleman had proved that blown-out shots of gunpowder might in the presence of coal dust, even when gas was absent, produce explosions of great violence. The result of Mr. Hall's report was to discredit still more the use of gunpowder in coal mines, and to give a fresh impetus to the demand of safety explosives fired by electricity.

**Production of Phosphorus by Electricity.**—This process, to which we alluded on page 450 of our present volume, is now in operation at the Wednesfield Works of the Phosphorus Company (Limited), who now depend exclusively upon this process for their supply of phosphorus. A new plant of 700 H.P., was officially inspected in full work on Monday last by the Directors and officers of the Phosphorus Company (Limited), and of the Electric Construction Corporation (Limited) (the contractors for the plant), when the results, both as to quality of material and cost of production, were considered to be eminently satisfactory.

**Cable Extensions.**—A Bill will shortly be laid before the Reichstag for laying down an additional cable to Heligoland from the island of Wangeroog, as well as another from Emden to Lowestoft, the two existing ones between Germany and England being quite insufficient for the increased traffic. England will undertake half of the cost of this third cable. The supplementary German estimates for these two new cables, which are to be at once taken in hand, will amount to about 1,200,000 marks. The Imperial Government is also busy negotiating for laying extension cables to its chief colonies in East Africa and the Cameroons.

**Frankfort Exhibition.**—In order to show the application of electricity to aerial navigation, a captive balloon, capable of seating ten persons, will be exhibited by Captain Rodeck at the forthcoming Frankfort Exhibition. The pulley which controls the ascent and descent will be operated by an electric motor, and a telephone wire will enable conversation to be carried on between those in the balloon and the people at the starting-point below. Experiments will be made with the view to the steering of the balloon by electricity, and in the filling of the balloon with electrically prepared water-gas. Messrs. Siemens and Halske will make the electrical apparatus.

**Belting.**—At a recent meeting of the Manchester Philosophical Society, Prof. Osborne Reynolds gave an account of an observation in the laboratory of Owens College during the late foggy weather. Some new belting was kept running four hours, at about 4,000ft. per hour. The belting was bright and new when started, but on being stopped was found to be black and loaded with dirt collected during its rapid passage through the foggy air. It was much the dirtiest thing in the laboratory. Prof. Reynolds pointed out that this was due to the fact that the rapidly moving belt came in contact with a greater quantity of air in a given time than if it had been stationary, and therefore picked up a greater quantity of atmospheric pollution.

**The Central London Railway.**—At the last meeting of the Commission of Sewers a memorial, largely and influentially signed, from citizens of London against the Central London Railway scheme was submitted. The petitioners were headed by Mr. Jacques, of the firm of Messrs. Thomas Wallis and Co., who said the project would materially affect the stability and safety of the various buildings along the line of route. All the main streets would be injured by it, and there would be not only a detrimental effect upon trade, but a depreciation in the value of property, and a consequent reduction in the assessments of the districts. Such an underground railway was not really wanted. The memorial was sent to the Finance and Improvement Committee for consideration.

**The Jablochkoff Patent.**—On Wednesday, the case of *in re* the Jablochkoff patent of the Electrical Engineering Corporation came before Lords Watson, Hobhouse and Morris, and Sir R. Couch, at the Judicial Committee of the Privy Council. Mr. R. Wallace applied to their lordships to appoint as early a date as possible for the hearing of this petition, on the ground that Mr. Jablochkoff, the inventor, who was acting for the Russian Government in a professional capacity, could not remain in this country after the 15th of next month. He (the learned counsel) understood that their lordships did not sit at all until the 14th of April. The patent expired on the 22nd of May. Lord Watson said their lordships would fix Wednesday, April 15th, for the hearing of the petition.

**Launch of the "Electric."**—On Tuesday, the electrically propelled pinnace "Electric" was launched from the Strand Electric Launch Works, Chiswick. This pinnace has been built by Messrs. Woodhouse and Rawson for the conveyance of troops between Her Majesty's dockyards at Chatham and Sheerness. The "Electric" has a tonnage of 4¾, is 48ft. 6in. long over all, by 8ft. 9in. beam, with an average draught of 2ft. 3in., her full complement being 40 fully-equipped soldiers. The battery consists of 70 Epstein cells, and the motor, which drives a two-bladed screw 22in. in diameter, will develop 5½ B.H.P. at 750 revolutions. The anticipated speed is eight knots. It is the intention of the Royal Engineers to make some exhaustive trials with this type of boat.

**Godalming.**—At the last meeting of the Town Council the report of the Electric Lighting Committee recommending the adoption of the electric light was carried, after some discussion, by 11 votes to 3. The proposed municipal plant will comprise two 65-H.P. engines, two arc-light dynamos, and three incandescent-light dynamos. The mains are to be laid in subways; the street lamps to be 35 arcs of 300 c.p. each; provision for private lights to be 800 incandescent lamps of 16 c.p. It is estimated that the site and necessary buildings will cost from £1,200 to £1,500, making the total outlay for plant, site and buildings nearly £7,000. The profit shown amounts to £352. 10s. per annum. This is based on the condition of 700 lights being taken up at an average price of 27s. 6d. per light.

**Personal.**—Messrs. Miller and Woods have commenced business as electrical engineers and contractors. Mr. Miller, the inventor of the Miller ammeters and voltmeters, has been for the last three and a-half years in charge of the dynamo testing department of the Maschinenfabrik Oerlikon, near Zurich. He has erected many of the important transmission-of-power plants installed by the Maschinenfabrik, including the 600 H.P. transmission plant at Schaffhausen, referred to by Mr. Kapp in his recent Cantor Lecture. Mr. Woods has been for the last two years with the Liverpool Electric Supply Company. He is one of the joint authors with Prof. Ayrton of a Paper on Accumulators, read before the Society of Electrical Engineers at Edinburgh, and the winner of the Silver Medal at South Kensington Technological Examination.

**London County Council's General Powers Bill.**—In the Committee of Referees at the House of Commons, on Friday last, Mr. C. Parker presiding, the petitions of the various companies supplying the electric light in the Metropolis, to be heard against the London County Council (General Powers) Bill, were down for hearing. On the petitioners being called on, Mr. Wallace said he had come to an arrangement with Mr. Cripps, who appeared for the London County Council. It had been decided to strike out the petitions of the Brush Company, the Chelsea Electricity Supply Company, the Kensington and Knightsbridge Electric Light Company, the Metropolitan Electric Supply Company, and the Notting Hill Electric Light Company, leaving in the London Electric Supply Corporation and the Westminster Electric Supply Corporation. The Committee sanctioned the arrangement.

**Telegraphic Charges.**—"We agree with Mr. Henniker Heaton," says the *Financial News*, "that a State Department

Digitized by Google

with an annual surplus of £3,000,000 should be above profiting by lurking quibbles which would be discreditable to a struggling attorney. But the quibbles still lurk. Why should a telegram addressed to 'the Editor of the *Financial News*' be charged at full rates, while a communication addressed simply 'the *Financial News*' is treated as a press message? Why should 'Newcastle-on-Tyne' be one word and 'Clapham Junction' two words? Why should 'can't,' 'won't,' and 'don't' count as one word, while 'shan't' is treated as two? Possibly it is for the purpose of conveying a lesson in manners —at the price of one halfpenny; but that does not explain the fact that 'upstairs' is charged as one word and 'downstairs' as two."

**The National Telephone Company and its Border Subscribers.**—According to the Edinburgh *Evening News* of March 5th, a private meeting of the subscribers in the Border district of the National Telephone Company was held at Galashiels that afternoon to consider what steps should be taken with regard to the contracts and charges of the National Company. It was unanimously agreed that all the subscribers should give immediate notice to the Company to remove their telephones, and that those who had agreements with the Company which did not expire for six months should retain their instruments for that period. Notice was also to be given to the Company to remove their poles and wires from the subscribers' property at once. There are nearly 200 subscribers in the Border district. We are informed, however, that the National Company has received no confirmation of this announcement from their manager.

**United States Patent Publications.**—On Tuesday evening last Mr. Leng asked the Under-Secretary of State for Foreign Affairs whether he would direct the attention of Her Majesty's Minister in the United States of America to the fact that, while complete sets of the publications of the British Patent Office were presented to 12 of the most important cities in those States, a corresponding number of sets of the publications of the United States Patent Office were not sent to similar cities in this country, and that inventors were put to the inconvenience of visiting London to consult the only set of United States Patent Office publications accessible to them.——Mr. Stuart-Wortley stated, in reply, that the fact was as stated, but the matter was one which concerned the Board of Trade. The publications of the British Patent Office were not presented in consequence of any application made through the diplomatic channel from the Government of the United States. No application had been made to the Foreign Office to request from the United States Government copies of their publications in exchange.

**The Mica Industry in the United States.**—With the extraordinary growth of the electrical industry in the United States for a number of years past there has been created a new and steady demand for mica, says the *Engineering and Mining Journal*, which, curiously, has failed to stimulate the mica mining industry; the most important mines, indeed, show a decided decrease in production during this time, and the business is now in a depressed condition. In the construction of dynamos, electric motors, and other electrical appliances, mica is a very important element, valued on account of its flexibility and excellent insulating qualities. For this purpose, however, there is a decided preference for foreign mica, the Canadian "amber mica" being generally used. The foreign mica is considered preferable to that of North Carolina for electrical purposes, in that while the latter can be split into thin sheets, it is by no means so tough. The chief mines in the country are in New Hampshire and North Carolina, but principally in the latter State, these producing an excellent quality of the mineral. The total value of the production in the United States decreased from $368,525 in 1884 to $70,000 in 1890. During the same time the imports of mica, which, prior to 1884, had been of but trifling importance, increased from $28,284 to $57,541.

**Sibley College, Cornell University.**—The following extracts from a letter sent by Prof. R. H. Thurston to the Editor of *Industries* may be of interest:—"Until recently its charter permitted the holding of only $3,000,000, but that provision of the charter was repealed by the Legislature of the State of New York immediately upon the discovery that it was likely to cause the loss of a bequest, which now proves to have a value of about $2,000,000. The University has actually met with this great loss; but, the horse being stolen, the stable door has been effectively locked, which gives us the privilege of receiving and holding, hereafter, any number of millions. I am happy to say that this institution, pledged to make its 'leading object' for ever the promotion of the useful arts, now has above a million of pounds invested, and so well placed that its trustees receive an average of 6 per cent., and have never lost a fraction of a per cent. of the principal. We shall have, at the close of the current, or at the beginning of the coming collegiate year, about $200,000 in equipment. It will include an 'experimental steam engine' of about 200 H.P. triple-expansion, with Corliss valves, adjustable in all possible ways to enable us to make investigations of the effects of varying ratios of expansion from 0 to unity, varying steam-pressures from 2 to 15 atmospheres, varying speeds from a minimum to probably 200 revolutions a minute, and all desirable adjustments of steam and exhaust valves for other purposes. A number of other engines—steam, gas, and hot-air—are used in the regular course of laboratory instruction, a collection of dynamometers, steam-boiler injectors, hydraulic apparatus, and a great variety of testing machines, including—standing in a row—one of 50, one of 100, and one of 150 tons capacity, and a number of smaller ones of various types and sizes. With such an outfit we handle 200 students in the laboratory, having 450 (nearly) in all classes, including graduate students engaged in research."

**The Flow of Current Through an Electric Arc.**—In a recent number of the "Repertorium der Physik" there is a Paper by H. Luggin, which contains a minute description o experiments made to determine the laws which govern the flow of current across an electric arc between carbon-points, and from an abstract of this Paper, published by the Institution of Civil Engineers, we take the following facts. Referring to the anode, Luggin distinguishes two kinds of discharges, the one taking place from the crater with considerable current density, and the other from the surrounding rim with a smaller current density, and at lower temperature. The vertical variation of potential was investigated by means of test-pencils inserted at different points. When the point of the test-pencil (a carbon rod 1·3 millimetre diameter) was placed well within the crater, the mean potential difference between the luminous surface of the anode and the layer of hot gases immediately contiguous to it was found from a mean of five observations to be 33·7 volts. The corresponding value at the kathode was found from six observations as 8·78 volts, whereas Uppenhorn had previously determined the potential differences as 32·5 and 5·2 volts. According to the author's estimate, that part of the potential differences between the electrodes, which is caused by the transition from the solid to the gaseous conductor, and is therefore independent of the length of arc, amounts to 42·5 volts, which is the sum of the values above given. The experiments were made with currents up to 20 amperes, and electrodes of sufficient size in each case to prevent the arc from hissing. A series of experiments was made to determine the hissing-point, which the author found is reached when the current density exceeds about ½ ampere per square millimetre (323 amperes per square inch) of crater surface. For hissing arcs the potential difference between the anode surface and the layer of hot gases next to it is greater, but it does not increase in proportion with the current density, and it would therefore be incorrect to ascribe this potential difference to the existence of a constant resistance. Although this consideration would naturally lead to the assumption that the arc is the seat of a counter-electromotive force, the author has failed to detect the slightest polarisation of the electrodes after the current was interrupted. By carefully-contrived mechanism he was able to make connection between the electrodes and a delicate electrometer within the 0·005 part of a second after cutting off the current, and yet not a trace of charge could be detected in the electrometer needle. The author does not, therefore, believe it possible that the arc can be the seat of a counter-electromotive force of 40 volts as suggested by Dub.

## ELECTROMAGNETIC THEORY.—VI.

BY OLIVER HEAVISIDE.

*(Continued from page 508.)*

§ 33. The two sets of quantities, the electric and magnetic forces, with their corresponding fluxes and currents, and the connected products and ratios, may be considered quite independently of one another, without any explicit connection being stated between the electric set and the magnetic set, whether they coexist or not. But to have a dynamical electromagnetic theory, we require to know something more, viz., the cross-connections or interactions between **E** and **H**. Or, in another form, we require to know how an electric field and a magnetic field mutually influence one another.

One of these interactions has been already partially mentioned, though only incidentally, in stating the meanings of permeance and inductance. It was observed that the electric current in a simple conductive circuit was measured by the gaussage in the corresponding magnetic circuit.

A word has been much wanted to express in a convenient and concise manner the property possessed by some fluxes and other vectors of being distributed in closed circuits. This want has been recently supplied by Sir W. Thomson's introduction of the word "circuital" for the purpose. Thus electric current is a circuital flux, and so is magnetic induction. The fundamental basis of the property is that as much of a circuital flux enters any volume at some parts of its surface as leaves it at others, so that the flux has no divergence anywhere. This qualification, "anywhere," should be remembered, for a flux which may diverge locally, as, for instance, electric displacement, is not circuital in general, though even electric displacement may be circuital sometimes. Further, as a flux need not be distributed throughout a volume, but may be confined to a surface, or to a line, we have then specialised meanings of circuital and of divergence. Or a volume-distribution and a surface or line-distribution of a flux may be necessarily conjoined, without, however, any departure from the essential principle concerned.

The word "circuital," which will be often used, suggested to me the word "circuitation," to indicate the often-occurring operation of a line-integral in a closed circuit; as, for instance, in the estimation of circuital voltage or gaussage. Now, in the case of a moving fluid, Sir W. Thomson called the line-integral of the velocity in a closed circuit the "circulation." This is curiously like "circuitation." But "circulation" seems to have too specialised a meaning to be suitable for application to any vector, and I shall employ "circuitation." The operation of circuitation is applicable to any vector, whether it be circuital or not.

§ 34. Now in the case of a simple conductive circuit, we have two circuital fluxes. There is a circuital conducting core supporting an electric current, and there is a circuital flux of induction through the conductive circuit. In the electric circuit we have Ohm's law,

$$E = RC, \quad \dots\dots\dots \quad (1)$$

where E is the circuital voltage, C the current, and R the resistance. And in the magnetic circuit we have a formally similar relation,

$$H = L^{-1}B, \quad \dots\dots\dots \quad (2)$$

where H is the circuital gaussage, B the induction, and $L^{-1}$ the reluctance. Or,

$$B = LH, \quad \dots\dots\dots \quad (3)$$

where L is the inductance (or the permeance, when there is only one turn of wire).

Now, the cross-connection in this special case is implied in the assertion that H and C are the same quantity, when measured in rational units. The expression of the law of which this is an illustration, is contained in any of the following alternative statements.

The line-integral of the magnetic force in any closed circuit measures the electric current through any surface bounded by the circuit. Or,

The circuitation of the magnetic force measures the electric current through the circuit. Or,

The electric current is measured by the magnetic circuitation, or by the circuital gaussage.

The terminology of electromagnetism is in a transitional state at present, owing to the change that is taking place in popular ideas concerning electricity, and the unsuitability of the old terminology, founded upon the fluidity of electricity, for a comprehensive view of electromagnetism. This is the excuse for so many new words and forms of expression. Some of them may find permanent acceptation.

The above law applies to any circuit of any size or shape, and irrespective of the kind of matter it passes through, meaning by "circuit" merely a closed line, along which the gaussage is reckoned. By "the current" is to be understood *the* current; not merely the conduction current alone, or the displacement current alone, but their sum (the convection current term will be considered separately).

It is also necessary to understand that a certain convention is implied in the statement of the law, regarding positive senses of translation and rotation when taking line and surface integrals. Look at the face of a watch, and imagine its circumference to be the electric circuit. The ends of the pointers travel in this circuit in the positive sense, if you are looking through the circuit along its axis in the positive sense. Also, you are looking at the negative side of the circuit. Thus, when the current is positive in its circuit, the magnetic induction goes through it in the positive direction, from the negative side to the positive side. Otherwise, the positive sense of the current in a circuit and the induction through it are connected in the same way as the motions of rotation and translation of a nut on an ordinary right-handed screw. This is the "vine" system used by all British writers; but some continental writers use the "hop" system, in which the rotation is the other way, for the same translation. It is useless trying to work both systems, and when one comes across the left-handed system in papers, it is, perhaps, best to marginally put the matter straight, and then ignore the text.

§ 35. The other cross-connection required is a precisely similar relation between voltage and magnetic current, with, however, a change of sign. Thus :—

The negative line-integral of the electric force in any circuit (or the electric circuitation) measures the magnetic current through the circuit. Or

The voltage in any circuit measures the magnetic current through the circuit taken negatively.

Magnetic current is measured by the circuital voltage reversed ; and other alternative equivalent statements.

§ 36. In the above laws of circuitation the currents are the concrete currents (surface-integrals), and the forces also the concrete voltage or gaussage. When we pass to the unit volume it is the current-density that is the flux. The circuitation of the force is then called its "curl." Thus, if **J** be the electric current and **G** the magnetic current, the two laws are

$$\text{curl } \mathbf{H}_1 = \mathbf{J}, \quad \dots\dots\dots \quad (4)$$

$$-\text{curl } \mathbf{E}_1 = \mathbf{G}, \quad \dots\dots\dots \quad (5)$$

where $\mathbf{E}_1$ and $\mathbf{H}_1$ are the electric and magnetic force of the field. We may now say concisely that

The electric current is the curl of the magnetic force.

The magnetic current is the negative curl of the electric force.

There is nothing transcendental about "curl." Any man who understands the laws of circuitation also understands what "curl" means, though he may not himself be aware of his knowledge, being like the Frenchman who talked prose for many years without knowing it. The concrete circuitation is sufficient for many problems, especially those concerning linear conductors in magnetic theory. But it does not suffice for mathematical analysis, and to go into detail we require to pass from the concrete to the specific and use curl. How to manipulate "curl" is a different matter altogether from clearly understanding what it means and the part it plays. The latter is open to everybody; for the former, vector-analysis is most suitable.

Let a unit area be chosen perpendicular to the electric current **J**. Its edge is then the circuit to which $\mathbf{H}_1$ belongs in (4). The gaussage in this circuit measures the current-density. Similarly, regarding (5), the voltage in a unit circuit perpen-

Digitized by Google

dicular to the magnetic current measures its density (negatively). In short, what circuitation is in general, curl is the same per unit area.

§ 37. In the statement of the laws of circuitation, I have intentionally omitted all reference to impressed forces. That there must be impressed forces is obvious enough, because a dynamical system comprehending only the electric and magnetic stored energies and the Joulean waste, is only a part of the dynamical system of Nature. We require means of showing the communication of energy to or from our electromagnetic system without having to enlarge it by making it a portion of a more complex system. Thus, taking it as it stands at present, the activity per unit volume we have seen to be

$$\mathbf{EJ} + \mathbf{HG} = Q + \dot{U} + \dot{T}, \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where the left side expresses the activity of the electric and the magnetic force on the corresponding currents, and the right side what results, viz., waste of energy, Q per second, and increase per second of the electric energy U and the magnetic T; and, as there are supposed to be no impressed forces, if we integrate through all space, we shall obtain

$$0 = \Sigma\,(Q + \dot{U} + \dot{T}), \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where $\Sigma$ means summation of what follows it. Or, if $Q_0$ be the total waste, and similarly $U_0$ and $T_0$ the total energies,

$$0 = Q_0 + \dot{U}_0 + \dot{T}_0,$$

meaning, that whatever energy there be wasting itself is derived solely from the electric or magnetic energy, which decrease accordingly. This is the persistence of energy when there are no impressed forces.

Now, if there be impressed forces communicating energy at the rate A, the last equation must become

$$\Sigma\,\mathbf{fv} = A = Q_0 + \dot{U}_0 + \dot{T}_0, \quad . \quad . \quad . \quad . \quad (8)$$

and A must be the sum of the activities of the impressed forces **f** in the elements of volume, in whatever way space may be divided into elements, large or small, and however we may choose to reckon the impressed forces. There may be many ways of doing it; **f** may sometimes, for example, be an ordinary force, and **v** the velocity to match is then a translational velocity. But for our immediate purpose, it is naturally convenient to reckon the impressed forces electrically and magnetically; so that the corresponding velocities are the electric and magnetic currents. We shall then have, if **e** be the impressed electric, and **h** the impressed magnetic force,

$$\mathbf{eJ} + \mathbf{hG}$$

to represent their activity per unit volume, and in all space,

$$\Sigma\,(\mathbf{eJ} + \mathbf{hG}) = \Sigma\,(Q + \dot{U} + \dot{T}) \quad . \quad . \quad . \quad (9)$$

instead of (7). This is the integral equation of activity. We cannot remove the sign of summation and make the same form do for the unit volume, for this would make every unit volume independent of the rest, and do away with all mutual action between contiguous elements and transfer of energy between them. This matter will be returned to in connection with the transference of energy.

38. The distinction between $\mathbf{H}_1$ and **H** and between $\mathbf{E}_1$ and **E** is often a matter of considerable importance. We have

$$\mathbf{H} = \mathbf{h} + \mathbf{H}_1, \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

$$\mathbf{E} = \mathbf{e} + \mathbf{E}_1. \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

Now it is **E** and **H** that are effective in producing fluxes. Thus **E** is the force of the flux **D** and also of **C**; and **H** is the force of the flux **B**. On the other hand, in the laws of circuitation, as above expressed, the impressed forces do not count at all; so that we have, in terms of the forces **E** and **H**,

$$\text{curl}\,(\mathbf{H} - \mathbf{h}) = \mathbf{J}, \quad . \quad . \quad . \quad . \quad . \quad (12)$$

$$-\,\text{curl}\,(\mathbf{E} - \mathbf{e}) = \mathbf{G}, \quad . \quad . \quad . \quad . \quad . \quad (13)$$

equivalent to (4) and (5). To distinguish from the forces of the fluxes, I sometimes call $\mathbf{E}_1$ and $\mathbf{H}_1$ the forces "of the field." Of course they only differ where there is impressed force. As the distribution of the energy, as well as of the fluxes depends upon **E** and **H**, it is usually best to use them in the formulæ.

## ELECTRO-MAGNETIC REPULSION.*

BY PROF. J. A. FLEMING, M.A., D.SC., M.R.I.

§ 1. On the 2nd day of October, 1820, Ampère presented to the Royal Academy of Sciences in Paris an important memoir, in which he summed up the results of his own and Arago's previous investigations in the new science of electro-magnetism, and crowned that labour by the announcement of his great discovery of the dynamical action between conductors conveying electric currents.† Respecting that achievement, when developed in its experimental and mathematical completeness, no less a writer than Clerk Maxwell calls it "one of the most brilliant in the history of physical science." Our wonder at what was then accomplished is increased when we remember that hardly more than two months before that date John Christian Oersted had startled the scientific world by the announcement of the discovery of the magnetic qualities of the space near a current-traversed conductor. Oersted called the actions going on around the conductor the "electric conflict," and in his first Paper,‡ in describing the newly-observed facts, he says:—"It is sufficiently evident that the *electric conflict* is not confined to the conductor, but is dispersed pretty widely in the circumjacent space." "We may likewise collect," he adds, "that this conflict performs circles round the wire, for without this condition it seems impossible that one part of the wire when placed below the magnetic needle should drive its pole to the east and when placed above it to the west." These few words are taken from the original paper, which stimulated the philosophic thought of Ampère and his contemporaries, and started into existence a wave of discovery, placing us in possession of the facts which form our starting point to-night.

§ 2. It will be unnecessary to spend more than a moment or two in illustrating the now familiar interactions of two circuits traversed by currents in the same or opposite directions. Holding a circular coil traversed by a continuous electric current near to a similar circuit free to move, we are well aware that when the circuits are parallel to each other there is an attractive force between them if the currents in adjacent parts of the circuits flow in the same direction and a repulsive effect if they flow in the opposite. This is the electro-dynamic action discovered by Ampère and utilised in the construction of instruments for the measurement of electric currents in practical work. If one such conducting coil, such as that of the electro-magnet now before me, is traversed by an alternating current, and the other is simply a closed circuit or coil placed a little distance off, but in its field, I feel sure I am free to assume that all here are aware of the effect which will be produced. The closed circuit becomes the seat of an alternating induced current, which, if our inducing current is sufficiently powerful, can be made to render itself evident by illuminating a small incandescent lamp placed in the secondary circuit.|| Notice, however, that in performing the experiment the secondary circuit must be so placed that the magnetic lines of force of the primary coil perforate through the secondary circuit. If the secondary circuit is held in such a position that the reversal of direction

* A discourse delivered at the Royal Institution of Great Britain on Friday evening, March 6, 1891.

† Mémoire Présenté à l'Académie Royale des Sciences le 2 Octobre, 1820, où se trouve compris le résumé de ce qui avait été lu à la même Académie les 18me et 25me Septembre, 1820, sur les effets des courants Electrique par M. Ampère. *See* Vol. XV. *Annales de Chimie*, 1820.

‡ In the *Annals of Philosophy* for October, 1820, Vol. XVI., p. 274, is to be found an English translation of Oersted's original Latin essay, dated July 21, 1820, describing his immortal discovery. This Paper is entitled "Experiments on the Effect of a Current of Electricity on the Magnetic Needle," by John Christian Oersted, Knight of the Order of Danneborg, Professor of Natural Philosophy in Copenhagen.

|| The experiments here referred to were mostly performed with an alternating-current magnet, having a core of divided iron about 3in. in diameter and 12in. long, excited by a Siemens alternating-current dynamo giving a current at an electromotive force of rather less than 200 volts. A small shelf around the core a little above the middle serves as a support for rings, &c., to be projected. The performance of these experiments on a scale suitable for large audiences requires from 10 to 15 horse-power at least, and can hardly be shown well unless the alternator can provide a current of 100 amperes at 100 volts available at the moment of maximum demand. The magnet of course takes very little actual current until the metal plate or ring is held near it, when the impedance is immediately reduced.

Digitized by Google

of the primary current causes no reversal of direction of the magnetic field traversing the secondary circuit, because it is not linked with any of the lines of force of the primary, the secondary circuit is no longer the seat of any induced current.

Note also that this electro-magnetic induction whilst taking place across space, is not interfered with by the interposition of a non-conducting screen. The magnetic induction passes freely through an inch board or a plate of glass, but if we interpose a thick copper sheet (Fig. 1.) we cut off the secondary current or screen the secondary circuit from the inductive action of the primary. The secondary coil is, in fact, an electro-magnetic eye which can *see through* an inch of wood, but to which a sheet of zinc is semi-transparent, and a thick sheet of copper quite opaque, as far as the electro-magnetic radiation of the wave-length employed is concerned. The rapid heating of this copper screen makes us aware that the secondary currents are now being induced in the copper sheet in the form of eddy currents, and it screens the secondary circuit because the inductive action of these eddy currents on the side remote from the magnet is exactly equal and opposite to that of the primary circuit on the secondary coil.

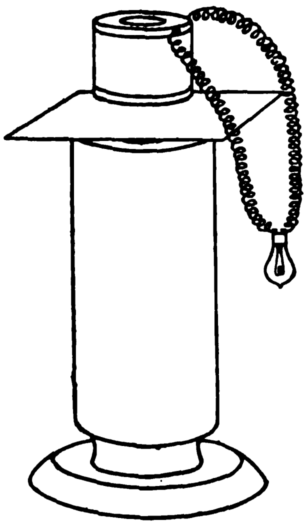

FIG. 1.—Copper Plate interposed between a Primary and a Secondary Coil, and shielding the Secondary from Induction.

§ 3. Connecting together these elementary facts, we are easily able to explain another well-known fact. If a continuous current is sent through the coils of a large electro-magnet, and we magnetise its iron core very powerfully, it is found to be impossible to strike the pole of the magnet a sharp blow by means of a sheet of copper. Holding a sheet of copper over such a magnetic pole, and energising the magnet, the hand holding the copper sheet feels a repulsive action at the moment when the current is put on and an attractive action when it is cut off. If we try to slap the magnet sharply with the copper sheet, it is found that this repulsive force prevents anything like such a sharp blow being given to the pole when the current is on, as can be given when the current is off. Moreover, when a very powerful electro-magnet is employed, it is found that a disc of copper let fall over the pole does not fall down sharply and quickly on to it when the current is flowing through the coils of the magnet, but settles down softly and slowly as if falling through some sticky fluid. We know that the correct explanation of these facts is to be found in the statement that the motion of the conductor towards the magnetic pole causes eddy electric currents to be generated in it by electro-magnetic induction, and that these being in the opposite direction to the energising current of the magnet cause a repulsive force to exist between the inducing and secondary circuits which creates the apparent resistance we feel.

In order to exhibit the stress brought into existence between an electro-magnet and a metal sheet held near it when induced currents are set up in the disc, we have arranged the following experiment :—Over the pole of a powerful electro-magnet we have balanced a small disc of copper, the size of a penny, carried on one end of a delicately-balanced bar. A mirror attached to that bar serves to reflect on to the screen a ray of light indicating the smallest motion of the copper piece. On magnetising the magnet the copper is suddenly repelled, but comes to rest again immediately in its initial position. When the magnet is demagnetised the copper experiences a momentary attraction. These attractions and repulsions are obviously due to the Ampèrian stress set up between the magnet and the metal by reason of the induced currents set up in the latter. Impulsive effects of this nature have been particularly studied by Mr. Boys (see *Proc. Phys. Soc. of London*, Vol. VI., p. 218, *A Magneto-electric Phenomenon*).

§ 4. Let me, in the next place, ask you to contemplate a circuit, say a closed conducting ring, suspended in front of the

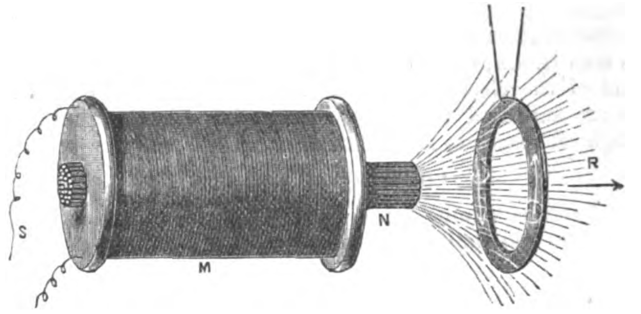

FIG. 2.—Copper Ring hung in the Field of an Electro-magnet, and repelled or attracted when the Current is put on or cut off.

pole of an electro-magnet, and that the coils of the electro-magnet are transversed by an alternating-current of electricity (Fig. 2). The magnetic field of the magnet is then an alternating field. We shall suppose it to vary in strength, according to a simple periodic law. The closed circuit is therefore subjected to an inductive action, and we know that the induced electromotive force in that circuit is at any instant proportional to the rate of change of the magnetic field in which it is immersed. If, therefore, the variation in strength of that field is represented geometrically by the ordinates of a periodic

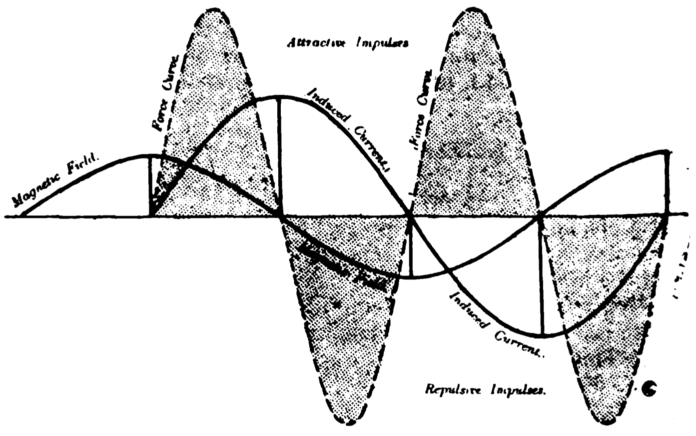

FIG. 3.—Diagram showing the equality of the attractive and repulsive impulses in a non-inductive circuit when held in an alternating Magnetic Field.

curve, the varying electromotive force acting in the ring circuit is represented by the ordinates of another such curve of equal wave length, shifted a quarter of a wave length behind the first. In the diagram before you the variation of the induced magnetic field, and the induced electromotive force in the circuit, are represented as usual by two harmonic curves. This induced electromotive force creates an induced current flowing backwards and forwards in the ring, and we shall, in the first instance, suppose that this current flows in exact synchronism with its electromotive force. The induced current and the inducing magnetic field may therefore be represented as to relative phase and strength by the curves in the diagram (Fig. 3). The dynamical action, or the force which the ring experiences, is at any instant proportional to the product of the strength of the magnetic field

Digitized by Google

in which the ring is immersed and to the strength of the induced current created in it. If we multiply together the numerical values of the ordinates of these two curves at any and every point on the horizontal line, and set up a new ordinate at that point representing this product, the extremities of these last ordinates define a curve, which is a curve representing the *force* acting on the secondary circuit, and it is, as you see from the diagram Fig. 3, a wavy curve having a wave length equal to half that of the first two curves. Moreover, the whole area enclosed between the outline of this force curve and the horizontal line represents to a certain scale the time integral of that force, or the *impulse* acting on the secondary circuit, and the theory shows us that, under the assumptions made the secondary circuit so acted upon experiences in each period of the current four impulses, two positive or repulsive, and two negative or attractive. Hence, it comes to this, that such an ideal conducting circuit held in front of an alternating electro-magnet should experience a rapid alternate series of equal pushes and pulls, or of little impulses to and from the magnet. These equal and opposite impulses in quick succession would neutralise one another, and our supposed circuit would not, on the whole, be subject to any resultant force.

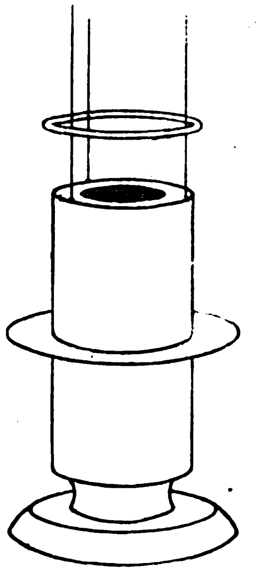

FIG. 4.—Aluminium ring projected rom the pole of an alternating electro-magnet, and floating over the ole when restrained by three strings.

§ 5. Quite otherwise is it, however, when we present a real conducting circuit to the pole of an electro-magnet traversed by a powerful alternating current. We find that under the actual circumstances there is a powerful repulsive action between the pole and the circuit. The exact nature of the electro-magnetic repulsion it is our business now to explore.

Taking in my hands a copper ring, I hold it over the pole of this powerful vertical alternating electro-magnet, and find at once that there is a perceptible and strong repulsion. Letting the ring go, it jumps up into the air, impelled so to do by the electro-magnetic repulsion acting upon it (Fig. 4). All good conducting rings will execute this gymnastic feat, and rings of copper and aluminium are found to be most nimble of all. Rings of zinc and brass are sluggish, and a ring of lead will not jump at all. We owe the discovery of this striking effect to Prof. Elihu Thomson, and he has explored in all directions the consequences and nature of this interesting effect. Why is it that our real copper and metal rings behave so differently, when immersed in an alternating field, to ideal rings of conducting matter? The explanation is not very difficult to find. The real ring possesses a quality, called its inductance, of which we took no account in our examination of the case a moment ago.

§ 6. Before me lies a very large bobbin of wire (Fig. 5), and the ends of this coil are connected to an incandescent lamp. We send a current of electricity through the bobbin and the lamp, and have arranged matters as in the diagram before you, so that the current divides through the two circuits of lamp and bobbin. Under these circumstances, the divided current is just sufficient to illuminate faintly the lamp. I break the circuit of the battery, and you see that the lamp flashes up for a moment, and we are well aware that this effect is due to the electro-magnetic momentum of the coil, or to its inductance, in virtue of which the current continues to flow on in the bobbin for a short period after the impressed electromotive force is withdrawn. Also, we know that there is a small but definite time required before the current practically reaches its full strength in the bobbin when the electromotive force is again applied. These effects are the self-induc-

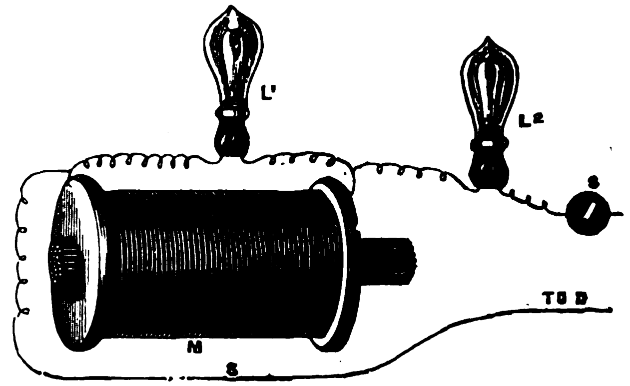

FIG. 5.—Incandescent Lamp and coil arranged to exhibit the effect of the inductance of the coil.

tive effects of a coil first noticed by Prof. Joseph Henry in 1832, and subsequently fully examined in the ninth series of Faraday's Experimental Researches in Electricity. Every circuit of any kind, disc, ring, or coil of wire, possesses a certain degree of this quality of self-induction, and, as a natural consequence, it follows therefrom that if that circuit is subjected to a periodically varying electro-motive force acting upon it, that the current produced in it will always be in arrear of the electromotive force in phase. The current induced lags in phase behind the inducing electromotive force. This "lag" of the current behind the impressed harmonically varying electromotive force in conse-

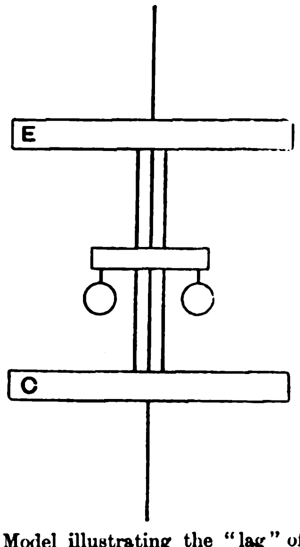

FIG. 6.—Mechanical Model illustrating the "lag" of the current in an inductive circuit.

quence of self-induction may be illustrated mechanically thus: Three light wooden laths are connected together by a flat steel band, and the system hung up by a string like a pair of astatic magnetic needles (Fig. 6). If we take hold of the upper rod and move it backwards and forwards on a horizontal plane, compelling it to execute harmonic oscillations, the upper and lower rods move together synchronously. Let the upper rod symbolise impressed electromotive force, and the lower rod resulting current. Under present circumstances, these two move always in step with one another. Next load down the middle rod or connecting mechanism by means of two lead weights, and give it *inertia*. On again taking hold of the upper rod and causing it to execute forced harmonic oscillations, the

Digitized by Google

lower rod no longer vibrates in tune with it. It lags in phase behind the top one, and we thus illustrate, though not perhaps by a perfect mechanical analogy, the effect of electric inertia in the intermediate mechanism in causing a lag of current behind impressed electromotive force.

§ 7. Returning for an instant to the diagram we considered just now, we must correct it to make it fit in with the facts of nature, and we must represent the periodic curve which stands for the fluctuations of the induced current in the ring as shifted backwards or lagging behind the curve which represents the electromotive force in the circuit brought into existence by the fluctuating magnetic field. Making this change in our diagram (Fig. 7), and forming as before a force curve to represent the impulses on the ring, we now find that owing to the "lag" of the secondary current, one set of the impulses, namely, the positive or repulsive impulses have been enlarged at the expense of the negative or attractive impulses. Theory, therefore, points out that as a consequence of the self-induction of the ring the balance between the attractive impulses and repulsive impulses is upset and that the latter predominate. Our real ring behaves, therefore, very differently to our ideal ring. The real ring, is strongly repelled because the resultant action of all the impulses is to produce on the whole an electro-magnetic repulsion. This repulsion is evidence of the self-induction of the circuit exposed to the magnetic field, and it forms a new way of detecting it. But although this is part of the truth,

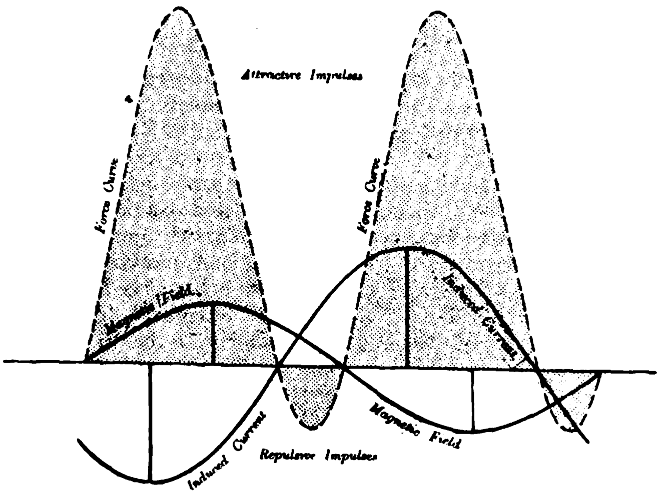

Fig. 7.—Diagram showing the inequality of the attractive and repulsive impulses in the case of an inductive circuit when held in an alternating Magnetic Field.

it is not the whole truth. The lag of the induced current in the ring, and hence the predominance of the repulsive impulses depends on the conductivity of the material of which the ring or circuit is made; and the better this conductivity the greater is that repulsion, both because the induced current and the "lag" are thereby increased. Hence it comes to pass that there are two factors involved in making this repulsive effect, the conductance of the ring or disc and its inductance. For equal conductivities, the greater the self-induction the greater the repulsion. For equal self-inductions, the greater the conductivity of the circuit so much the more repulsive effect will be produced. Time does not permit me to enlarge on the strict analysis of the effect. Its broad outlines are indicated, perhaps, sufficiently by what has been said.

§ 8. We can show the effect of the relative conductivity by discs of equal size, and therefore of equal self-induction, of *weighing* similar discs of various metals over an alternating pole. Here, for instance, are discs of copper, zinc, and brass of equal form and size. Placing these discs on the scale pan of a balance, and suspending them over the alternating pole, I am able to prove that the repulsion on the copper disc is greater than that on the zinc, and that on the zinc greater than that on the brass.*

* Experiments of this kind have been made by M. Borgman. See *Comptes Rendus*, No. 16, April 21, 1890, p. 849, and also February 3, 1890, Vol. CX., p. 233.

The same result can be illustrated by placing over the pole of our alternating magnet a paper tube. Taking one of the copper rings in my hand, and first exciting the magnet, I let the ring drop down the tube. It falls as if on an invisible cushion that buoys it up, and it remains floating in the air. If rings of different metals and equal size are placed on the tube, they float at different levels like various specific-gravity beads in a liquid. The greater the conductivity of the ring the greater is the repulsion on it, in any given part of the alternating field, and hence the highly conducting rings will be sustained on a weaker field than the

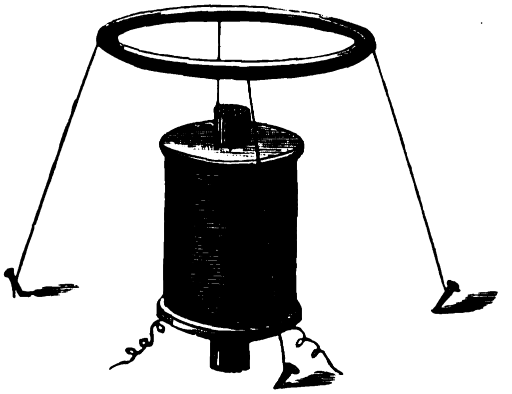

Fig. 8.—Copper ring "floating" in air over the pole of an alternating current electromagnet, when restrained by three strings.

feebler conducting rings, assuming the rings to have about equal weights. Moreover, we are able to show by another experiment the fact that these rings are traversed, when so held, by powerful electric currents. If we press down the copper ring upon the zinc or brass ring floating beneath it, the rings are attracted together and the copper ring holds up the zinc. This is obviously because the rings are all traversed by induced currents circulating in the same direction.

§ 9. It is, of course, an immediately obvious corollary, from all that has just been said, that any cutting of a ring or disc

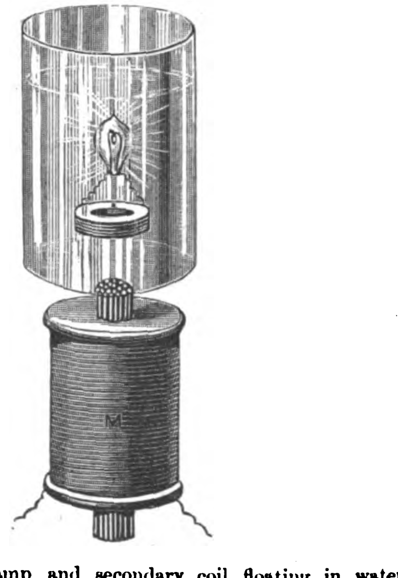

Fig. 9.—Incandescent lamp and secondary coil floating in water and repelled by an alternating current electromagnet, placed beneath.

which hinders the flow of the induced currents causes the whole of the repulsion effects to vanish. We illustrate this by causing a ring of copper wire to jump off the pole, and then cutting it with pliers, find it has ceased to be capable of giving signs of life. When the metallic masses or circuits which are presented to the alternating magnetic pole are of very low resistance the electromagnetic repulsion may become very powerful, many pounds of thrust or push being produced by apparatus of quite moderate size. It is, in fact, quite startling to hold over the pole of such an alternating magnet as I have before me a very thick

Digitized by Google

plate of high conductivity copper. It would greatly surprise any one not acquainted with these principles to be told that a massive copper ring weighing eight or ten pounds could be made to float in the air, but you have ocular demonstration before you that this feat can be performed. The ring needs to be tethered by a couple of light strings, to prevent it from being thrown off laterally, although these strings in no way support its weight (Fig. 8).

One of the most beautiful of Prof. Elihu Thomson's experiments exhibits this effect of electro-magnetic repulsion on a closed coil, which is buoyed up in water by a small incandescent lamp in circuit therewith. In the glass vase before you floats a little glow-lamp like a balloon (Fig. 9). The car consists of a coil of insulated wire, and the ends of this coil are connected with the lamp. The whole arrangement is accurately adjusted to just, or only just, float in water. Placing the vase over an alternating magnetic pole, you see that the magnetic induction creates a current in the coil which lights the lamp, and, moreover, that the electro-magnetic repulsion on the coil causes the lamp and coil to rise upward in the water.

*(To be continued.)*

## PHYSICAL SOCIETY.

At a meeting of this society on March 6, 1891, Mr. James Swinburne read a

**"Note on Electrostatic Wattmeters."**

After referring to the history of the electrometer method of measuring power developed by alternating currents, the author pointed out that the necessity for taking two readings from which to determine the watts might be obviated by having the quadrants

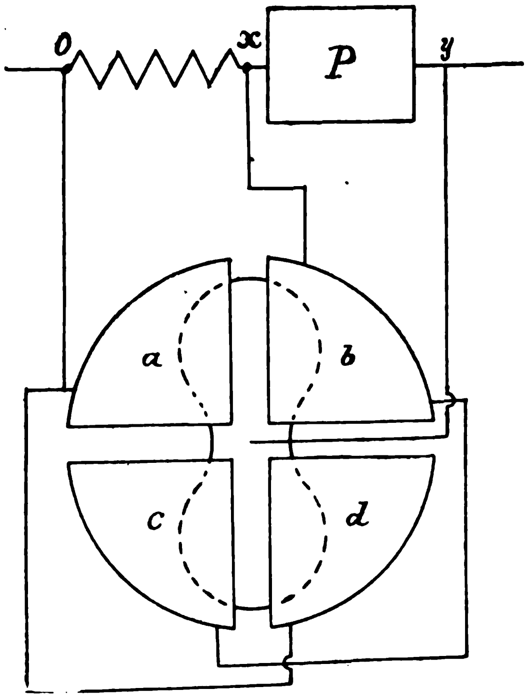

Fig. 1.—Electrometer arranged to measure watts with two readings.

separate instead of connected in pairs, as in the ordinary method. When Joubert published his tests of a Siemens dynamo, Profs. Fitzgerald and Ayrton simultaneously suggested the use of an electrometer as wattmeter. Non-inductive resistances are connected to the transformer, motor, or other apparatus in which the power is to be measured, so as to be in series with the apparatus, and on opposite sides of it, and the four ends of these two resistances are connected with the four quadrants. Under these circumstances the deflection of the needle is a measure of the watts. The disposition is shown in Fig. 1. A non-inductive resistance, $o$, $x$, is in series with the part of the circuit to be measured, and the quadrants, $a$, $b$, $c$, $d$, are in shunt to it, so that their potentials are $o$ and $x$. The needle is connected to the other side of the circuit to be tested, and is at potential $y$. If the fall of potential over the resistance is small, the instrument is not sensitive—if large, it is not accurate. Prof. Ayrton has, therefore, introduced an accurate method depending on two readings. By using two equal resistances the quadrant electrometer may be arranged to read power directly. This is shown in Fig. 2. The quadrants, $a$, $b$, $c$, $d$, are at the potentials $o$, $x$ and $y$, and $x+y$ respectively. As this arrangement involves an end, or a side pull on the needle, another arrangement

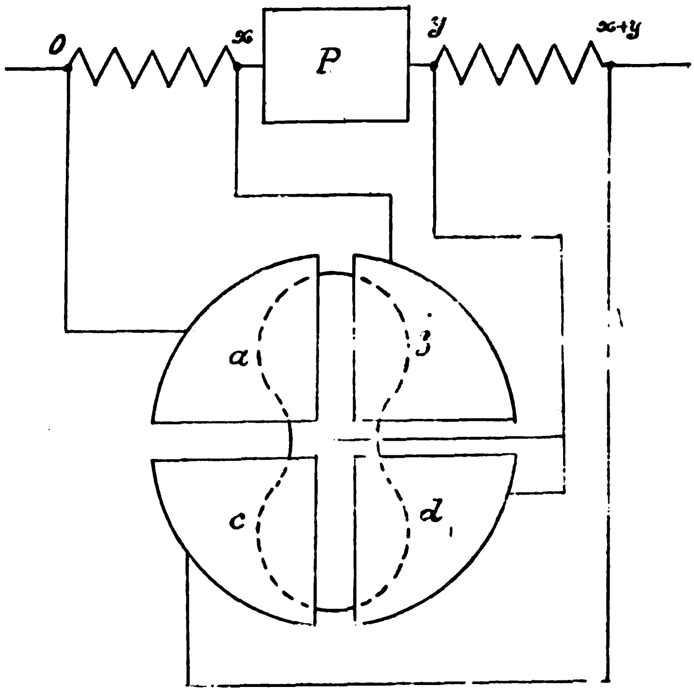

Fig. 2.—Electrometer arranged to read Power directly.

shown in Fig. 3 is better for commercial work. To increase the maximum deflection obtainable so as to make an instrument capable of being read by a pointer, the needle is made in two halves fixed one below the other on the same stem, and, instead of quadrants, semicircular boxes are employed. The needle consists of two half-discs, each between pairs of fixed half-discs. A metal torsion suspension may then be used, and the needle may have a mirror or index. It can be made to read direct, through an arc of 120° or so. The electromagnetic wattmeter is the most suitable instrument for measuring low pressure powers, but it needs many spare coils to

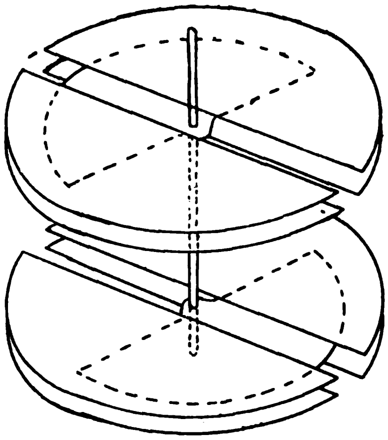

Fig. 3.—Electrometer with semicircular "needles" for measuring watts.

give it a large range. For high pressure work, such as measuring power lost in condensers, the electrometer is more convenient.

Prof. Perry inquired as to what kind of *law* the instrument had, and Mr. Blakesley asked whether it was convenient to use.

Mr. E. W. Smith pointed out that there was no necessity to take two observations in the ordinary electro-meter method, for, by using a false zero, one deflection gave the watts. Further, the use of the false zero rendered it unnecessary to employ any other voltmeter when experimenting at constant pressure.

The President said the historical part of the Paper was not quite correct, and recalled attention to the fact that when high pressures were used, a single reading obtained with the ordinary method of connecting up gave the power. For ordinary low voltages, however, the false zero method, described by Mr. Smith, was very convenient.

Digitized by Google

Mr. Swinburne, in reply to Mr. Smith, said the observation of the false zero really meant another reading. As to the law of his wattmeter, referred to by Prof. Perry and the President, he said he never calculated a law, but calibrated the instruments directly.

Prof. S. P. Thompson, D.Sc., now took the chair, and a Paper on "Interference with Alternating Currents," by Prof. W. E. Ayrton, F.R.S., and S. Sumpner, was read by the latter. The Paper relates to the phenomena which occur when alternating electric pressures are impressed on circuits made up of various combinations of resistances, condensers, arcs, and inductive coils; to the characteristics of alternators, to the properties of transformers, and to the peculiarities exhibited by the Ferranti mains. In one of the experiments an inductive coil and a condenser were connected in series, and a pressure of 25 volts, as measured by a Cardew voltmeter, impressed on its terminals; the pressures on the two parts, measured in the same way, were 110 and 104 volts respectively, thus showing that each of the two parts was much greater than the whole. On joining a condenser and inductive coil in parallel, an ammeter in the main circuit indicated 5·5 amperes, whilst those in the branches showed 6·4 amperes passing through the condenser and 10 amperes through the coil. Other experiments of a similar nature were described, and it was pointed out that the ratio of the sum of the two parts to the measured total may be large, being about eight in the case first mentioned. Theoretically this ratio might be anything, depending as it does on the phases of the pressures in the two parts, and these phases are determined by the ratio of the impedance of the coil to its resistance; practically, however, it was not easy to get a coil of large self-induction and very small resistance.

Alternate-current arcs and condensers give results of the same general character as those above described, as also do arcs and inductive coils, such as the regulating coils of lamps; this may cause considerable error in estimating the power supplied to such lamps. The magnitude of the error was found to depend greatly on the quality of the carbons and the character of the arc. With bad carbons and a hissing arc the error was very great, but with good cored carbons, burning steadily, it was not very serious.

Combinations of inductive and non-inductive coils exhibit marked peculiarities, particularly if the inductive one be a transformer coil. This last arrangement gave distinct evidence of interference or difference of phase when the secondary of the transformer was open, but when closed and with a moderate load, the difference of phase disappeared, thus showing that under these circumstances the primary coil had no appreciable self-induction.

On the subject of alternator characteristics, a graphical method of drawing the E.M.F. curve from the terminal curve was described, and the dependence of the terminal curves on the character of the external circuit pointed out. Keeping the speed, exciting current, and armature current constant, the pressure between the terminals was shown to be dependent on whether the external circuit consisted of condensers, resistances, or inductive coils, the pressure being greatest in the former case and least in the latter. The true E.M.F. of the dynamo, however, was the same in all the cases, but it became less as the armature current increased. From these results the authors conclude that the drop in E.M.F. with large currents is due to reaction on the field, but that the change of terminal pressure cannot be all attributed to this cause.

Transformers, it was shown, are powerful controllers of phase, for the primary and secondary currents are nearly always circulating in opposite senses, the phase angle for a 1 to 1 Mordey transformer experimented on, varying from 170deg. at no load to 180deg. at full load. The relation between the strengths of the primary and secondary currents, $A_p$ and $A_s$ was found to be a linear one, of the form $\frac{P}{S} A_p = a + \beta A_p$, where P and S are the number of turns in the primary and secondary respectively, and $a$ and $\beta$ constants; $a$ representing the exciting current and $\beta$ being nearly unity. The phase angle $\phi$ between the currents was given by the equation

$$-\cos\phi = \frac{\frac{1+\beta^2}{2} A_s + a\beta}{\beta A_s + a}$$

The results of numerous experiments on a transformer of the Mordey type, in which coils having different numbers of turns were put in parallel with each other, were given. In some cases resistances were put in circuit with the coils, and in others one or more of these resistances were cut out. Remarkable interference effects were thus produced, for in some combinations the volts or currents were additive, whilst in others they were nearly differential. In connection with the Ferranti effect, experiments had been made by putting a condenser on the terminals of the secondary of a transformer, and noting the resulting increases in pressure, both in the primary and secondary circuits. The results obtained with a given condenser, and approximately constant secondary pressure show:

1st. That whether the transformation be up or down, the percentage rise in the secondary is greater than that in the primary.

2nd. That these percentage rises diminish as the secondary current increases.

3rd. That they increase with the ratio of transformation.

4th. That the rise in the secondary may be considerable without that in the primary being appreciable.

5th. That the rise in the secondary still persists, even when large currents are flowing.

These facts lead the authors to believe that the "Ferranti effect" is due to some kind of interaction between the cable condenser and the self-induction of the transformer, and that is not wholly due to armature reactions in the dynamo.

DISCUSSION.

In the discussion on the Paper, Mr. SWINBURNE said the character of the "Ferranti effect" had been wrongly stated, for he understood Prof. Ayrton to say that the pressure between the Ferranti mains was greater at the London end than at Deptford. This, he contended, was impossible. He also said the effects now described of putting a condenser on the secondary of a transformer, and noticing the rise in both primary and secondary volts, were due to the waste field of the transformer. In large transformers such as those at Deptford the magnetic leakage was proportionately much less, and no such effects would be noticeable with them. Referring to the relation between the primary and secondary currents in transformers, he said it was convenient to look at the primary from two points of view, and consider one part of it as producing the magnetisation and the other as neutralising the effect of the secondary current.

Mr. MORDEY described an experiment on armature reactions in alternators in which one of the armature coils of a 50-H.P. machine was isolated from the rest and connected directly to a Cardew voltmeter. On varying the load from 0 to the full output (20 amperes) the voltmeter on the isolated coil was quite stationary, thus showing that no appreciable armature reaction occurred.

Mr. E. W. SMITH remarked that the formula connecting the primary and secondary currents holds true over a very wide range, for he had experimented on a Kapp transformer which gave ($a$) constant and ($\beta$) = 1 for frequencies varying from 20 to 200.

Mr. BLAKESLEY gave the following formula as applying to transformer currents generally:—

$$\left(\frac{A_p}{A_s}\right)^2 = \frac{n^2}{m^2}\left\{(1 + k\,r_2^2) + \frac{q\,r^2}{v}\right\},$$

where $r_2$ = resistance of secondary, $v$ is proportional to the frequency, $m$ and $n$ the primary and secondary terms, and $k$ and $q$ are constants depending on the disposition of the iron. This formula he found to very nearly represent Ferrari's results, and he hoped others would test its applicability to various types of transformers. He believed himself to be the first who carried out an interference experiment, when he put a condenser in parallel with an inductive coil six years ago. He mentioned the matter now because that arrangement had been put forward by Mr. Glazebrook in explanation of the "Ferranti effect." Mr. Glazebrook, however, had made an error in stating that under certain conditions one of the currents may become infinite.

Dr. THOMPSON thought the word interference had been used in a somewhat different sense to its ordinary usage in optics, and asked for an authoritative definition of its meaning in the Paper under discussion. The experiments on the alternating arc he considered very remarkable, as well as those on the dynamo, which give various terminal pressures when its E.M.F. and current were the same, but the external circuit of different character.

Prof. AYRTON pointed out that the measurements on the rise of volts by putting on condensers, mentioned in the Paper, were not strictly analogous to those made by Mr. Ferranti, for his were made by pilot transformers, one placed between the primary terminals of the Deptford transformer, and the other on the secondary of the London transformer; whereas in the cases now brought forward the volts measured were those at the primary and secondary of the same transformer. On the subject of arc lamps, he said Messrs. Kolkhorst, Thornton, and Weekes, who made the experiments, found that great lag only occurred when the carbons were bad and the arc hissing. If the apparent and the true power spent in such an arc were measured, a great difference existed between them. Dr. Hopkinson, he said, had shown that this might be expected if the arc had a constant back E.M.F. which changed sign with the direction of the current.

A Paper on "The Theory of Dissociation into Ions and its Consequences," by Prof. S. U. Pickering, F.R.S., and another on "Some Points in Electrolysis," by Mr. J. Swinburne, were postponed.

Addendum to Report of Physical Society Meeting on February 27, 1891. The transformer on which the tests described in Prof. Ayrton and Mr. Taylor's Paper were made, was of the Mordey type, having been kindly lent by the British Electrical Engineering Corporation.

## THE PARIS-NEW YORK TELEGRAPH COMPANY.*

The big *coup*, upon the strength of which during the past eight months the initiated on the Bourse have been manipulating for an upward movement and some premium upon the shares of the P.Q. Cable, was officially announced last week, by which time it was an open secret. The following is the basis of this operation which one might well wish to have been realised otherwise than by a company without a future and virtually in a state of liquidation. The project consists in connecting the solitary P.Q. Cable with a new cable

* From the *Bulletin de l'Electricité.*

Digitized by Google

going from New York to Puerto-Plata, where it would join the important system which the Société Française des Télégraphes Sous-marins has established amongst the Antilles and along the coast of Guiana and Brazil. The cable is to be laid by Messrs. Siemens Bros., of London, which is very curious for reasons we shall enlarge upon later. The money will be provided by an Anglo-French syndicate, which will take 14,000 shares, 5,000 of which will be immediately issued to the public. The Société Française will obtain by this new line the important advantage of direct communication with Europe, and of being able to transmit by its cables messages from the Antilles, Guiana, and Brazil to Europe and *vice versâ*, which will stimulate its traffic. The P.Q. Company should also have an element of increased activity, and it is pretty certain to make use of this fact, especially to solicit new favours from the French Government under the cover of its concession for the benefit of its American proprietors, the Commercial Cable Company, and Messrs. Bennett and Mackay. It is well known that these gentlemen are holders at the present moment of nearly half the shares of the P.Q. Company, bought at a very low price, and are the real masters through a Council of Administration absolutely in their interests. We will briefly detail the history of this capture and the causes which led to it.

We understand, however, that the news, published in advance by several journals, of an arrangement between the Société Française and the P.Q. Company is at least premature. Another thing that renders the project sufficiently problematical, is that the financial syndicate which is to take the 14,000 shares has imposed as a condition the termination of the lawsuit now pending between the Anglo-American Telegraph Company and the P.Q. Company. This action is based on the breaking of an agreement made between the two companies and repudiated at the end of December, 1886, by the new Board placed at the head of the P.Q. Cable by Mr. Mackay to continue in Europe the war which he had declared in the United States against Mr. Jay Gould, a participator in the Anglo-American Pool through the American Cable Company. The P.Q. Company lost its case before the Tribunal of Commerce of the Seine, and was condemned to pay to the Anglo-American Pool an amount equal to 2,000fr. for every day since December 31, 1886, up to the date of renewing the agreement with the Pool. By this judgment the tidy sum of nearly £120,000 damages to be paid by a Company which has no reserves but only debts. The P.Q. Company appealed from this judgment and invoked the famous letter from M. Granet of December 18, 1886, which ordered it to break the agreement in question concluded without the express and written authority of the French Government, an authority which M. Cochery, M. Granet's predecessor, did not consider necessary according to the *cahier des charges* of 1889. The Court of Appeal did not wish to decide before this particular incident was dealt with by the Administrative Tribunals, and it is in this position that the matter has been for more than two years, first before the Council of the Prefecture then before the Council of State. It will be seen that the action lost in the first instance by the P.Q. Company has not arrived at its second stage, that of appeal, which will only commence after the Council of State have pronounced upon the interpretation which ought to be given to the letter of M. Granet; whether it was a case of *force majeure*, or whether the letter only convenient complaisance intended to furnish the P.Q. Company with a pretext. A previous Minister did not consider necessary that which one of his successors declared indispensable. It will thus be seen that the accomplishment of this new cable scheme is deferred to a date which appears to be distant. If, however, it does ultimately come off it will give rise to a very curious consideration which ought to place M. Jules Roche, Minister of Commerce, Posts and Telegraphs, under the necessity of intervening afresh as M. Granet's successor. In fact, if the P.Q. Company is so dependent on the French Government by its *cahier des charges*, which we will consider later, that it cannot make an agreement without its consent (see letter from M. Granet of December 18, 1886), it is absolutely indispensable that in exchange for this Governmental control M. Jules Roche should take the following decision: "The P.Q. Company in virtue of its French origin, of its *cahier des charges*, and of the privileges it possesses on this account, ought now that French firms have established in France factories for the manufacture of submarine cables to apply to French industry for all new cables which it is about to lay." This will be so much the more easy for the P.Q. Company that it will enable it to use its ship, the "Pouyer-Quartier." It seems to us that this decision of the Minister would be logical and would perhaps operate in favour of the Company with the Council of State, by strengthening the letter of M. Granet and the arguments of its advocate. The *employés* of the Company nominated by Mr. Mackay should seriously consider this new means of defence to safeguard the interests of their patron. But this question of the manufacture and laying of the projected cable between New York and Puerto-Plata by the P.Q. Company is much more serious than appears. And this is why :—

When this Company was established in 1879 by M. Pouyer-Quertier, with a capital of 42 million francs, it undertook to lay two cables from France to the United States, through Messrs. Siemens Brothers, at the price of £800,000 per cable. The Company was to complete the purchase of the second cable, upon which it paid Messrs. Siemens £400,000 on account, by issuing bonds for the purpose, its share capital being exhausted by the cost of ships, land lines, formation of the Company, &c. But the £400,000 on account of the second cable, paid to Messrs. Siemens, who now undertake to make the new cable, have never, it is presumed, been returned by them to the P.Q. Company, or, at least, if they have been, the shareholders have seen and known nothing of it. At all general meetings which have taken place since 1881, there has never, in fact, been the slightest allusion to this point, which is as delicate as it is important. Before 1886 the writer asked many times for explanations from the old Board, but was treated as indiscreet. Nevertheless, the new Board, which is entirely devoted to the cause of the shareholders, cleared up the question. It has talked and done nothing, as if it were an akward matter, and has contented itself with living peacefully at No. 53 in Rue Chateaudunas, worthy *employés* of Messrs. Mackay and Bennett, of the Commercial Cable Company. However, of two things, one, either Messrs. Siemens have returned the money, and it is useless to create new obligations to pay for the new cable, which should not cost more than £200,000, or Messrs. Siemens have not returned the money, and it is still more useless to create new obligations. In either case the shareholders should unite and take severe measures against their directors, and we will assist them with all our power.

A. R.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, March 13th.**

SOCIETY OF ARTS.

*4.30 p.m.* Popular Afternoon Lecture: "The Science of Colour," by Captain ABNEY, C.B., F.R.S.

INSTITUTION OF CIVIL ENGINEERS.

*7.30 p.m.* Students' Meeting. Paper to be read: "The Lanarkshire and Ayrshire Railways," by A. P. TAIT, B.Sc., Stud. Inst.C.E.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse: "The Culture of the Singing Voice," by FELIX SIMON, M.D.

**SATURDAY, March 14th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "The Forces of Cohesion," by LORD RAYLEIGH, F.R.S.

**MONDAY, March 16th.**

SOCIETY OF ARTS.

*8 p.m.* Cantor Lecture IV. 2. "Photographic Chemistry," by Prof. R. MELDOLA, F.R.S.

**TUESDAY, March 17th.**

INSTITUTION OF CIVIL ENGINEERS.

Ordinary Meeting. Paper to be discussed: "On the Subterranean Water in the Chalk Formation of the Upper Thames, and its Relation to the Supply of London," by JOHN THORNHILL HARRISON, M.I.C.E.

**WEDNESDAY, March 18th.**

INSTITUTION OF CIVIL ENGINEERS.

*2 p.m.* Students' Visit. The Goods Depôt of the London, Tilbury and Southend Railway, at Whitechapel.

ROYAL METEOROLOGICAL SOCIETY.

*7 p.m.* Ordinary Meeting. Paper to be read: "A Contribution to the History of Rain Gauges." By G. J. SYMONS, F.R.S.

SOCIETY OF ARTS.

*8 p.m.* Ordinary Meeting. Paper to be read: "Harbours, Natural and Artificial." By F. H. CHEESEWRIGHT.

**THURSDAY, March 19th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "Modern Chemistry in Relation to Sanitation," by Prof. C. MEYMOTT TIDY, F.C.S.

INSTITUTION OF MECHANICAL ENGINEERS.

*7.30 p.m.* Ordinary General Meeting. Papers to be read and discussed, as far as time permits: "Fourth Report of the Research Committee on Friction: Experiments on the Friction of a Pivot Bearing." "On recent Trials of Rock Drills." By EDWARD H. CARBUTT, and HENRY DAVEY.

**FRIDAY, March 20th.**

PHYSICAL SOCIETY.

*5 p.m.* Ordinary Meeting. Papers to be read: (1) "The Theory of Dissociation into Ions and its Consequences," by Mr. S. U. PICKERING, F.R.S. (2) "Some Points in Electrolysis," by J. SWINBURNE. (3) "The Variation of Surface Tension with Temperature," by A. L. Selby, M.A. (4) "On Magnetic Proof Pieces and Proof Planes," by Prof. S. P. THOMPSON.

# The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher, "*THE ELECTRICIAN,*" Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "*THE ELECTRICIAN*" Printing and Publishing Company, Limited, and be crossed "Coutts and Co." All other letters to be addressed to the Editor.*

*All letters intended for insertion in "*THE ELECTRICIAN,*" or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

*"*THE ELECTRICIAN*" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

*"*THE ELECTRICIAN*" is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of "*THE ELECTRICIAN*" commence in May and November.*

## SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months | 6 months. | 12 months. |
|---|---|---|---|
| | s. d. | s. d. | s. d. |
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.*
**It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued "*THE ELECTRICIAN*" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. The DIRECTORY was established in 1883, and the 1891 Edition, published on the 23rd February, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS.

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "*THE ELECTRICIAN*" Printing and Publishing Company, who are proprietors of the well-known "*ELECTRICIAN*" Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## ELECTRICAL STANDARDS.

The preparation of recommendations to Her Majesty in Council, relating to electrical standards (a task upon which the Board of Trade is just now engaged), is one, perhaps, of greater importance to electrical progress than any which that Department has yet been called upon to undertake. Electric Lighting Acts may be passed in haste and repealed at leisure; inquiries may be held, reports presented, and model Provisional Orders drafted. It is never too late to mend all these. Experience shows how one point is unworkable and how another has been overlooked, and ultimately the law of electric lighting will be found rather in the Provisional Orders than in the Acts themselves. But when the question of electrical standards comes before Parliament a subject will be dealt with whose very purpose is fixity, and whose nature is accuracy. A mistaken clause in an Act of Parliament can be set right as soon as it has been proved beyond doubt, to the satisfaction of all parties, that the need for revision exists; a defect in a Provisional Order can be remedied, and in such cases there is little beyond mere words to be undone. But the legalisation of standards of measurement is a matter which affects every member of the electrical industry, and whatever is done must stand. The need for such special care arises from the correlation of electrical with mechanical and other measurements. Fifteen years ago electricians—for there were no electrical engineers —were satisfied with a Daniel's cell as a unit of voltage, and they were wont to express a resistance as being equal to so many miles of telegraph wire. They did not feel the want of a unit of current, and the output of batteries and of the earliest dynamos was estimated by the heating to redness of so many inches or feet of platinum wire.

All ordinary measurements, scientific or otherwise, are based upon three units—length, mass, and time. There is no absolute reason for this selection, but they are more convenient than units of energy, or density, or acceleration, and, except, for certain problems in thermo-

Digitized by Google

dynamics, they are sufficient for all physical science. In electrical science, too, all quantities can be referred to length, mass, and time, but only by means of very clumsy expressions fringed with fractional indices. Practically, all ordinary electrical measurements are made in terms of, or can be referred to, the common units of resistance, current, and voltage. To the determination of the ohm we need not refer. It is a unit which is very conveniently expressed as the resistance of a column of mercury 106·3 centimetres long with a constant cross section of one square millimetre, and it may be very conveniently embodied in a coil of metal wire. This metal wire will then become the imperial ohm, precisely as the bronze bar made by Bird in 1760 was declared to be the standard yard of the British empire by the Act of 1824. In event of the ohm being lost or damaged, it is to be replaced by comparison of other copies, as was the yard, when the original standard was destroyed only ten years after it was legalised.

It would at first sight appear that the units of current and pressure cannot be embodied in such a tangible and passive a manner as the ohm. One cannot keep a standard ampere in a massive cast iron box, such as that which contains the imperial yard, in the cellar beneath the Jewel Tower at Westminster. Accordingly, it is proposed that the ampere shall be defined by the description, in a few words, of a very delicate laboratory operation which could not be properly explained in less than two of our pages. And this explanation, with full practical directions, being given, a skilful experimentalist would still be required to execute the work which has to be carried on continuously and with perfect regularity for a considerable time. The definition, then, consists in a reference to the electro-chemical equivalent of silver, and throws upon anyone who wishes to determine the strength of any current a research comparable to that which would be necessary if he attempted to arrive at a yard by the definition given in the Act of 1824. Here it was stated that "in the event of this bar and all authentic copies and facsimiles of it being destroyed, its length should be considered equal to 36 inches such that 39·13929 of them are equal to the length of a pendulum vibrating seconds in vacuo at the sea-level, in the latitude of London." Now this definition was omitted in the Act of 1885, no doubt because Captain Kater and others had made careful pendulum experiments, and had discovered that the figure given was erroneous, more recent determinations making it 39·1383 inches. The present proposals of the Board of Trade Committee recognise the principle of the second Act, in recommending that the ohm, if lost, shall be replaced by means of copies, but do not carry this out with the unit current. They do not suggest that in the event of any catastrophe the ohm shall be redetermined, and as the sale of amperes, or rather of ampere-hours, is far more common than that of ohms, it seems that every facility should be given for multiplying copies of it. It may be argued that Prof. Threlfall may at once set to work at the antipodes, and deposit his 0.001118 gramme of silver per second, and thus arrive at the imperial ampere without troubling any of our instrument makers for any material construction of brass, glass and ebonite. He would perhaps be justified in placing more reliance on his silver deposition than on the accuracy of an instrument which had been at the mercy of the packers and the waves. We should like, however, to see an ampere deposited in some such imperial sanctuary as that which is guarded by Mr. Chaney beneath the shadow of the Victoria Tower, and the form of it would be a simple pair of rings of wire, by which "on the principle of a balance" their mutual attraction might be determined, either by suspension in parallel, horizontal, or vertical planes, or by angular displacement as in a dynamometer, weighing, of course, against gravity.

Having arrived at a standard ohm and ampere, there is no scientific reason why any definition need be given of a volt. The Standards Department of the Board of Trade have a foot and a pound, but they do not keep a foot-pound as a unit of work. Electrical engineers have to measure volts every day of their lives, and they ought to do so to within one-quarter per cent. for ordinary commercial purposes, and one-tenth per cent. for special occasions, while any accurate laboratory measurements should be carried considerably farther. But this affords no reason for the introduction of a third imperial unit. The volt is defined very properly as the pressure which if steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere. With proper instruments for measuring current and resistance, the officers of the Board of Trade would have no difficulty whatever in calibrating a voltmeter, and similarly Mr. Chaney could, if called upon, measure velocity, moment of inertia and density in terms of the standards of which he is the custodian. Besides the yard and the pound there are indeed at the Standards office numerous other measures, such as the gallon and the cubic foot. Parts and multiples of the cubic foot were deposited with the Comptroller-General of the Exchequer in 1860, and were subsequently transferred to the Board of Trade in pursuance of the Standards Act of 1866. But these are all secondary, and have been determined from the imperial standard pound and yard.

The final clause of the draft resolutions of the Board of Trade Committee (*Electrician*, February 13th, p. 451) introduces the Clark cell as a practical standard, and very wisely refers to a specification of its construction. Given such a specification, it is comparatively easy for any one to make up a few dozen, and to discard those which fail to agree, and to take the mean of the remainder. Of course it will not do to take a mere text-book description, but the directions must be followed with care. Not so much care, indeed, is required as in the determination of the ampere by deposition of silver or of copper, and there is the farther advantage that the result in the one case is a standard which will at any time produce a steady deflection on an electrometer, to be leisurely read, or will give a balance on a galvanometer when arranged for potentiometer methods. The sole precaution to be taken is the observation of the temperature, and, by a modification of the arrangements, this need introduce no additional factor into the calculation. Well-made cells remain constant within the limits of excellent laboratory measurements for many years. They may be, and have been, sent across the Atlantic and back, by post, without the smallest deterioration, and they are familiar to every electrician. This being so, and the cell being officially recognised, it is not surprising to learn that, in the opinion of several practical men, the scientific arguments should be put aside, and the Clark cell should be used, not only to measure volts, but amperes. All the arguments are readily reversible if the cell be once accepted. That simple arrangement, which is known by the sonorous title of potentiometer, will measure current in terms of a standard of pressure with the no less ease and accuracy than it will measure voltage when a standard current is passing. It is thus that electric currents may be most easily measured in the laboratory, and it is used for workshop purposes every day.

Under these circumstances it might seem desirable to separate the strictly definitive matters from those relating to measurement. There is no question about the theoretical

Digitized by Google

definitions, but we venture to think that the proposals before us confuse two distinct functions; for we look to the Crown for standards, and to the Board of Trade for methods of comparison. To follow the precedents of the Standards Department, the ohm would, as proposed, be practically defined as the resistance of a certain coil of wire deposited with the Board of Trade. The additional piece of information that it should have the value 1,000,000,000 in terms of the centimetre and second can only be of value in future centuries as showing the skill of our experimentalists in their adoption of the figure 106·3 as the result of their determination of the specific resistance of mercury. To carry out the system, the ampere practically should be the current which will cause a certain deflection in a certain dynamometer deposited with the Board of Trade. Any official statements about deposition of silver would be valuable; but as they refer to an experiment which may be made, and not to an actual concrete standard, they cannot be classed as definitions. Similarly, reference might be made to the relation between the ohm, the Clark cell, and the ampere, as being an excellent way of reproducing a definite current. Having defined the ohm and the ampere, the standard of electrical pressure is perhaps best defined as in §12 of the draft resolutions referred to above as being "the pressure which, if steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere." Unless the third unit is derived from the other two, the door is opened as is the case with the dictum about the silver ampere, and as was the case with the pendulum definition, to uncertainty in the future. But having adopted the Clark cell as a valuable method of measurement, it of course is pre-eminently adapted to determine, for practical purposes, but not to define for legislative purposes, the unit of electrical pressure.

## THE ELECTRIC CURRENT AND ITS LAWS.—III.

BY JOHN T. SPRAGUE.

*(Continued from p. 544.)*

§17. Figures 1 and 2, p. 543, exhibit several things which vary in a different manner and at different parts of the circuit, and our theory must take them all into account and explain them. We have—

(*a*) *Current* which both theories admit to be carried *by the conductor*: this is exactly equal at every part of the circuit, including the source.

(*b*) *Magnetism*, also equal at every part of the circuit; to be found in the conductor, but extending to a considerable distance, and existing as we know and can show experimentally in the form of closed rings around the whole length of the circuit.

(*c*) *Heat* developed *in the conductor* and proportional to the physical properties and dimensions of the conductor and also to the square of the current.

(*d*) *Static electric stress* outside the conductor, dependent upon the nature of the matter surrounding the conductor, and upon the voltage or E.M.F. of the source, and other conditions.

(*e*) *Electric pressure*, or stress related to the last, but irrespective of the matter around the conductor, proportional to the effective E.M.F. existing between any two parts of the circuit. This, which is called the slope or fall of potential, may be expressed either as one line or slope or as two, that is, as + and − pressure. I shall use the latter plan, as it corresponds with the double direction of energy, as shown in Figs. 1 and 2, and also to the analogies I shall have to employ.

(*f*) *Chemical powers* proportioned exactly to the current, and related to the molecular construction of the substances made to form part of the conductor.

(*g*) *Chemical Energy* controlled solely by the chemical affinities of the substances the current travels by and acts upon.

§18. Now we have to show how energy reaches the positions in which each of these conditions or things exists. Does it come from the outside as in Fig. 1, or from the conductor as in Fig. 2?

Let us first consider that it comes from the outside, as in Fig. 1, originating in the source, which it leaves at the poles to enter the "medium," where its direction is controlled by the conductor. It appears to follow that the current is not really produced by the source, because the source does not send energy into the conductor at all; it sends it into the medium. It follows that at every point of the circuit an amount of energy must enter the conductor, sufficient to work the mechanism, be it what it may, which transmits, or is the current. We have now to solve this problem, how does the current which does not exist, attract from outside space the energy which is to produce the current and control the outside energy? That problem is the concern of those who hold the new doctrines.

§19. But the current is exactly equal at all parts: the energy needed is not equal at all parts; it increases in the same ratio as the capacity of the conductor diminishes; at the narrow ends of Figs. 1 and 2, it would require per unit of length twice as much energy as the same current would need at the thick part adjoining the source. Here is another problem: it seems that after all it is not the current which controls the energy and prevents it from taking its normal radiant course. Problem: How does the external energy distinguish where much or little of it is wanted?

§20. Then at the arc lamp A, what brings the energy crowding down upon it? Not the current; the current exerts no more action there, *qua* current, than at any other two inches in length of the current, as its magnetic reaction will prove. But if we examine that arc, and enlarge it by lenses, we can, as a matter of well-known fact, see mechanical actions—that is to say, energy traversing the arc *longitudinally*; we see nothing pouring into it from surrounding space; we do see lines connecting the two ends of the conductor, and, in fact, completing the circuit itself; and we see energy going outwards.

How are we to conceive the energy rushing inwards from space, merely to rush out again as radiant light and heat?

§21. Space, again, and medium are good words; what do they mean? How far from the controlling conductor do the streams of energy extend? What should limit them? Does this shell of energy extend as far as the magnetism §17 (*b*) extends? It must do so if the energy of this magnetic field is derived from streams of energy flowing inwards towards the wire; it would seem also that these streams must come perpendicularly to the conductor, and twist about in all directions in outside space to follow the conductor.

§22. But I quoted, §4, Mr. Heaviside, as saying that in a sheathed cable "the energy is transmitted wholly through the gutta-percha." In this case we have a current in opposite directions supplied with energy by a stream in one direction, internal and external conductors both being connected to the source; or do the usual two streams of energy divide the gutta percha between them.

§23. Will anyone explain what confines that stream of energy to the gutta-percha? If the outer sheath were not there that energy would extend to outer space, for that is the hypothesis, that it issues radiant from the poles of the source, and is turned back on the conductor. But here there is no manifestation of magnetism, only because two equal opposite tendencies exist in the two conductors and neutralise each other.

§24. Let the sheath be insulated from the water, and let one end only be connected to the source. What results? The electrostatic action (*d*) is confined within the gutta-percha, the cable becomes a long Leyden jar. But the magnetic action (*b*) extends as far into space as if no sheath were present, if the sheath is non magnetic, or it is nearly confined in the sheath itself, if it is of iron, and capable of taking up the whole magnetance of the current.

Digitized by Google

§ 25. Space, it appears, is very obliging. Why should it surrender its functions to the gutta-percha, except to an extent proportioned to the relative capacities of gutta-percha, air, and ether? Is space conscious, or how does it distinguish between the calls of these various functions?

§ 26. Turn now to the chemical actions in the decomposition cell D (Figs. 1 and 2). The current here is equal to that in all other parts; but we learn something here which no other parts manifest, viz., that the mechanism of the current is identical with the structure of matter. This will have to be examined later on, as will the other points I have indicated here, merely to show what we have to consider.

§ 27. But we have a new and special call upon the lines of energy. At the plates an action occurs (at least wherever products of decomposition are really set free) which absorbs energy and renders it latent; it disappears; it does not become heat, or work. Unless, between the two plates, there exists the stress ($e$) representing energy adequate to furnish this energy (*g* 17), the current will not be generated in any part of the circuit; but a stress will be set up between the plates equivalent to the energy actually available, and the cell D becomes a condenser, or charged Leyden jar. How do the outside streams of energy recognise this peculiar call upon them?

§ 28. As we consider all this, it seems more and more evident that the conductor, which we are told "conducts nothing," and is a mere waste-pipe, exerts absolute control over all these functions, and that the "so-called current" is the active agent. But I will leave my orthodox opponents to explain these points, if they can, only claiming that they shall not bury the explanation in abstract symbols, but give us an intelligible conception of what may really occur. Of course, some of the points may be met, in the usual fashion, by attributing any necessary properties to the air or the ether; but unless there is evidence that these properties are really possessed, this is merely stating the fact itself in another form, not explaining it. Nor will that explain away the fundamental difficulty. Why should the energy, being developed within the conducting circuit in the source, leave that circuit merely to get back to it in a roundabout manner?

§ 29. On my theory, the old and practical theory, the "source" is a mechanism which sets up the current, and transforms the energy it receives into electric energy, which is charged upon the current and the conductors, exactly as other sources or motors set up a transmission of energy by means of belts, wheels, &c. The most perfect analogue is to be found in the hydraulic current, and this analogy I shall fully work out; the form of hydraulic current I shall employ, as most perfectly comparable with electric conditions, is a completely closed circuit of water piping, with a turbine for the source of power, drawing in the water at one end and forcing it out at the other; similar turbines will represent various forms of work done by the current. But I must defer the working all this out to my next article.

## THE GOVERNMENT AND THE TELEPHONES IN BELGIUM.

The question of State purchase of the telephone system, which was settled in a characteristically high-handed manner in France in the summer of 1889, and treated in an equally charateristic manner by our own Government last July, is now about to come prominently to the front in Belgium. M. Bede has, it seems, recently been refused a telephone concession, and the result is an indictment of the Compagnie Belge du Téléphone Bell, in *L'Ingenieur-Conseil*, from which it may be gathered that the situation in Belgium is very similar to that which obtained in this country at the time of the amalgamation of the telephone companies.

The 25 years' concession granted to the Bell Company is dated September 22, 1883, and stipulates that the State shall be at liberty to purchase the system from the tenth year of exploitation by giving those concerned one year's notice. The Company, it is thought, will probably maintain that means that the State may only purchase *after* the tenth years, that is to say, after September 22, 1893. The Minister of Posts and Telegraphs does not, however, read the clause in this way; according to him, "from the tenth year" is to be interpreted "from the *commencement* of the tenth year," that is to say, on and after September 22, 1892.

In either case the question of what action the Belgian Government shall take will soon have to be settled. The clauses of the *cahier des charges* bearing on the subject of purchase are Nos. 26 and 27, which run as follows:—§ 26. The purchase includes the system, material, and installations of all descriptions. It involves the subrogation for the benefit of the State of all the rights of the concessionaires in respect of third parties. If the Government obliges the concessionaire to substitute an underground for an aerial system, the power of purchase only commences at the expiration of the third year from the date fixed for this substitution. § 27. As the price of the purchase, the concessionaire will receive until the expiration of his concession, an annual sum equivalent to the average net profit of the last three years, plus a premium of 15 per cent. The net profit will be calculated by deducting from the gross receipts, general expenses, working expenses, and commercial depreciation.

These conditions obviously afford scope for the exercise of a little book-keeping ingenuity, and, according to the *L'Ingenieur Conseil*, this is not being overlooked by the Bell Company. For the first six years of its existence the Company apparently languished, the ordinary shareholders received but a modest interest, and the founders none at all. But the seventh year was prosperous, the eighth still more so, and the ninth is expected to be better still; the result being that the State, if it purchases without examination, will have to pay the Company an annual income of 565,000 francs for 15 years, which the author of the article considers to be excessive, in view of the fact that the wires are overhead, the circuits earthed, and the instruments antiquated. As the State, however, may, in virtue of clause 2, either grant competing concessions or become a competitor itself, there can scarcely be any danger of too high a price being paid to the Bell Company, a conclusion, indeed, which is finally arrived at by the writer of the article in our Belgian contemporary.

## THE ELECTRIC ARC AND ITS USE IN LIGHTING.*

BY ELIHU THOMSON.

It is curious that notwithstanding the fact that as a source of illumination the electric arc has been known since the beginning of the century, the scientific study of its nature has been but little pursued. It began to be known as a sort of scientific curiosity, being at first set apart as one of the many phenomena observed in the use of powerful batteries. It was not till about 20 years after its discovery by Sir Humphrey Davy that any proposals were made to use it in lighting, and, subsequently, for many years it was occasionally employed either in lecture demonstration or in obtaining an intense light for some special purpose.

The efforts to use it in lighthouses led to the designing and construction of machines on the magneto-electric principle to replace the cumbrous and costly batteries otherwise required. I remember vividly the hours of labour and time necessary to prepare a battery of 40 Bunsen cells for use in working a single small arc light for, at most, two or three hours. But I remember far more vividly the suffocating fumes and risk of acid spilling, with accompanying ruin concomitant on the taking down of a partially exhausted battery. Even to work with the arc for an hour or two was, however, adjudged a sufficient compensation for the disadvantages in obtaining the current. All this has, however, been changed, and the past 10 or 15 years has made the arc as a source of illumination one of the indispensables of a progressive community. Instead of the original sticks of boxwood or charcoal used as "points," which were only "points" because is was not expected that the arc would be burned for more than a few minutes without exhausting the battery, there came later on the little hard carbon sticks about two inches long and three-sixteenths square, sawn from hard gas-retort carbon, or from battery plates, and lastly came the moulded and forced carbons

* Abstract of a Paper read at the Electric Light Convention, Providence, U.S.A., February, 1891.

Digitized by Google

made from a paste in a powerful press, millions of which are now required every week to keep the lamps at present in use supplied.

The charcoal points of Davy were touched together horizontally after attachment of the wires to the battery, and were then separated. The stream of hot flame which followed or joined the points being deflected by air currents took the form of an arch or curve, which gave the name to the phenomenon. Even with one carbon directly over the other, the curved form of the stream is the rule when the carbons are widely separated. Davy's original experiment was made with a battery of 2,000 cells, with zinc and copper plates about six inches square, the exciting fluid being very dilute sulphuric and nitric acids.

Davy's description is as follows:—"When pieces of charcoal about an inch long and one-sixth of an inch in diameter were brought near each other (within the thirtieth or fortieth part of an inch) a bright spark was produced, and more than half the volume of the charcoal became ignited to whiteness; and, by withdrawing the points from each other, a constant discharge took place through the heated air in a space equal at least to four inches, producing a most brilliant ascending arch light, broad and conical in form in the middle." This was evidently a long-flaming and horizontal arc. I find this form shown in a book published as late as 1846, "Davis' Manual of Magnetism." Indeed, I know of no more forcible example of the persistency of old ideas than is afforded by the accounts given in the books concerning the nature of the electric arc. The carbons are generally shown crusted over with dense masses of impurities melted into globules or adhering to their sides. Such figures would not now be recognised as resembling arcs formed with good, pure carbons, such as must be used for commercial results in arc work.

In regard to the idea put forward as to the nature of the electric arc there is even a wider divergence than in the figures used for representing it. But these views are remarkable for their general inaccuracy or crudity, and evidently have been handed down with modifications. Few of those who have written about the electric arc, at least in the text-books, seem to have had the courage to look at the arc, or they may have seen it "through a glass darkly and not face to face." It would require too many and lengthy quotations to give these various views. In most of them the light of the arc is attributed to intensely heated carbon particles transported by the current from one pole to the other. In most of them the idea of carbon vapour as a possible factor never seems to have arisen. Others attribute the arc to the heated air between the carbons which carries carbon particles, some of which are burned.

The following quotation from a book on electric lighting, published in 1884, is a type of many such accounts:—"In arc lamps, as we have already stated, the resistance which converts the current into heat is that of the heated air between the ends of two carbon rods, from one to the other of which the current passes. The light is produced by the incandescence of the ends of the carbon poles, and of the minute particles of carbon which become detached and float in the heated air between them. The heated air containing the particles of carbon forms what is called the electric arc." Here the heated air and carbon particles floating therein are definitely stated to form the "electric arc." Nothing is said of carbon vapour having anything to do with it.

Even the statement that the positive carbon burns twice as fast as the negative is very frequently found unqualified in any way whatever. The experience of the lamp trimmer is, I need scarcely say, not in accordance therewith, the fact being that the rate of consumption, even in direct current arcs with the same size carbon in both holders, varied sometimes quite widely from the proportion stated. However, we shall make better progress if we discard at once the older notions, and, adhering only to that modicum of truth which often accompanies error, supplant the error by the results of our own observations and experiments. My endeavour will, therefore, be to state as briefly as I can such views of the nature of the electric arc as seem to be borne out by observation during many years, and under greatly varying conditions of its production.

Let an attempt be made to separate any part of a circuit in which the current is maintained by a sufficient E.M.F. or potential, and we find that if the separated ends are moved quickly we get a flash or spark of varying length, which becomes a flame of great heating effect if the current be of large rate of flow. If the separation of the two parts of the circuit be made slowly, a continuous flame or discharge will take place between the ends if they be not too widely separated, or so widely separated that the potential or pressure of the current is not sufficient to force current across the space. With considerable potentials and heavy currents a space of many inches may thus be bridged. Whether the separated ends be of iron, copper, platinum, zinc or other conductor, the hot discharge is still formed. Therefore, while the electric arc is generally spoken of as that flux occurring between *carbon* ends separated, of course it cannot be so limited, and we frequently, therefore, refer to copper arcs, iron arcs, carbon arcs, to distinguish one from the other. What, then, is the arc so formed? Is it heated air between the ends separated containing detached particles of the conductor in process of carriage, as was apparently thought for a long time to be the case? No, the arc proper is composed of a stream of vapour arising from the actual boiling or vaporisation of the solid of fused ends of the separated conductors. In so far as the surrounding air mixes or combines with this vapour stream, it is modified by the presence of oxygen and nitrogen, but the air, or any other gas, is not essential to be present and is merely incidental to the formation of the true arc stream in air. Indeed, it may seem strange to some to speak of vapour of carbon, copper, iron, platinum, &c., but their production is merely a question of temperature in any case. In the electric arc there is a real distillation of the conductors forming it, and this accounts for the variation of colour and temperature to be found in different arcs. The copper arc evolves a peculiar green light, which is exceedingly trying to the eyes, as those who have experienced its effects well known. Zinc gives a whitish blue, while the carbon arc proper is purplish in tint. The arcs from various metals give, in the spectroscope, the characteristic lines of the vapour of each metal.

As a curious incident, showing the presence of the metal vapour in the arc, I may mention the fact that when by accident a person has had a portion of his clothing bathed for an instant in a heavy copper arc caused by a short circuit of heavy current mains there has been found a considerable deposit of copper, enough, in some cases, to give the reddish colour of copper to the surface bathed, which if moistened turns green by oxidation. It also gives a deep blue to dilute ammonia in which it is washed, thus showing the presence of copper. In like manner these metallic arcs will give a deposit of the metal on cold surfaces which they touch.

It appears to be the positive pole which gives out the vapour stream. With carbon the positive vaporises steadily, and is consumed much faster than the negative. In the use of the arc, however, for lighting, we have learned to distinguish between what is called a "short-arc" and a "long-arc" system. In short arc systems the carbons are burned much nearer together than in the long arc systems. Let us suppose the case of two carbons touching each other with a current passing, and then that we very slowly separate them, stopping to observe effects. When the contact is light, before actual separation a visible heating of the meeting ends is seen. On attaining a small separation the space between seems filled with hot vapour, and we have a short arc where the separation is perhaps not over two to three one-hundredths of an inch. There is also noted an active transfer of carbon from the flattened end of the positive and a deposition of carbon on the end of the negative carbon. This deposited carbon takes the form of a mushroom end after a time, and breaks off. Meanwhile combustion goes on at both poles, and wears away the sides of the positive carbon while the transfer of carbon wears away its tip or crater. The burning also wears away the negative at the sides, while the tip is built up by the mushroom deposit from the arc. But the cutting in of the negative finally severs the mushroom tip, and it falls away. Hence both carbons are eventually consumed. To develop a short arc there is required a little over half the potential that is needed for a long arc, or about 25 volts more or less, and therefore to give out equal heat energy in the arc the current must be doubled in the short arc over what it would be in the long arc. The short arc is subject to the objection of a continual frying sound emitted and great variations of luminosity; it requires a very dense and hard carbon to conduct the current without great loss, and involves line loss of at least four times the amount with the long arc if equal gauge wires be used.

In fact, while in the past such arcs were common, their number is diminishing, as they are being replaced by the more efficient and completely developed arcs called "long arcs," which are so-called to distinguish them from the "short arcs." Returning to our separating carbons, we find that as the space or arc is lengthened from the short arc condition we pass a stage of great flickering and unsteadiness and a fluctuating potential between the carbons, and then reach the stage of production of the long or quiet arc. With 10 amperes the separation may now be about one-sixteenth to one-tenth inch or more. Smaller currents require less separation, and larger ones an increased separation. At this stage the arc is quiet, with good, pure carbons very steady, and the potential difference remains at about 45 volts, if, of course, the carbon is properly fed to make up for combustion. The perfect arc is really a beautiful phenomenon. While the positive carbon still loses by volatilisation from its tip or crater and by combustion from its sides, the negative gains no deposit, but wastes at a less rate than the other, and by combustion only. The carbon vapour carried off from the positive is consumed by the oxygen of the air before it can deposit on the negative. Hence, the outer zone of flame, which can easily be distinguished from the central zone or arc flux proper, is probably a zone of combustion similar to that existing in ordinary flames. The removal of carbon by evaporation from the positive end gives rise to the crater or cup which is so prominent a feature of carbon arcs produced by continuous currents. The size or area of the crater is a rough measure of current strength, but varies with different

Digitized by Google

qualities of carbon. With very long arcs the crater or hollowed end disappears and the ends become rounded. A well-formed crater with the arc or flame confined thereto means usually a steady light, since the chief source of light in an electric arc is from the positive crater, which shines like a diminutive sun, and represents the hottest part of the arc. The vapour light proper or flame-light is comparatively very feeble, and of a purple quality in air. Hence the arc light is as truly an incandescent source of light as is the incandescent carbon filament, with the difference that to run the latter at the temperature of vaporisation or boiling point of carbon, so to speak, means instant destruction, while by the necessities of the case the light obtained from the arc is chiefly that emitted from a surface of carbon at its temperature of boiling, or, more correctly, of sublimation at atmospheric pressure. This temperature is exceedingly high, and accounts for the well-known superior economy in light production of the arc over all other kinds of lighting. The temperature of the positive carbon crater is so high that the carbon exists there in a soft or plastic condition capable of receiving an impression like putty. I have proved this with very large arcs of 150 to 200 amperes by suddenly forcing the carbons together when the current had been cut off, and finding that they would fit each other perfectly, the negative impressing its form on the positive crater.

As an interesting fact in this connection I may state that I have been able to bend carbon sticks of three-sixteenths to one-quarter of an inch in diameter by passing current through them of sufficient amount to almost vapourise the sticks and cause them to emit an intensity of light approaching that of the arc.

These facts would point to the possible fusion of carbon into liquid carbon at arc temperature under a high pressure of inert gas. No one has yet seen carbon in this liquid condition, and the electric arc alone has made us acquainted with carbon vapour. One cannot fail to be impressed with the fact that the conveyance of carbon in the arc has a striking resemblance to a plating process where metal is taken up by the bath from the positive plate and deposited on the negative. In the arc the hot vapour stream of flame takes the part of the bath and probably acts by molecular interchanges of carbon atoms in molecules of carbon to cause the transfer which occurs, just as in the plating bath the molecules of the plating compound are polarised and allow atomic interchange, which results in conveyance of metal through the bath.

Another curious fact in relation to the arc is the distribution of potential in it. Dr. A. J. Fleming has recently shown that the difference of potential between the positive carbon and the arc flame is about 40 volts; and the few volts which express the difference between the flame and the negative make up the total potential, say 45 volts. Hence the real work of the arc is not in the flame, the energy is not used in overcoming flame resistance, but chiefly in vapourising carbon in the positive crater. It is certainly not strange that, with 40 volts and, say, 10 amperes or 400 watts expended virtually at the crater surface of the positive carbon, the temperature and luminous effects should there be so great.

The distribution of potential in the arc just noted was also brought out about the year 1884 in some testimony in an interference in our Patent Office concerning an arc lamp cut-out which I had invented, and which took advantage of the potential differences between the carbons and the arc flame to cut out the lamp when the arc was too long. It is of course well known that the value of an arc light for general illumination is greatly enhanced by the fact of the distribution of light being mainly in a downward direction in continuous-current arcs. This, of course, follows from the fact of the positive carbon crater being above, such crater being the part from which most of the light comes.

This matter has been very thoroughly investigated, and many diagrams of distribution are to be found in the literature of the subject as published from time to time. They show that with the long arc the maximum intensity of light is from 40 degrees to 60 degrees downward from the horizontal, and that the horizontal intensity is generally much less than one-half as great, while of course the intensity diminishes above the horizontal direction and ultimately becomes zero before reaching the upward vertical direction. In like manner the approach to the downward vertical from the direction of maximum intensity is attended with similar rapid diminution.

The spherical candle-power of arc lights would therefore be only a fraction of the rated candle-power which is generally taken at the maximum light obtainable in the best direction from the particular arc or kind of arc in question.

For this reason the term 2,000 C.P. arc has little significance as indicating the illuminating power of an arc. It is a conversion only, and a poor one at that. It is now generally taken to mean an arc with 10 amperes and not less than 45 volts potential difference between the carbons, or a 450-watt arc. The quality of the carbons will determine whether the 450 watts will be expended in obtaining the most light or not, or whether that light will have a maximum intensity at one angle or another within certain limits.

When arcs are operated on by alternating currents, the effects mentioned are only partially exhibited, and the phenomena of the crater are, of course, masked or obliterated on account of reversal of function of the carbons. Unless the alternations are rapid such arcs are liable to extinction at the zero points of current, particularly when run in a draft of air. A strong draught of air or a displacing magnetic field may of course so disturb an arc as to cause its extinguishment.

In the early years of the growth of arc lighting, as a means of illumination, the effects obtained were not of the best. Unsteadiness was the rule, and it required much persistent effort to discover the causes and find the remedy.

The prominent defects were, and we may add are still, hissing, sputtering, flaming, and general unsteadiness. Hissing or frying comes, of course, with too short an arc, and may be connected with too vigorous vaporisation. They may also be due in some cases to a carbon of too coarse a grain. Sputtering may arise from impurities in the carbons, and flaming from too long arcs, from impure carbons, or from carbons insufficiently baked and containing unexpelled gases. Running an arc at a length between the long-arc condition and the short-arc condition may cause great unsteadiness of light. There is, in fact, a critical point in the length below which there is a considerable fall of luminosity and a drop of nearly one-third of potential. As an arc lengthens by combustion of its carbons beginning below this critical point, great unsteadiness will be manifested on arriving at the critical state; and a little longer arc brings about a sudden and very marked increase of potential, of illumination, and of steadiness.

Any observer may easily detect these conditions without special effort. The earlier carbons used with arc lamps in the United States were both badly conducting, impure and badly made. Copper coating was a necessity. French or Carrè carbons were much better, but were too costly to import. The use of the petroleum carbon, or the carbon obtained by the carbonisation of the tarry residue left in the distillation of crude oil, made a wonderful difference in the purity of the carbons, and improved machinery gave accuracy of form and cheapness. To one familiar with the former cost of same carbons for battery arcs, the reductions in cost are very striking. Carbons three-sixteenths of an inch square cost a number of cents an inch before the year 1878.

Another important matter in relation to carbons is that the size of section or diameter must be proportioned to the current used. Where attempts have been made to prolong the hours of burning of a carbon by enlarging its diameter beyond certain limits it has resulted in injury to the character and distribution of the light. Large diameters of carbon may burn too blunt to let the light out between them. Likewise, where attempts have been made to prolong the hours of use by employing a harder or denser carbon than before, it has frequently been found that a sacrifice of light has been incurred, rendering the results much less satisfactory.

One of the chief obstacles to the employment of very small arcs with currents of three or four amperes is the difficulty of obtaining suitably uniform carbons. Arcs of even as low as two amperes at 45 volts are easily produced, and such small arcs might even have commercial utility if the difficulties in relation to carbons were removed. An arc consuming 90 to 100 watts means, of course, about seven or eight to the electrical horse-power.

On the other hand, very large or heavy current arcs are difficult to control. They are apt to be unstable at times, and when they get to hissing, or rather roaring, it is difficult to restore quietness and steady action. The introduction of cored carbons for the positive has, however, done much to remedy the difficulty, and, indeed, to render it possible to obtain very uniform results from arcs in general wherever such results are indispensable. The introduction of the central soft core into the carbon locates the arc centrally, hold it from fluttering or shifting its position on the end of the positive; in other words, the core fixes the position of the crater, and so benefits the light.

The fall of resistance with increase of current has an important bearing on the construction of dynamos for arc lighting and the running of lamps on constant potential or incandescent circuits, and will be referred to later on. Attempts have been made at various times to save carbons in arcs by excluding the oxygen of the air, which is the cause of their waste or consumption by burning. The gain has not apparently compensated for the disadvantages incurred, particularly as the total exclusion of oxygen means that the carbons become blunt. They would be prevented from pointing themselves or acquiring tapered ends by burning, a condition essential to good working and distribution of light. Even when the arc is formed in a vacuum the carbons, though not burned, are slowly consumed and carbon deposited as a soot on the sides of the vacuum chamber, an effect consequent upon the vapourised carbon in the arc being carried off and condensed again as soon as the vapour escapes the heat of the arc stream. In fact, I have found it possible to coat objects on the inside of a bulb with silver or other metals volatilised suddenly by arcs in vacuo, and have obtained in some cases coherent brilliant deposits. The metal is raised in

Digitized by Google

vapour as a metallic arc and distils and condenses on the surfaces near at hand.

Before passing to the consideration of the running of arc lamps in series, or in multiple, and the conditions to be fulfilled in each case, we may state that, although in ordinary cases an arc is formed by a single pair of electrodes or carbons, and by a single-circuit current, compound arcs, or arcs produced by combinations of two or more currents with three or more electrodes, are possible. I am not aware that any others than myself have experimented in this direction. I have, however, produced lights with two positives and one negative, with one positive carbon, or crater, and two, three, or more negatives, and with two positives and two negatives. I have caused arcs to cross each other, as when four carbons are used, pointing towards a centre, the two pairs opposite being respectively connected with different circuits. In this way direct arcs have

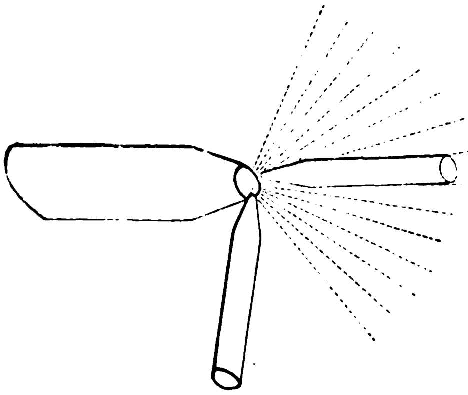

FIG. 1.—Arrangement of three carbons for projectors.

been, as it were, mixed with alternating arcs and a curious compound effect produced by crossing two arcs made with two alternating currents, the waves of which are displaced in phase. Without going fully into these experiments, I will present figures showing two good examples. Fig. 1 is formed by two currents sent into a positive and dividing after passing the crater into two streams going to the two negatives. In this case the positive crater is fully exposed horizontally, and gives a most intense light in a direction forward. Such an arc is well adapted for projection by mirrors or lenses.

Fig. 2 shows the arc formed by crossing two alternating currents out of phase. In this case there is at successive times an exchange of current between all four carbons in varying directions, so that the arc flame becomes, as it were, a ball or disc of very hot flame,

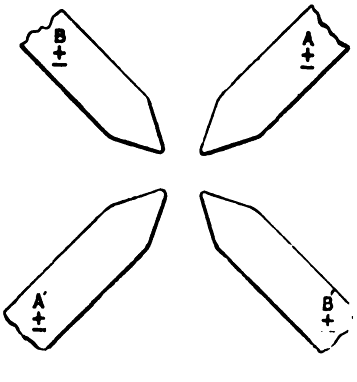

FIG. 2.—Four carbons arranged for use with alternating currents out of phase.

supported by the four carbons. These experiments have not been fully described as yet, owing to the lack of time ; but they show very well that even when we have fully studied the single, simple, arc we will not then have exhausted the subject, as these compound arcs may be varied in character to a great extent and present new effects.

In regard to that portion of our subject which concerns the use of the electric arc for lighting, it is true that there is a wide field before us. I cannot hope to do more in this Paper than to outline, in addition to the considerations already alluded to, some of the other prominent features of this subject. It is well known that by far the larger proportion of electric arc lights in operation is run on circuits of constant current, the lights being in series. If arc lamps be connected in parallel, as on low potential incandescent mains, special devices are required to keep the current supplied to each lamp at the right amount. It may appear at first to one who has not had occasion to closely study these matters that, given a constant potential circuit of 50 volts, arc lamps requiring 50 volts could be connected in multiple or parallel without difficulty. The fact is, however, that the condition of electric arcs being supplied with a constant potential involves a theoretical impossibility. Theoretically such an arc would take an infinite current and energy. Practically the current in an arc with constant potential becomes very heavy, and if the carbons be separated to cut the current down as by a lamp-magnet mechanism, a condition of fluctuation and instability results. This is a direct consequence of the fact before stated, that the resistance of an arc is not like a wire resistance, but falls with increase of current, and *vice versa*. For stability the resistance should not be dependent wholly on the current passing. To remedy the instability a resistance known as a "choking coil" or "sluggishing coil" is inserted in the arc branch, and the potential raised to 65 or 70 volts. Under these conditions, that is, with a resistance taking up 15 to 20 volts in series with the arc, it may be run in multiple with incandescent lamps or with other arcs. There is, however, a waste of energy equal to the product of the current strength by the loss of potential, 15 or 20 volts, in the resistance. A great deal of useless experimenting has been and probably is yet carried on with the vain endeavour of getting rid of the resistance or choking coil in this case, but the difficulty is inherent in the nature of the arc, the relation of resistance to current giving rise to instability of current in the arc.

Similarly, not all dynamos, even if of sufficient potential, will run arc lamps in series. Arc machines require special properties, or the current will be unstable and the lights will fluctuate, or "surge," as we sometimes call it, possibly to an extent amounting to extinctions and relightings occurring at short periods apart. This action, like the other, is dependent on the relation of current and resistance as inherent in electric arcs, and the series of lights would in each case require dead resistance up to a certain amount in circuit to render the current stable. Then, whether a series be operated or a single arc be operated, either a dead resistance must exist in circuit or the current-supplying apparatus must have special properties. The arcs produced from batteries were stable because the resistance of the battery itself was sufficient to insure this. Arcs are not stable as fed from accumulators of very low internal resistance unless the arc is one of enormous current.

Briefly, the property required to be possessed by an arc dynamo is that, as its current rises above the normal, the electromotive force must fall ; as the current diminishes to a little below the normal, the electromotive force of the dynamo must rise. It is not sufficient to secure this changing E.M.F. by regulators, as they are generally behind time for causing stability of current, however well they may operate to regulate for varying numbers of arcs in the series to be supplied.

The properties of dynamos are sometimes expressed by what are called "characteristics" or "characteristic curves," obtained, for example, by laying off vertically or on the ordinates the electromotive forces corresponding to varying currents given out by a machine, which currents are laid off horizontally or as abcissæ. In arc machines the curve so produced is convex upward, and droops at its outer end. Assuming normal current at 10 amperes, and an E.M.F. of 500 volts at 11 amperes, the E.M.F. may have fallen to 420 volts and at nine amperes risen to 530. We would then be working on the "droop" of the curve when at 10 amperes, and such a machine is stable as to current for running arc lamps. There appears to be required not merely a droop in the curve for securing stability, but more than a certain amount of rate of droop or dip. If the line could be made to droop or dip vertically after passing the normal current the machine would regulate without a regulator, or be a constant-current automatic machine.

In what respect, then, do arc dynamos differ from others to produce this relation of droop in the characteristic curve? Without doubt the effect is mostly due to the reactionary effects of the armature on the field, which effects in arc machines are made greater than in others ; and the field magnets meanwhile are frequently saturated magnets, so called, and not greatly sensitive to the current in their coils. The armature of an arc machine is indeed so powerful an electro-magnet that it is able to control the magnetism of a portion of the field in which it turns. A sort of balance of magnetic forces is established at certain portions of the field, which on an increase of current in the armature produces polarity opposing the field polarity at the portions mentioned, such as will cut off some of the lines of magnetism from entering the armature core and so lower its electromotive force ; while a lessened current in the armature will weaken its polar portions and an increased number of lines will enter the armature core from the field and so increase the electromotive force at the brushes of the commutator.

Could the droop or fall in the characteristic curve be made a vertical, as stated before, then we should have a self-regulating machine not needing a regulator to preserve a constant current under all loads. This condition can be arrived at by interactions occurring between the armature and field. In this case the armature currents react upon the field with a force producing at times a balancing of magnetism between the two. In the recent alterna-

Digitized by Google

ting machine for constant current brought out by Mr. Wm. Stanley we have an excellent example of the application of similar principles of construction, the arc lights are run from the transformers with the primary coils in the Stanley apparatus.

The relation of current to constancy is, however, in continuous current dynamos for arc lighting generally effected by regulators, as they are called, which so alter the dynamo on a slight increase or decrease of current as to raise or lower its electromotive force according to the resistance in circuit or speed.

It follows, from the fact that the voltage required to sustain an arc with large or small currents ranges about 45 to 50 volts, that the larger the current passing in an arc the less its electrical resistance. Hence, well developed arcs with 4 amperes will have about 11 ohms; with 10 amperes 4·5 ohms resistance, and with 100 amperes ·45 ohm. This fall of resistance with increasing current is easily explained by the broadening or thickening of the arc stream and the widening of the crater on the positive carbon. This widening of the crater also gives increased illuminating power without increase of temperature. It is probable that the actual crater temperature is as great in the small arcs as in the large ones; in fact, this is implied by the quality of the light remaining the same. Nevertheless, the larger the arc the greater the economy or the greater the light-giving power per unit of energy. This would naturally be expected, as the concentration of heat and lessened chances for escape of heat by convection and conduction would conduce to that result.

On account of the fact that with the addition of arc lights in a series a higher and higher potential difference is required at the terminals of the dynamo, it becomes a question how far this increase may properly be carried. It is not unusual in the present practice to run from 50 to 60 lights in a series, each demanding from 45 to 50 volts, or a total of, say, 3,000 volts. In going beyond this amount, the difficulties of insulation are greatly increased, as well as the dangers of high potentials, while the consequent risk of breakdowns resulting from failure of insulation or leakage are often sufficient to offset any saving of wire conductor that might be obtained by running more lights in series. Instances have occurred in which, with ordinary wiring and precautions, 120 to 150 arcs have been run for days together, but such a practice is to be condemned as involving hazard of all kinds.

It has been supposed by some electricians that there existed a peculiar fitness for arc lighting in series in dynamos of the open-coil type, such as the Brush or Thomson-Houston, over those of the closed-coil types, such as the Gramme or Siemens forms. While personally I have never been prepared to admit this peculiar fitness, constructors of machines of the closed-coil type have certainly succeeded in removing any doubts on that score.

I had intended at the outset of this Paper to discuss in a general way the question of the different types or classes of lamps used for arc lighting. It is a department of the subject which is of considerable importance, but for the present I will simply allude to one or two general features. Concerning the manner of feeding the carbons, the mechanisms in use may roughly be divided into clutch and gear mechanisms. Whether one or the other type is to be selected will depend largely on the conditions of use, assuming both to be equally well constructed and kept clear. Arc lamps may also be divided according to the way in which the magnet system acts to control the feed of the carbon. Before arc lamps were run in series it was sufficient to have the controlling magnet in the main circuit, and this was the case in almost all the older forms of lamp. At the present time the differential lamp magnet system is of several kinds, according to the relative disposition of the main and shunt coils. In the Brush arc lamp they are disposed one over the other on the same axis and affecting the same magnetic cores. The only objection to this disposition, which has the advantage of simplicity, is that the shunt circuit can never act positively to feed the carbons or release the clutch or gear, but can only weaken the effect of the main coil or overpower its lighting or separating action on the carbons.

Other forms of differential lamp embody the two circuits acting on separate magnets pulling in opposite directions, the main circuit to separate the carbons and the shunt to feed them. In this case the action of the shunt is more definite and positive, as it is not limited simply to overcoming the force of the direct or main magnet. A third arrangement involves the application of the repulsive action of the two coils, as when the direct coil is wound on the fixed magnet and the other, or shunt, upon the feed controlling armature therefor, and tending to cause repulsion of the armature from the main magnet. The arrangement is both simple and positive in its action.

The differential types of lamp act well when the circuit current is kept constant, and require readjustment generally for each change of current strength by which they may be operated. Hence, if a portion of line be leaky the lights are apt to burn badly, owing to diminished current, while the dynamo may be furnishing full current. Of course, such a line ought to be condemned and its insulation improved. Nevertheless I have frequently seen lights suffer from leakage on extended circuits in cities, especially in very wet weather. This is a state of things which the line superintendent can do more than any one else to correct by attending to the correct disposition of the wiring, and its character as regards leaks.

The type of arc lamp in which the shunt magnet alone controls the feed of the carbons is not sensitive to slight variations of current, but maintains a full, quiet arc with the current it gets. This is because the main current is not concerned in the feeding action, but the action is solely dependent on the potential difference of the carbons. Hence its behaviour is, on the whole, more uniform than the differential type, and within limits it does not require readjustment for different current strength.

This principle has been extensively introduced in the Thomson-Rice lamp of the Thomson-Houston Company. In this lamp the carbons are separate at the start and are brought together on the first passage of the current, after which they separate solely under the influence of the shunt circuit magnet, and the feed is likewise controlled thereby. The carbons in these lamps are not so apt to slide by or alongside each other by jarring when no current is on the lamp, as may occur, particularly with careless trimming, in those lamps in which the full weight of the upper holder and carbon must be borne by the under carbon when the lamp is not lighted.

Arc lamps have been made with many variations in the magnetic arrangements controlling the carbons, a brief statement of some of which is as follows:—Carbons lifted or separated by direct or main magnet; shunt magnet acting on a variable resistance to cut out the main magnet in feeding. Carbons lifted by main magnet as before and shunt acting to put the main magnet (made movable) into position for feeding.

Carbons separated by main magnet armature; shunt circuiting magnet acting to divert or shunt the magnetism of the main magnet from its armature.

Carbons separated by main magnet and shunt acting to free the carbon holder independently of the support given by the main magnet.

Carbons separated by a spring allowed to act by the main magnet lifting a weight which otherwise holds the spring from acting; shunt magnet acts against the spring to feed and regulate length of arc.

One carbon, generally the lower, separated by main magnet, while the other holder is released for feeding only, such feeding being under the control either of a differential system or a shunt magnet only.

Carbons separated by main magnet, which lifts the shunt and its armature together, while the shunt magnet armature acting on the feeding mechanism controls the arc and feed of the carbons.

Carbon feeding mechanism independently attached to main magnet armature and to shunt armature, so as to receive opposite movements of separation and feed from each respectively.

Carbons separated by a feeding mechanism moved by the main magnet and fed by a further movement of said mechanism, causing release or return of same under the accumulated force of both shunt and main magnets acting in the same direction.

Differential clock gear for separation and feed of carbons under control of the regulating magnet system, either simple or differential. Some of the older clockwork lamps embodied this principle.

Carbons controlled by armature of a small electric motor under control of a differential field which turns the armature in one direction for separating and in the other or reversed direction for feeding the carbons.

Carbons controlled by a motor running at a certain speed when the arc is of normal length and varying in speed when the arc is too short or too long, combined with a centrifugal governor on the shaft of the motor acting on variations of speed to gear motor shaft to screw carbons together or apart as needed to maintain the normal arc. This mechanism has been applied by me to large arc lamps such as naval search lights, and has the advantage of great positiveness and an ability to handle heavy mechanism.

There are also a considerable number of modifications from these principles stated which cannot be referred to here.

Another excellent mechanism, and one of the most powerful and positive in feeding the carbons, embodies a main magnet separating the carbons and striking the arc and an intermittently acting shunt magnet for working a pawl, which by a suitable gearing forces the feeding action on approach of the carbons as required. I have used an endless screw gearing with the pawl acting on a ratchet wheel to turn the screw, the worm-wheel being on a shaft carrying a pinion meshing into a rack on the carbon rod. The worm-wheel gearing is lifted by the main magnet to strike the arc, and the shunt magnet in operating its pawl breaks its own circuit and repeats its feeding action as often as may be necessary.

It is interesting to note in this connection that I have built such lamps in which each feeding movement of the carbon is not over one-five-thousandths of an inch, and that if the upper carbon rod is held in a vice the mechanism will lift the whole lamp, of about 20lb. weight, in feeding, so positive is the action. At the same time the length of arc is maintained constant at all times. With so slight and yet positive a feeding action the feed takes place almost continuously.

## REPORT OF THE COMMITTEE ON THE PROPER CLASSIFICATION OF THE LIGHTING POWER OF INCANDESCENT LAMPS.*

DR. LOUIS BELL, CHAIRMAN.

The necessity for some rational rating of the candle-power of incandescent lamps becomes evident in the experience of nearly every central station manager who has enterprise enough to keep watch of the lamps he is using. Now, evidently it is for the best interest, both of the central station man and of the consumer, that each should know exactly what is intended by 16 C.P. glow lamps. The questions that arose were as follows:—First, how shall we classify the power of incandescent lamps at all? Shall we classify it entirely by candle-power? Or if not by candle-power, to what standard shall we refer the light? Or shall we classify it by watts consumed with specifications for efficiency or by watts consumed with specifications of candle-power to some limitations on the efficiency? After a considerable amount of deliberation your committee came to the conclusion that the last-mentioned method of classification was the simplest one to enforce—that is, incandescent lamps should be rated by the watts consumed, the actual power for which the consumer pays, but with a specification as to the candle power to limit the efficiency of the lamp to a practical value. By practical value I mean such as will not on the one hand produce an inordinate waste of energy, or on the other hand force the lamp far above its proper candle-power, and consequently rapidly burn it out. The interest of the lamp manufacturer lies towards greater efficiency, because, by producing a very efficient lamp he is enabled in the first place to give a fine, brilliant light that pleases customers. Unfortunately, when this is carried beyond a certain point, the life of the lamp is enormously shortened. Having determined the proper way in general of rating incandescent lamps, there arose the important question of proper limitations to be set. We have been so long used to speaking of and dealing in 16 C.P. lamps, it seems inadvisable to abandon that standard. Do we mean by that, 16 candles mean horizontal, or 16 *candles mean spherical illumination?* Your committee is emphatically of the opinion that the mean horizontal candle power should be specified; in other words, that the normal 16 C.P. lamp should give 16 C.P., taking the average of the horizontal illumination in all azimuths.

Next came the question of practical limits within which the candle power might be allowed to vary. Taking the limits as they are found in actual practice, we find them 5 C.P. on either side of 16, sometimes even 7 or 8. These limits your committee considered far too wide, and, therefore, it entered into consultation with the lamp makers for the purpose of ascertaining how close to 16 C.P. the limits could be set, and yet leave the manufacturer a simple and practical process. The result of this deliberation was to settle on about 1 C.P. on either side of 16; that is, on the one hand, the largest variation which we could agree to admit in defining the normal lamp, and on the other hand being a variation which came easily within the lines of commercial manufacture.

As to the possible efficiency of incandescent lamps giving a reasonably long life, there are as many opinions as there are lamp makers, besides a few stray opinions advanced by theorists, and still fewer advanced by practical electricians. Some experts advocated lamps giving the candle-power on not less than four watts; others, three or two and a-half watts. In this regard we shall have to appeal to the central station manager. Your committee, after a large amount of consultation, considered for general central station use, taking into account the fact that sometimes they sell light by contract and sometimes by meter, a consumption of more than four watts per candle undesirable, particularly if the electricity is furnished by meter, for when the consumer is paying for more than four watts per candle he objects very seriously to the bills sent as not representing the proper quantity of light. Then, as to the limits of efficiency—on how small a number of watts is it possible to produce a candle-power and at the same time have a lamp of reasonably long life and giving a reasonably uniform efficiency throughout its life? The very best commercial practice seems to set the figure at a little over three watts. Without specifying, then, the efficiency of the normal standard lamp, your committee would suggest that a lamp giving over 15 and not over 17 mean horizontal C.P. on a consumption of less than 60 and not less than 55 watts represents the average conditions of central station practice better than any other type of lamp that could be readily found. I am quite aware that in setting this 55 watt limit your committee is running in the face of opinions which are entitled to some consideration, but it would call the attention of anyone who is opposed to that limit to the fact that with the normal standard lamp thus defined, if any lamp can be produced giving a candle-power with good life on a little over 3 watts it still falls within the standard. The effect in that case would simply be this:—That the manufacturer who could produce a lamp giving the candle power well and steadily on a little over 3 watts could furnish as the standard lamp a lamp that would come very near to the 17 C.P. limit; in other words, he would get the credit of having a little brighter lamp than some of his contemporaries, and so would not in any way suffer by the establishment of the 55 watt standard.

Now as to determining the mean horizontal candle power. In the first place, the distribution of light that is given by incandescent lamps is not altogether uniform. In lamps with twisted filaments, particularly if of round section, the distribution is very uniform, in lamps with straight filaments of round section fairly uniform; in lamps with straight filaments of square or nearly square sections showing the maximum at very nearly 45 degrees from the plane of the filament; when filaments of rectangular section are employed having a considerable difference between the sides of the rectangle, the light varies in the most erratic fashion.

There is one way, however, to determine the mean horizontal candle-power, and that is by spinning the lamp above an axis as it is being tested; if a lamp be mounted in a rotating socket and spun rapidly about its own axis, the mean horizontal candle-power can be obtained at once if the velocity of the rotation rises to about 300 or 400 turns per minute. This process has been tried several times with more or less success; it is tried in at least one lamp factory with uniform and unvaried success, and it is certainly worth an experiment in case we have to deal with very irregular lamps which throw their light erratically around a horizontal axis.

* Abstract of a Report presented to the Electric Light Convention, Providence, U.S.A., February, 1891.

## ELECTRICITY IN RELATION TO THE HUMAN BODY, ITS DANGERS AND ITS USES.*

BY H. NEWMAN LAWRENCE AND ARTHUR HARRIES, M.D.

It is manifest that any consideration of the relation between electricity and the human body must divide itself into two parts: the one, *possible dangers* to the body, and the other, *possible advantages*. First among the dangers is that from lightning. The physiological problems connected with lightning stroke are many and interesting, but beyond our present scope. We have rather to deal with dangers arising from accidental contact with conductors which are used to convey electric currents to and from the various lamps, machines, or apparatus they are intended to actuate. That electric engineers (in England at any rate) have done, and will do, all that is possible to safeguard the public we gladly believe and acknowledge. With proper care on the part of the engineer, and with a minimum of caution on the part of the public, accidental contact by the human body with conductors carrying dangerous currents becomes almost an impossibility.

The results of contact with currents passing at a fixed rate of E.M.F. (as is generally the case in light and power circuits) depend upon resistance, sensation, and local effect. Upon the resistance offered by the body depends the quantity of current passed; sensation and local effect are produced upon the body by such current as it really receives. Resistance, in its turn, depends upon the condition of the skin at the sites of contact, and upon the extent of the contact area. These points are all-important in deciding the seriousness or otherwise of accidental contact. We have noted with regret that there is a tendency among electrical engineers to draw unfair inferences from the slight results which have sometimes followed accidental contact. They argue that because A received no harm from an accident on a particular circuit, therefore no harm can come to B and C, or anyone else, on the same or some similar circuit, quite forgetting that A's hands may have been exceptionally dry, or that the area of his skin in contact may have been very small. We have made experiments on both these questions, and find that, with continuous current, resistance with the skin moist at point of contact, is about one-third the average of that found when the skin is dry. With wet skin, resistance is further reduced to one-fourth. With alternating current, the proportionate decrease of resistance between the conditions of dry, moist, and wet skin is slightly less, but is still well marked. We find also that, other conditions being the same, the current passed with a given E.M.F. is as nearly as possible in direct proportion to the surface area in contact. In other words, the possibilities for harm are dependent upon these factors to such an extent, that when both are favourable to the subject, contact with wires carrying current in the highest degree dangerous may produce results in no sense serious on the other hand, when both are unfavourable, the subject may receive serious if not fatal injury from a circuit which might be safely handled under conditions more favourable to himself.

* Abstract of a Paper read before the Society of Arts, March 11, 1891.

*Sensation.*

We have made many experiments to determine how the sensations of individuals are affected by currents of such strength as could be borne. We find with dynamo generated currents, when bare metal electrodes, having a surface area of 45 sq. c. each, are grasped in the hands so that the current passes through the arms and chest, that with continuous current at 104 volts, an average current of 0·0183 ampere produced what we have called discomfort point, while with alternating current at about the same voltage (and a frequency of 23 per second) 0·007 ampere was sufficient to produce comparable discomfort. Further, that with the alternating current 0·0079 ampere produced muscular fixation, while with the continuous current in no case was muscular fixation, or any sensation approaching thereto, reached.

*Local Effect.*

*A.*—With continuous currents we observe :—

1. Electrolysis at the parts in contact, accompanied by a gradually increasing sensation of heat.

2. Shock to the muscles in the neighbourhood is felt with sudden make or break.

3. The parts become reddened, more so at the negative than the positive pole.

*B.*—With intermittent and alternating currents :—

1. Repeated shock, with more or less tonic contraction of neighbouring muscles, which is practically persistent during the time of contact. Closure of circuit is marked by painful jerk, felt not so much in neighbouring muscles as in those some short distance away.

2. Reddening of the parts.

Light and power circuits carry currents very many times stronger than any used in the above experiments; and we may fairly conclude that the result of contact therewith would be severe shock to the nervous system, and strong burning sensation at the points of contact with either form of current.

*The Uses of Electricity to the Human Body.*

The health of the body seems to be intimately connected with and, perhaps, to a large extent dependent upon electricity, or the immediate results of electrical action both internal and external. That electricity ordinarily exists in the air we breathe has been shown by many well-known experimentalists, from Lemonnier, in 1752, downwards, and we have it on the authority of Sprague that the average electrical condition of the atmosphere has an important bearing upon the climatic qualities of any place, though he adds "as yet very little is known on the subject." Again, ozone is a most important constituent in a healthy atmosphere, and it is probable that electrical action is one of the chief factors in its production. Physiologists have long taught us that electricity is generated in our bodies during each functional process of whatever nature. It has been shown to be present during the action of the heart by Dr. Augustus Waller in his beautiful experiments before the Medical School of St. Mary's Hospital, in October, 1888, and more recently at the International Medical Congress at Berlin. We are ourselves engaged upon a long series of experiments which, so far as they have gone, clearly indicate that small but measurable currents of electricity are being continuously generated in the body. We further find that these currents differ in potential according to the parts tested, and we have reason to believe that such difference of electric potential is produced at the centres of function—thus in muscle, brain, gland structures, lungs, and various parts of the digestive system there is a separate, continuous, though apparently irregular, generation of current. We are thus brought face to face with the fact that electricity forms a most important factor in the processes and functions which together constitute life. A confirmation of our conclusions is found in the experiments of Dr. B. W. Richardson upon the effect of administering frequently used oxygen to animals. He found that oxygen alone will not continuously support life—in presence of nitrogen, of course—unless it be frequently revivified by the passage of electricity through it. The same action of electricity and its revivifying power upon the atmosphere is found after a thunderstorm, when, as is well known, ozone is largely present owing to the electric disturbance accompanying the storm. The artificial electrical generation of ozone for restorative purposes may also be considered as one of the uses of electricity to the body. It is one, moreover, which may probably prove of considerable importance in large cities, where the atmosphere is vitiated by the exhalations of a large and crowded population. We have made certain investigations into this subject, and carried out some interesting experiments with persons placed in an ozonised cabinet, wherein the air was charged with ozone by electrical action. The results seem promising; but the number and extent of the observations necessary prevent the rapid completion of such research, and we must postpone more definite conclusions for the present.

The next part of our Paper deals with the uses of electricity in disease. Such uses are numerous, valuable, and steadily on the increase. Without trespassing upon the distinctly medical aspect of the subject, we may refer to those well known but little under stood effects of electricity upon the nerves and muscles of the body, by means of which many diseases depending upon nerve derangement may be ameliorated or even cured. Speaking generally, continuous currents, properly applied, tend to promote disintegration and nutrition, while alternating currents act as local stimulants. But in this connection it is most necessary to bear in mind that it is only by accurate measurement of the currents used, and by careful attention to the electro-physiological or electro-chemical changes it is desired to bring about, that satisfactory results can be obtained. Extreme care is necessary in making electrical applications to the body. Care in diagnosis, so that a definite idea may be obtained as to what it is the electricity is to be directed against; care in the selection of that form of current best suited to do the work required to be done; care in choosing the position of the electrodes and the direction of the current; and, lastly, care in measuring the dose precisely, both as regards current, strength, and time.

With the methods of electrical treatment this Paper has nothing to do, but there is one use of electricity in disease not indicated above, which is new as regards its practicability, and which, moreover, opens up a field of usefulness little expected a short time back. We refer to "cataphoric medication," or the process of passing drugs in solution through the skin by means of the cataphoric power of continuous electric currents. Experiments have been made both in Germany and America, within the last few years, by which evidence, more or less uncertain, had been obtained of the power of electric currents to carry drugs in solution with them through the skin; but as far as our information goes nothing reliable had been arrived at, and some of the experimenters were even uncertain as to which pole should carry the solution to the body. In the early autumn of 1889 we conducted a series of experiments in this department of work, and found the results so promising that we at once proceeded to use it as a method of treatment. We have been much gratified with the results of its application in many cases of actual disease. From the reports of the International Medical Congress at Berlin in 1890, we find that subsequent to our adoption of this method in practice, Mr. Edison, of New York, has been making experiments in the same direction.

1. We note that a continuous current, passing from one vessel to another along a moistened conductor, will carry with it from + to − sufficient of the drug in solution at the + to produce a precipitate in the solution at the − pole. 2. That a portion of the drug in solution will pass through a porous septum in the direction of current flow. 3. That a portion of a drug in solution will pass into the human body through the skin also in the direction of the current flow, the skin here representing the porous septum.

Repeated qualitative tests have shown clearly that the drug used has passed into the system, and we are now endeavouring to obtain quantitative tests which we hope may lead to the adoption of definite dosage by this method.

In conclusion, it may perhaps be well to say a few words by way of summary. The dangers of electricity to the body are considerable, but, fortunately, they are provided against, and generally in a very secure manner. In fact, they concern only the comparatively few whose work necessitates their constant presence among such conductors. The uses, however, affect a far larger number and outweigh the dangers to an enormous extent.

## THE ELECTRIC LIGHT AT BRISTOL.

At the meeting of the Bristol Town Council on Tuesday last, the report of the Electrical Committee came up for consideration. The report advised the Council as to the area to be at first lighted. The installation recommended by Mr. Preece was, it stated, only intended as a commencement, and was so designed as to be capable of future extension to every portion of the city to which it might be considered desirable to extend electric lighting. The report recommended that the alternate current transformer system should be adopted; that the committee should be authorised to carry out an installation, capable of supplying electricity to 100 arc lamps for street lighting, and 10,000 glow lamps for private lighting, at a cost estimated not to exceed £66,000.

Mr. Preece, in his report, stated that the site selected for the central station, in Temple Backs, was admirable. The space was ample for the purpose, and being on the water side secured all the advantages of cheap transit in coals and easy disposal of cinders and a supply of water for engine purposes. He estimated the capital expenditure necessary for carrying out the installation to be £66,000, divided as follows:—Buildings £5,000, machinery and plant £24,000, mains, &c., £20,000, distribution £6,000, working

Digitized by Google

capital £5,000, 10 per cent. for contingencies, £6,000; total, £66,000. The annual revenue to be derived from this installation, regarded as a distinct undertaking, if all the lamps be taken up and used, was estimated as follows:—Arc lamps £2,500, glow lamps, £10,500; total £13,000. Working expenses:—Arc lamps £2,500, glow lamps £7,100; total, £9,600. Profits £3,400, or about 5 per cent. on the capital expenditure (£66,000). The estimated revenue was based on the assumption that each lamp alight and in daily use earned 21s. per annum, which meant that each lamp fixed earned 10s. 6d. per annum. Companies derived an average annual income of 24s. 6d. per lamp alight, or 12s. 3d. per lamp fixed. The estimated working expenses were based on actual experience, and had been checked in various ways. The working expenses per unit could be tabulated thus:—1. Manufacture of Electrical Energy —Coal, labour, oil, and waste and water 2·25 pence. 2. Repairs and renewals, 0·8 pence. 3. Distribution and maintenance, 0·8 pence. 4. Management, 0·4 pence. Total 4·25 pence. The report then went on to state that the alternate current transformer system was the only one suitable for Bristol. Six transformer sub-stations would be required at first, and their probable positions had been chosen. The public and private lighting should be kept entirely separate. For public lighting at first only 500 watt arc lamps fixed at an average distance of about 50 yards apart, and arranged in two circuits along the streets would be used.

Mr. G. PEARSON moved—"That the area to be at first lighted by electricity under the Bristol Electric Lighting Order, 1883, be the area recommended in the report of the committee."

Alderman PROCTOR BAKER seconded the resolution, and said, though he did not throw the slightest doubt upon Mr. Preece's figures, he would remind the council that the committee had entirely to rely upon Mr. Preece for the calculation, and that the figures were those of Mr. Preece, and not those of the committee.

Several members then spoke in favour of the area being extended, and finally the motion was agreed to.

Mr. PEARSON next moved—"That the high-pressure alternate current transformer system be adopted for electric lighting by the authority."

This was agreed to.

Mr. PEARSON proposed—"That the committee be authorised to carry out the installation recommended in the report, and to obtain tenders for the necessary machinery and works, and to employ such professional and other assistance as they may require."

The resolution was agreed to, as also was one sanctioning the appropriation of properties in Temple Backs for the erection of a central station.

The Council then rose.

## PARLIAMENTARY INTELLIGENCE.

### The Central London Railway Bill.

BILL BEFORE THE HOUSE OF COMMONS SELECT COMMITTEE.

THURSDAY, MARCH 4TH.

The Select Committee of the House of Commons, consisting of Mr. Hanbury (chairman), Mr. Barran, Mr. Gane, and Mr. F. Parker, on Thursday, resumed the consideration of the Central London Railway Bill.

The case for the promoters having concluded on the previous day, Mr. LITTLER, Q.C., addressed the Committee on behalf of the Ecclesiastical Commissioners and the City of London. He said that as negotiations were still proceeding between the representatives of the promoters and of the City, he did not propose to deal with the opposition of the latter. The proposed scheme would pass under the most important line of streets in what they all knew to be the greatest metropolis in the world, and he asked the Committee not to hand over such an important thoroughfare to a speculating syndicate on the mere statement of an enterprising American. If the promoters desired to construct a railway they ought to bring in a Bill for the construction of an ordinary railway, with an ordinary gauge, so that it might be brought into communication with other systems. The learned counsel said that clause 56 of the Bill proposed that the Company might, without making any payment or compensation, appropriate and use the sub-soil and under-surface of any street, road, or footway necessary for the construction, maintenance, working, and use of their railway; and the promoters had stated that they would not take the Bill without such a clause. That statement was conclusive evidence to his mind that the promoters knew they were going to do considerable damage to the property under which the line would pass. The promoters had made out no case to justify the clause depriving his clients of their rights as landowners to the sub-soil.

Mr. CRIPPS, Q.C., on behalf of the Vestry of Marylebone and Lord Portman, argued that the promoters of the Bill were not entitled to deprive the owners of property along the route of the proposed line of their common law right to compensation for disturbance of the sub-soil.

Mr. GRAHAM, on behalf of the Trustees of the Paddington estate, said his clients' property was worth about a million sterling. They opposed the scheme on two grounds, namely, that the promoters were not entitled to take the sub-soil without paying compensation; and that the proposed line was not the best that could be constructed.

Mr. BIDDER, Q.C., who represented the Trustees of the late Duke of Portland, said his clients' first objection to the Bill was that it proposed to confiscate some of the rights of owners of property. Another objection to the scheme was that they did not know whether it was likely to be successful and remunerative. According to the evidence of Mr. Greathead, the engineer, in the space of two months the City and South London Railway Company had carried 900,000 passengers, earned about £750 a week, and had had some twenty mishaps through short circuits, &c. Not a word, however, had been said as to whether or not the line paid its working expenses. Dr. Hopkinson, who was called for the promoters, said he did not know whether it did or not. Last year the promoters called Mr. Mather, who stated that he had entered into a contract to work the City and South London line at ninepence per train mile, and that he was prepared, if Parliament passed the present Bill, to work it also at ninepence per mile. Where was Mr. Mather now? That gentleman had had his experience; he had had two months of it, and he knew whether the line was succeeding or whether he had burned his fingers. Why had he not come before the Committee this year to tell them that he was still willing to work the line at ninepence per train mile? Because he is a wiser man now than he was last year. He had had two months' experience of the City and South London Railway, and that had sickened him. Mr. Mather would no more undertake to work the line at ninepence per mile now than he would think of financing the whole undertaking. Mr. Greathead, in his cross-examination, admitted that he could not say whether or not the City and South London line paid its expenses. Therefore he (the learned counsel) thought that Parliament acted wisely last year in saying that until the City and South London experiment had been tried it would not commit the public to further schemes of this kind. If the Committee agreed with that view then they ought to say that they would not sanction the scheme until it was shown that the line could be worked successfully from a financial point of view. It is now said that the City and South London Railway earned about £750 a week. The proposed line was double the length of the City and South London, and it might carry double the amount of traffic. The question of the cost of electric traction was an important one. On the proposed line there was to be a two minutes' service, and every train had to run six miles. If they ran for 16 hours they would have to cover 3,840 train miles per day. At Mr. Mather's figure of 9d. per mile the cost of traction alone would be £144 a day. That was considerably more than the gross earnings on the City and South London Railway. In addition to that sum the Company would have to provide for officials, drivers, wear and tear of plant and rolling stock, and rates and taxes. If the promoters got any person to take the contract at Mr. Mather's figure, they would have to pay £864 a week for the electrical traction alone. It was a very moot point whether the cost of working would not swallow up the whole earnings.

The CHAIRMAN: He qualified that statement to which you have referred by saying he had no doubt there would be a profit.

Mr. BIDDER, continuing, said he had no doubt the figures of the City and South London Company would show whether or not a profit was being made. Mr. Greathead was only able to say that, because he had not got the figures before him. Mr. Mather had got the figures; but he did not come to make such a statement. While he (the learned counsel) was not able to prove that the City and South London Railway was not working at a profit, he could with perfect confidence submit that there was a total absence of any proof of a profit having been made. The evidence with regard to the South London experiment, for which Parliament said it would wait before it sanctioned similar schemes, had been carefully kept back from the Committee, and he (the learned counsel) unhesitatingly asserted that the working of that experiment had been disastrously unremunerative, and that if evidence on the point had been called it would have been fatal to the present scheme. The scheme was really promoted by a few gentlemen who had come across the water to see what they could make out of the simplicity of the Londoner. In fact, the whole thing from beginning to end was an extremely clever Yankee speculation upon which Parliament should put its foot down. In conclusion, he submitted that the Committee ought to reject the Bill on the ground that it was premature, the witnesses called on behalf of the promoters having admitted that they could not say whether or not the City and South London Railway paid its working expenses.

Mr. POPE, Q.C., on behalf of the London County Council, said that if the Committee passed the Bill the County Council desired them to insert a clause enabling them to purchase the undertaking after the lapse of a certain period. The proposed railway was not a national but a local enterprise, though it was not to be carried out with local capital. The object of the promoters of the Bill was to make money, and he (the learned counsel) thought it was a reasonable request on the part of the County Council that they should have power to resume possession of the main arterial thoroughfare after the expiration of a certain number of years. Forty-two years was the period fixed for electric lighting, and he suggested that that period should be inserted in the present Bill. The proposed railway would be practically another underground street upon which electric tramcars would be run.

Mr. PEMBER, Q.C., having drawn the attention of the Committee to the fact that as the opponents of the Bill had not called any evidence, he was precluded from replying upon the whole case on behalf of the promoters.

The CHAIRMAN directed that the room should be cleared. On the public being readmitted, the Chairman announced the decision of the Committee. He said: We consider that the preamble is proved, but we also consider that the scheme must be carried out as a whole, if at all —that is to say, from one end to the other—and for that reason, when we come to clause 48, we shall have to consider whether it would not be advisable, although we know it is a clause which has been come to by agreement between the promoters and the Commissioners of Sewers, to alter that clause so as to limit by arbitration or otherwise the large powers given to the Commissioners by the clause in its present shape. We foresee that

Digitized by Google

the Commissioners might so use their veto that they might say, "The line shall not go under Holborn-viaduct." We say if it does not run the whole length then we do not grant it at all. With regard to the claim of the London County Council to have the right to purchase the undertaking, we refuse that. Then as to the sub-soil, we think it only fair that Mr. Pember should be heard upon that point.

The Committee then adjourned till Friday.

FRIDAY, MARCH 6.

Mr. PEMBER, Q.C., who appeared for the promoters, said, since the adjournment his clients had considered the Chairman's remarks with regard to clause 48, and had agreed to a modification of the clause. The clause at present provided that before the promoters commenced their works under Holborn-viaduct they should give the Commissioners of Sewers one month's notice of their intentions, and that pending the sanction or refusal of the commissioners they should not commence them. That clause appeared to give the commissioners the right of veto, inasmuch as there was no power to refer the question to arbitration. The commissioners had agreed to a sub-section being inserted to the effect that the withholding of their consent should be deemed to be a difference between the parties, and should be considered by an arbitrator. The promoters would also consent to a clause, providing that no part of the proposed line should be commenced until any question at issue between them and the Commissioners of Sewers with regard to passing under Holborn-viaduct had been settled.

With regard to the use of the subsoil, the CHAIRMAN, after the Committee had deliberated, said it was the opinion of the Committee that sufficient reason had not been shown for allowing the clause, to the effect that the promoters should not be liable to pay compensation for the appropriation and use of the sub-soil to remain in the Bill. It, therefore, would be struck out. The Committee, of course, gave the promoters leave to take the sub-soil, but they were not prepared to go beyond the provisions of the general law as to compensation.

It having been stated that there were clauses to be argued affecting the London County Council, the Marylebone Vestry, the Duke of Westminster, and the Dean and Chapter of St. Paul's, the Committee adjourned the consideration of them till Wednesday next.

WEDNESDAY, MARCH 11TH.

Mr. FREEMAN, on behalf of the promoters, said the clause with regard to the fares to be charged on the proposed railway had been modified. It now stated that the Company would run at least two trains each way every morning and evening, Sundays and holidays excepted, not later than seven o'clock in the morning or earlier than six o'clock in the evening, for artisans, at a halfpenny per mile. The proposed railway had to compete with the omnibus traffic, and he asked the Committee to bear in mind that while the latter contributed nothing to the rates, the former would have to pay a considerable sum.

Later on it was stated that the promoters would agree to run two trains each way at a minimum fare of twopence.

The CHAIRMAN: That won't do. We think you ought to fix the fare at a penny per journey for each passenger.

Mr. PEMBER said it would be hard on the promoters to insist upon their fixing such a small maximum rate for workmen's trains. The cost of constructing the proposed line would be £600,000 per mile.

The CHAIRMAN: We shall insist upon the penny fare.

Mr. PEMBER said he did not believe there was a single case in which a railway company was called upon to carry workmen at the rate of a penny for six miles.

The CHAIRMAN said the Committee were doubtful whether two workmen's trains each way would be sufficient. They therefore suggested that the number should be increased to three.

After considerable discussion the clause was amended in accordance with the decision of the Committee.

Mr. CRIPPS, Q.C., on behalf of the Marylebone Vestry, proposed a new clause, providing that no soil excavated in the construction of the railway should be conveyed along Oxford-street between the hours of 10 a.m. and 6 p.m.

Mr. FREEMAN objected on behalf of the promoters to the clause, which was rejected.

A clause agreed to by the promoters and the Westminster Electric Supply Corporation was then inserted in the Bill. It provided that the promoters should not sink any shaft in connection with their railway at any point within a distance of 100ft. from the north wall of the Westminster Corporations's central station or depôt, situate in Davis-street.

The Bill then passed through Committee, and will be reported, as amended, to the House in the usual way.

## The City and South London Railway Bill.

In the House of Commons, on Friday evening last, this Bill having been read a second time,

Mr. T. H. BOLTON moved:—"That the Committee do insert clauses in the Bill providing either (1) for payment to the local authority of a royalty or share of earnings after interest on capital and working expenses; or (2) for specially reduced fares on certain trains between hours most convenient for the working classes and for clerks and others engaged in business, the railway company being required to run a specified number of such trains daily." He said that the House would remember that during the discussion which took place a short while since on this subject he suggested two ways of compensating the public in these matters—namely, by giving a royalty to the local authorities, or by giving them a share of the earnings after interest on capital and working expenses had been paid. The right hon. gentleman the Chairman of Committees suggested another way, and that was by a provision for cheap fares. In deference to the right hon. gentleman he withdrew his instruction, but at the same time the impression was left on his mind, and he believed on the mind of other members of the House, that this question should be considered by the Committee; but counsel who appeared for the promoters ignored what had taken place in the House, and treated the subject of his motion with indifference, stating that he had withdrawn the motion because it had been unfavourably received by the House. He had, therefore, put the motion on the paper again. He did not propose to reargue the claims of the public, because he believed it was generally admitted that the public had a very substantial interest in the matter. The promoters themselves took a most sanguine view of these tunnel undertakings. In one of them it was proposed to provide facilities for carrying as many as 350,000 people a day, and the railway which was already working on the other side of the Thames had in a little over two months carried 900,000 passengers. That was conclusive evidence that the privilege asked for was one of enormous value, and therefore it was the duty of the House to take care that the public interests in the matter were very well looked after. Having no interest except the public interest at heart, he moved the instruction in no spirit of hostility to the undertaking, but he believed that this was so good a thing that the Company could well afford to give the public some return for the very large Parliamentary powers they asked for.

Mr. COURTNEY suggested that the hon. member should wait until the Committee finished their work before moving this instruction, which was premature. He strongly deprecated the moving of this instruction just at the time the Committee were considering the matter.

The House divided and the numbers were—

| | |
|---|---|
| For the instruction | 71 |
| Against | 111 |
| Majority against | 40 |

Mr. T. H. BOLTON moved a similar instruction in connection with the Central London Railway Bill. The instruction was negatived without a division, as was also a similar instruction moved by the hon. member in connection with the South Kensington and Paddington Subway Bill.

## North Metropolitan Tramway Company's Bill.

On Monday the North Metropolitan Tramways Bill came before a Select Committee of the House of Commons, consisting of Mr. Hanbury (Chairman), Mr. Barran, Mr. F. Parker, and Mr. Gane.

Mr. POPE, Q.C., in opening the case for the promoters, said the object of the Bill was to amend the Act of last year by giving an appeal to the arbitration of the Board of Trade against what was regarded as the unreasonable action of the West Ham Corporation in refusing the Company permission to use electricity as a motive power upon parts of their tramway. The Company desired to use electricity upon the line from Clapton to Moorgate-street, and also from Leytonstone to Stratford, and they applied for the assent of both the London County Council and the West Ham Corporation. The London County Council had assented upon the terms that the Company put the tram route into a proper condition for the use of electricity and submitted from time to time any requirements which the County Council might think necessary in order to secure the safety of the traffic and the safety of the passengers during transit; but the West Ham Corporation had refused to assent to the seven years' licence, insisting that the Company should be liable to remove their electrical engines and plant at 24 hours' notice. The Company, therefore, proposed that in the event of the West Ham Corporation refusing to grant them reasonable facilities, there should be an appeal to the Board of Trade.

Major-General HUTCHINSON, of the Beard of Trade, gave evidence in suport of the Bill. He said the Board of Trade had at their disposal electrical engineers and experts who would be able to assist the Board to arrive at a proper decision. He could not regard as reasonable the stipulation of the West Ham Corporation.

At the conclusion of the case for the promoters, the Chairman, without calling upon counsel on the other side—Mr. Sanders, Q.C., and Mr. Baggallay—ordered the room to be cleared. On the public being re-admitted, the Chairman announced that the Committee did not consider that the preamble had been proved. The Bill was accordingly thrown out.

# AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *February* 27, 1891.

**High Speed Electric Traction.**—The meeting of the Institute of Electrical Engineers on Tuesday evening last was of unusual interest. It has long been known that a remarkable series of experiments on electric traction at enormous speeds was carried out at Laurel, Maryland, about a year ago, under the direction of Mr. O. T. Crosby. No full report of the work, however, had been given until now, when Mr. Crosby read an elaborate Paper giving his experience in work under those very unusual conditions. In spite of a peculiarly bad track of narrow gauge, laid with rails weighing only 16lb. to the yard, and running part of the way on trestles over a swamp, a speed of 120 miles an

Digitized by Google

hour was actually reached with a car weighing 2½ tons. No difficulty whatever was experienced in the use of a travelling contact at this speed, and some interesting data as to air resistance were obtained. After some months of experiment the work was abruptly concluded by an accident, owing to the bad track, that disabled the car and wrecked some 300ft. of track and trestle. The output required to reach the higher speeds was considerable, rising to as high as 50-H.P. In spite of their unfortunate termination the experiments were so successful as to encourage their continuance on a large scale, and plans were made for an electric locomotive of 500-H.P. to run on a track of standard gauge, either for experimental or regular railway service. Nothing has as yet come of the designs arranged by Mr. Crosby for this work, but it is expected that the Weems Company, which carried on the original experiments, will continue them shortly on a larger scale. Mr. Crosby's Paper attracted a great deal of attention, as it represented a phase of electric traction that is quite unique, no such speeds having been reached by any machine of human contrivance. In the discussion that followed some interesting facts were brought out concerning the mechanical properties that must be possessed by a railway track to sustain these remarkably high speeds. It was pointed out that rails constructed with special reference to great stiffness were absolutely necessary for such work, and that with such rails and proper care in track construction there was no reason why 120 miles an hour should not be a safe speed. It has already been shown that stiff rails mean decidedly less power required for traction, in addition to increased safety.

**Rapid Transit in New York.**—The monthly dinner of the New York Electric Club was held on Thursday evening of this week, and was the occasion of a symposium on the subject of rapid transit in New York. The chief speaker was Mr. Frank J. Sprague, who has followed the subject persistently from the very beginning of his work on electric traction to the present. Mr. Sprague is a firm believer in electric railway work at high speed, and under almost all conditions; and he expressed a thorough conviction that the only available means for rapid transit in this unfortunate city was to be found in an underground system operated by electric motors. Although he did not expressly make such a statement he evidently favoured the Greathead tunnel, that has made so signal a success in London. Mr. Sprague's plea included not only a four-track trunk line around the city, but connections under the East River, joining the New York underground road to a similar structure in Brooklyn. Following Mr. Sprague, Mr. Louis Sterne explained in detail the construction of the City and South London Railway. He was listened to with the keenest interest, for all eyes are just now turned toward that pioneer electric underground road as almost our only source of information to aid in the solution of the difficult problem that is before the public. At present public sentiment is undoubtedly in favour of an underground railroad, rather than any system of elevated structures or viaducts. Poor service, and a total disregard of public comfort, have been displayed by the elevated roads for so long a period has created a strong prejudice against them, that it is very doubtful if any system whatever that contemplated the use of elevated structures in the existing streets would be tolerated for an instant. The viaduct plan is an attractive one, and has many friends, but the feeling is growing that its enormous expense quite prohibits its use in the portions of the city that most feel the need of rapid transit. Something must be done, and that quickly, and the Greathead or some similar tunnel system will probably meet a favourable reception.

**Davenport's Model Electric Railway.**—After dinner there was displayed what we may call the first electric railway in the world. A little circular model electric railroad, constructed by Thomas Davenport, the Vermont blacksmith, about 1837. The motor was on the end of the pivoted arm, carrying three Grove cells as a counterpoise, and a simple armature with a two-part commutator operating the one small driving wheel through the medium of a bevelled gear. This model was but recently discovered, and has special interest as the first attempt at an electric road of any kind.

## PARIS NOTES.

(FROM OUR OWN CORRESPONDENT.)

PARIS, *March* 10, 1891.

At the last meeting of the Société Internationale des Electriciens, M. Hospitalier published the results of some tests of the wonderful de Meritens cell carried out at the Ecole de Physique et de Chimie. On open circuit the E.M.F. was 1·8 volt, but after momentarily closing the circuit it was only ·8 volt. A single cell gave 6·8 amperes on first closing the circuit, the E.M.F. being ·68 volt; when only one-half of the liquid was exhausted the current was 5 amperes, and the E.M.F. ·5 volt. The consumption of zinc was that indicated by theory. Per kilowatt-hour (1·34 H.P.H.) 5 to 7 kilogrammes of sulphuric acid at 66° Baumé and 2·18 kilogrammes of zinc are consumed, the total cost being nearly 2½ francs, and the total weight of liquid concerned being 75 kilogrammes. In his original paper M. de Meritens made much capital out of his proposal to electrolyse the spent solution using iron anodes, and thus recover his zinc, and generate a useful disinfectant at the same time. M. Hospitalier showed that more power was required to perform this operation than was given out by the cell. Another feature of M. de Meritens' cell was the employment of a perforated carbon negative covered with a lamina of platinised lead. Without this adjunct of platinised lead, the output indeed slightly diminished, but there was a considerable gain in constancy. Again, M. de Meritens employs chemically pure zinc, but with ordinary commercial zinc and without the platinised lead lamina, the consumption of zinc was but slightly increased. Various inaccuracies in M. de Meritens' statements were next pointed out by M. Picou.

At the same meeting M. d'Arsonval described an arrangement employed by him to run a motor at a given speed, and keep it running steadily at that speed. A hoop of springy metal is arranged between the end of the motor spindle and an adjustable screw, the current passing into the motor *viâ* the screw and the metal hoop. The mode of action is analogous to Delzen's circle. M. d'Arsonval has applied this device to the determination of the mechanical equivalent of heat by causing the motor to revolve, at a constant speed, a copper tube filled with water in a constant magnetic field, and measuring the temperature and the quantity of the outflowing water. M. d'Arsonval then described a method of running an alternating motor at a constant speed by connecting one terminal to a tuning fork and the other to the centre of a secondary battery, the terminals of which are connected to the two stops, against which the tuning fork impinges.

The last Paper of the meeting was one by M. J. J. Heilmann, in which he described a decidedly original kind of railway locomotive. The locomotive of to-day is a very wasteful animal, as we all know, and M. Heilmann's idea is to employ a tubular boiler, and a triple-expansion low-pressure engine driving a dynamo which is to furnish current to two motors on the bogie axle. M. Heilmann showed numerous curves and diagrams to support his claim for economy.

The Société Générale des Téléphones announces that having won its case in the Court of Appeal, all makers and sellers of infringing apparatus will be prosecuted with the utmost rigour of the law. The patent in question covers the use of the induction coil in telephonic instruments. One result of the successful issue of this lawsuit has been an immediate rise in the price of the Company's shares.

M. de Selves has announced that the principal towns in the Northern district, Lille, Roubaix, Tourcoing, &c., are to be placed in telephonic communication with the Belgian towns across the frontier, and that a third wire will shortly be erected between Paris and Brussels.

By 24 votes to 20 the Conseil Municipal of Lyons has given permission to the Compagnie Lyonnaise des Tramways et Chemins de Fer to run an electric line from the Gare des Dombes to the Garo de Perrache.

The Babcock and Wilcox boiler company have entered into an agreement with the Creusot Works to undertake the construction of their boilers.

## CORRESPONDENCE.

### BARKING ROAD CARS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have to thank Mr. Kapp for his offer to publish the authorised figures of the Barking-road installation. When my Board think it desirable to do so, I shall have no difficulty in bringing them before the public. The effort that is being made to prove that five cars cannot operate at the same cost as 300

is quite unnecessary. I would only add that, in response to invitations from various tramways companies and corporations owning tram lines, my company have been and are issuing tenders to electrically equip and maintain tram lines by the overhead, conduit, and accumulator systems.

If electro-traction by accumulators were more expensive than horse traction the North Metropolitan Tramways Company, who have now had something like two years' experience of the work of these cars, would not be, as they are at present, applying to Parliament for powers to extend the system at a capital outlay to themselves of £50,000.—Yours, &c.,

W. G. M. MACKENZIE, Secretary.

THE GENERAL ELECTRIC POWER AND TRACTION COMPANY (LTD.)

London, E.C., March 9, 1891.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In his letter appearing in your last issue Mr. Fraser states the life of E.P.S. secondary batteries on tramcars to be ten months, or 300 discharges. As a matter of fact, the life of the ordinary positive traction type plates is about 400 discharges *more or less, according to the degree of care in handling.* The life of the negative plates is for effective work about 750 discharges, but I have not up to the present time seen a plate which has actually broken down from fair wear and tear. When, in February, 1890, the positives of the first set of batteries at Barking-road required renewal, it was decided by the Traction Company to renew both positive and negative plates, but it was afterwards evident upon inspection of old plates sent in that the majority of the negatives would have certainly run for another year.

The experience of the past year, from February, 1889, to February, 1890, has proved that the maintenance rate for E.P.S. batteries on the Barking-road line, with all the manifest disadvantages of a small installation, has not exceeded *one penny* per car mile, and this with batteries of the old traction type.

Crucial experiments have now satisfied me that the positives of the "K" type traction plates will endure in actual work from 800 to 1,000 discharges, and that the maintenance of batteries will hereafter be fully covered by two-thirds of a penny per car mile.—Yours, &c., FRANK KING.

65, Chelverton-road, Putney, S.W.

# LEGAL INTELLIGENCE

### Reg. v. The Fareham Electric Light Company (Limited).

This action was tried at Winchester on Tuesday last before the Lord Chief Justice of England and a common jury. Mr. Bucknill, Q.C., and Mr. Bovill Smith were for the prosecution; Mr. Bullen appeared for the Company; Mr. J. Alderson Foote appeared for a syndicate employed by the Company and indicted with them; Mr. James Blake, one of the defendants, appeared in person.

This indictment was against the defendants for having obstructed some highways in the town of Fareham by digging holes and erecting posts and wires for the purpose of inaugurating a system of electric lighting. It was said that the posts were an obstruction to the highway, and even in some cases dangerous. There was, however, no real dispute as to the facts. Early in 1890 an agreement was entered into by the Fareham Local Board and Blake, on behalf of the Fareham Electric Light Company, whereby the Local Board granted to the Company, "so far as they lawfully could," leave and licence to erect all necessary posts and wires for the supply of electric light. In June a contract was entered into between the Electric Light Company and the Local Board for the lighting of the town by electricity for a term of three years. At that time, and for many years past, the local gas company had supplied the Local Board with gas for lighting the town, and the gas proprietors were practically the prosecutors in the present case, their contention being that the Local Board could not delegate to the Electric Light Company the power of erecting posts in the highway.

At the end of the arguments his Lordship said he must direct an acquittal. Undoubtedly the posts would have been an obstruction but for the statutory powers given to the Local Board by the Public Health Act, 1875. He then referred to Section 161 of that Act, and said he considered "other means of lighting" mentioned in it included electricity, even although electric lighting was practically unknown when that Act was passed, and that under the section the Local Board could contract with the electric light company. He directed the jury to find all the defendants not guilty.

# TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891**

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

TENDERS WANTED.—The Town Commissioners of Ballymena, Ireland, are desirous of receiving tenders for lighting the town by gas or electricity from August 16th, 1891, until May 16th, 1892. Tables of lighting and other information are to be obtained from Mr. Henry O'Hara, Ballymena, to whom sealed tenders are to be sent by Monday next, the 16th inst.

THE LIGHTING OF BELGRADE.—The municipal authorities of Belgrade propose to grant a 41 years' electric lighting concession. The public lighting will comprise 65 arcs and 1,000 16 C.P. incandescents. Tenders (in German, French, or Servian) will be received up to April 13th. Further particulars can be obtained of Herr Peter Tipkov, Belgrade.

DISSOLUTION OF PARTNERSHIP.—The *Gazette* announces the dissolution of partnership between Messrs. Kent and Stapylton, 5, Denman-street, London Bridge, electric lighting engineers.

ST. PANCRAS VESTRY ELECTRICAL EXHIBITION.—The General Electric Power and Traction Company are exhibiting at this exhition a very interesting show of motors driving, dometic, and other machinery, such as knife cleaners, washing machines, &c., as well as electric light fittings, switches, lamps, &c.

ELECTRIC LIGHTING AT MARGAM CASTLE.—Several leading firms were recently requested to submit competitive schemes for the lighting of the above, and the order for the work has been entrusted to Messrs. Drake and Gorham. The installation consists of about 350 incandescent lamps, and will be the largest of its kind which has been erected in the neighbourhood. The work will be carried out under the superintendence of Mr. A. A. Campbell Swinton.

CLUB LIGHTING.—Messrs. Henry F. Joel and Co. have recently installed the electric light at the new National Sporting Club, which occupies the premises for so many years known as Evans's, in Covent-garden, London. The installation consists at present of 160 lights, but provision is made for an extension to 300 lights. The fittings have been specially designed to assimilate with the general design of the building. The current is supplied by the Metropolitan Company.

MESSRS. H. BINKO AND CO.—This firm have received instructions to fix with their patent electrical mercurial thermostat all the bunkers and refrigerating rooms of the Union Steamship Company's new ss. "Scot," recently built by Messrs. Denny Bros., of Dumbarton.

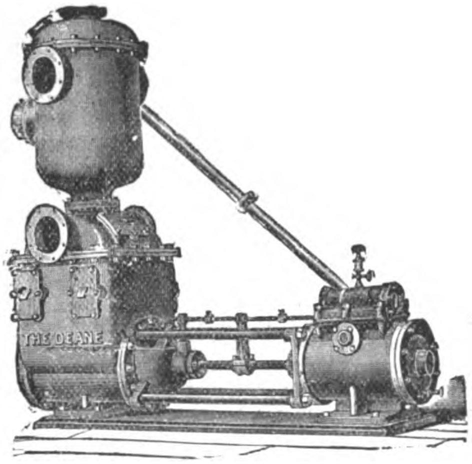
THE ACME ELECTRIC WORKS.—The West End business of the Acme Electric Works has been purchased by Messrs. Moat and Co., and for the future will be carried on under the name of C. Moat and Co., of whom all the "Acme" specialities may be obtained, as well as the goods of other manufacturers.

MESSRS. W. H. WILLCOX AND CO.—This firm forward us illustrated particulars of Ingall's patent boiler tube scraper and cleaner, and of a new and improved internal boiler tube cutter. Both tools are well made. The scraping arms in the former are made of cast iron with chilled working edges, and do not anneal from the effect of heat. The boiler tube cutter will cut a tube either inside or outside the tube plate, is constant feed, and is worked with a ratchet.

Digitized by Google

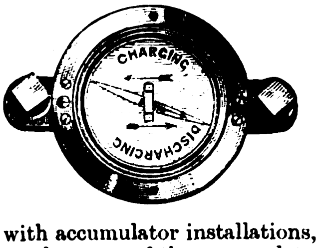
Mr. Wilson Hartnell.—Mr. Hartnell will open a branch office in London about the end of March at Mansion House-chambers, 11, Queen Victoria-street, E.C., which will be under the managment of Mr. Farrar, who is well known to many of our readers. In addition to electric lighting and power plant, Mr. Hartnell will continue the manufacture of general electrical work both for the home and foreign markets.

Independent Condensing Apparatus.—The Pulsometer Engineering Company are adding to their well-known manufactures, and are now making various types of condensing apparatus. Where water is to be had, these will undoubtedly contribute largely to the economy of high-pressure engines. One of the reasons why condensing has been so little used by electrical engineers, may, probably, be found in the fact, that while high-speed engines are particularly suited for running dynamos, they are, for two reasons, not readily suited for working with condensers. The single-acting engines depend largely upon uniformity of pressure in one direction, and air pumps are never run at such high piston speeds, as are usual in electric lighting engines. The condensing apparatus, which is



illustrated in the accompanying figure, is worked independently by a small cylinder of its own, on the principle of an ordinary direct steam-pump. It is possible, therefore, to connect two or more engines with one cendenser, and either can be stopped without interfering with the other. They run at a moderate speed and can readily be adapted to a varying load. Such a condensing apparatus is in use at Woking, where two vertical triple expansion 100 I.H.P. engines are working under 140lb. steam pressure at 300 revolutions, and we understand that the economy is very marked. We are also informed that it is proposed to place one at Queen Anne's Mansions in connection with the electric light engines, and to pump the water from the well. We are assured by the Pulsometer Engineering Company that sufficient economy can be gained to allow for the power required for pumping. Electrical engineers would do well to give more attention to the use of condensers which appears to have been very much neglected.

A Current Index.—We have received from Messrs. O. Berend and Co. some particulars of a new c rrent index, of which we give an illustration below. The inde is made by Messrs. Hartmann



and Braun for use with accumulator installations, and when in circuit shows at a glance the state of the accumulators whether charging or discharging. The instrument is well made and of compact shape.

## PATENT RECORD.

### APPLICATIONS FOR PATENTS.

February 17, 1891.

2,834. W. H. Elton. Exmouth. Automatically recording the value of shots upon targets by electric apparatus.

2,862. M. W. Dewey. London. Improvements in electric fire engines also applicable to other electrically propelled vehicles.

2,866. H. H. Lake. London. Improvements in electrical measuring instruments (E. Weston, United States).

2,902. G. S. Grimston and E. Wilson. London. An improvement in electric locomotives.

February 18, 1891.

2,985. E. Edwards. London. Improvements in apparatus actuated by electricity for stirring and turning over malt and grain (J. Sandt and H. Sturm, Germany).

February 19, 1891.

2,999. H. H. Bigland and J. Burns. Liverpool. Improvements in electric arc lamps.

3,003. E. W. Mayer. London. Improvement in element for electric battery.

3,030. M. R. Ward. London. Improvements in propelling vehicles by means of electric motors.

3,049. C. K. Mills. London. Improved circuit controller and alarm (C. M. Woolcott and A. E. Wilmot, United States).

February 20, 1891.

3,127. W. Cruyt. London. Apparatus for automatically indicating loss or diminution of current in electric circuits.

3,191. M. von Dolivo-Dobrowolsky and the Company Allegemeine Elektricitäts-Gesellschaft. London. Improvements in the transmission of alternating differential phase currents.

3,198. F. Poudroux. London. Improvements in galvanic batteries.

3,199. H. C. Harold and R. Jenkins. London. An improvement in electrical switches.

February 23, 1891.

3,239. J. S. Raworth, T. O. Callender, and C. E. Webber. London. Improvements in underground conduits for conductors of electricity.

3,262. E. A. Gimingham, of the Edison and Swan United Electric Light Company (Limited). London. An improvement in conductors for electrical glow lamps.

February 24, 1891.

3,331. S. C. C. Currie. London. Improvements in secondary or storage batteries.

3,336. H. H. Lake. London. Improvements relating to welding, brazing, or otherwise joining metal strips, bars, rods, and the like by electricity, and to apparatus therefor. (H. Lemp and L. M. Schmidt, United States).

3,338. J. A. Parker. London. Improvements in telegraphy.

3,349. M. W. Dewey. London. Improvements in electric welding apparatus.

3,357. H. H. Lake. London. Improvements relating to the jacketing of pipes and cocks, chiefly designed for use in connection with vacuum pumps for exhausting incandescent electric lamps (A. Berrenberg, United States).

3,364. H. H. Lake. London. Improvements relating to the manufacture of incandescent electric lamps (W. E. Nickerson and A. Berrenberg, United States).

3,373. G. F. Webb and J. A. Crisp. London. Improvements in and connected with medical batteries.

3,383. J. A. Kingdon. London. Improvements in dynamo-electric machines.

February 25, 1891.

3,398. A. E. Spencer. London. An improved electrical burglar alarm.

3,404. C. H. Elliot and E. F. Furtado. London. Improvements in switches for telephone circuits.

3,417. W. H. Munns. London. An improved galvanic battery (G. A. Smith, Canada).

3,426. H. J. Dowsing. London. Improvements in brushes and brush holders for electric machines.

3,449. P. Rabbidge. London. Improvements in telephones.

3,450. W. H. Power. London. Improvements in primary batteries.

3,455. W. A'Court G. Birkin. London. Improvements in electro-magnetic percussive rock drills and the like.

February 26, 1891.

3,495. C. M. Dorman and R. A. Smith. Manchester. Non-percussive quick-break electric switch.

3,518. E. Guyard. London. An improved inking device for use in telegraphic instruments.

3,524. R. D. Sanders. London. Improvements in apparatus for use in the manufacture of metal tubes by electro-deposition.

February 27, 1891.

3,538. J. Mackie. Glasgow. Improvements in electrical contact apparatus, and parts connected therewith, for automatic stop motions and analogous applications in spinning, twisting, winding and other machines or apparatus.

3,553. W. P. Thompson. Liverpool. Improvements in conduit electric railways (E. M. Reed, United States).

3,570. F. George. Southport. Improvements in electro-therapeutic apparatus.

3,589. H. H. Lake. London. Improvements in electric batteries (W. B. H. Dowse, United States).

3.592. W. Whitehead. London. Improvements in electric alarm apparatus.

## COMPANIES' MEETINGS & REPORTS.

### London Electric Supply Corporation (Limited).

The following is the full text of the annual report for 1890, to be presented by the Directors at the annual general meeting, to be held at the Cannon-street Hotel this day (Friday), the 13th inst., at 12 noon :—

The general position of the works is described in the engineer's report appended thereto.

The causes which led to the fire at the Grosvenor distributing station are stated in the engineer's report. The Directors are assured that with the measures now being taken for the equipment of the permanent distributing stations, any recurrence of such a calamity will be impossible in future. The premises damaged by the fire were insured, and are now being reconstructed in the most substantial manner.

The interruption to business and the loss of income caused by the fire has been serious, and the Directors regret that it will not be possible to declare any dividend upon the Preference capital. The portion of the year during which supply was suspended is a period at which the revenue is, under ordinary circumstances, at its maximum, but, owing to the severity of the winter, revenue in excess of the ordinary rate would have been produced, which, had it been received, would have enabled the Directors to pay a dividend on the Preference capital.

The results of working for the short period that ensued between the closing of the Grosvenor station and the cessation of supply on November 15th confirms the statement made in the last report, that the concentration of the whole of the generating machinery in one establishment, under the control of the Chief Engineer, would secure material advantages in supervision and economy.

During the past year statutory powers have been acquired over several metropolitan parishes, which have led to a more economical and beneficial disposition of the works. The Board are making no applications for further powers this year, and will limit their Parliamentary business to defending themselves against opposing interests.

Notwithstanding the loss of certain old customers after the fire, new applications for current are coming in from day to day, and large demands are arising in certain portions of the authorised area in which, hitherto, there has practically been none. Works are now in hand with a view to meeting the material extension of the business which may be anticipated. Meanwhile supply of current was resumed on February 15th, and customers are being connected to the new underground mains as rapidly as possible.

The Directors retiring, as provided by the Articles of Association, are Mr. Francis Ince, Mr. Joseph Pyke, and Mr. Arthur F. Wade, all of whom are eligible, and offer themselves for re-election. The auditors, Messrs. Kemp, Ford and Co., who retire in accordance with the Articles of Association, offer themselves for re-election.

#### ENGINEER'S REPORT.

To the Directors of the London Electric Supply Corporation (Limited).

Gentlemen: Since I had the pleasure to report to you a year ago the engineering work of the Corporation has gone through a period of considerable activity under my direction. The concentric mains which you have manufactured under my patents have proved to be a complete success. Four concentric trunk mains have now been laid from Deptford to London, consisting in all of some 25 miles; they are laid in 20ft. lengths, and thus in the above distance there are no less than 6,500 joints. The work of laying was of necessity performed by unskilled labourers, who had neither experience nor training in such work, and I am glad to say that on first testing the mains only some 20 joints out of the entire number proved to be defective; these defective joints are easily found and rapidly replaced. The mains have been thoroughly tested with a pressure of 17,000 volts, and have stood this test perfectly, and as you are aware they are now in daily use at a pressure of 10,000 volts, the normal pressure of your permanent work.

With the sanction of the Board of Trade, earthing arrangements have been made in connection with the mains and other portions of your system, and the working is so satisfactory that no disturbance whatever is caused to the telephone or telegraph systems; in fact, neither the Post Office nor the Telephone Company are able to say when your machinery is working.

During the past year the whole of the machinery from the Grosvenor station has been removed to Deptford. The dynamos, which were designed to give 10,000 lights each, have been found capable of supplying with ease 15,000 lights each, consequently two larger engines for working these machines to their full capacity have been erected at Deptford during the year. These dynamos have been put into a thoroughly efficient state, and with this plant the work is now being done. In addition, two larger engines, each of 1,500-H.P., which had just been erected at the date of my last report, have been got into efficient running condition, and the necessary alterations are being made to the two larger dynamos (each capable of giving 30,000 lights), that will enable you to use them, now that your concentric mains are complete, at a full pressure of 10,000 volts (for which the machines were originally designed), instead of 5,000 volts, the pressure first used. These machines will be working at 10,000 volts pressure within the next three months, and you will then be in a position to generate current for 90,000 lights. It is not, however, proposed to supply more than two-thirds of this number at the same time, in order that a reserve of power sufficient to meet the requirements of the Board of Trade may be always kept in hand.

With these two large machines supplying your circuits the first important stage of your undertaking will be completed.

Great progress has also been made towards the next stage, though this work has not been pressed in view of making more rapid progress with that of the first stage. Nevertheless, more than three-fourths of the work of the next pair of dynamos has already been done. They will each be capable of supplying 200,000 lights; but in the first instance it is intended to supply engine power to each dynamo for 100,000 lights only, and by the end of another year from the completion of what I have called the first stage of your work, I expect to be in a position to report the completion of the second stage. You will then be able to supply 290,000 lights, less a proper reserve. Sufficient mains are already laid between Deptford and London to transmit the current which you will then have to dispose of.

I desire to call attention to the fact that from the commencement of your operations to the present time, no engineering or electrical difficulties whatever have arisen which I have not been able to overcome, and at the present moment I know of no weak point in your system, and consider success to be now assured.

It is a matter of great regret that a fire in your temporary distributing station in November last has caused a loss of the revenue which would otherwise have been earned, and which, owing to the extraordinary severity and darkness of the winter, would have been more than usually profitable. I am glad to say that this fire was not due to any defect of principle in your system, and could not have happened had your permanent distributing station been erected; but as you are aware, it was an impossibility to erect the permanent station, the premises being occupied by the machinery which was then in course of removal to Deptford. The fire has, however, in some sense been beneficial, as it has allowed the permanent work to be pushed forward to an extent which could not otherwise have been possible, progress having been much delayed by the necessity of keeping a running business going during a period of progressive changes in the permanent system. The loss occasioned by the fire was not serious, so far as destruction of apparatus was concerned, but was principally felt in decreased revenue returns. The suspension of supply enabled good progress to be made with the laying of distributing mains, there being at the present time some 18 miles laid and in use.

It was important that this work should be pushed on, as the right to use overhead cables expires in the summer of this year, and the distributing mains being so well advanced, it has been deemed wise to discontinue the use of those cables. Your customers are now being connected to the permanent underground mains with the utmost possible speed.

A most important work has been completed during the past year in erecting at Deptford switching gear, which allows all or any of the machines to be used separately, or in combination. It has been further proved that the various machines can be worked together in parallel, a matter of considerable importance to successful working, as ensuring the maximum of efficiency and economy.

The Corporation has secured sites for three additional distributing stations, and the work of installing them with the necessary apparatus is being proceeded with. The stations will all be in work during the present year, each having two separate sources of supply at 10,000 volts pressure, which is lowered at these stations and distributed at 2,500 volts, being further reduced to 100 volts before entering the wires of the customer, as in the case of the low-pressure system.

At the time of my last report there were many parts of the system which were generally considered doubtful and more or less experimental; I refer more especially to the supposed difficulties of transmitting current from Deptford to London. The fact that current of 10,000 volts pressure is transmitted every day to London is the most complete answer to such doubts.

The great advantage of the high-pressure system is apparent, in that the loss involved in transmission of current from Deptford to the distributing stations is inappreciable, while the facilities for procuring coal and water there, sufficiency of room for machinery and appliances, and freedom from the legal and financial consequences attending the erection of generating stations in crowded neighbourhoods, cannot fail to tell their own tale in the working expenses of the current year.—I am, gentlemen, you obedient servant, S. Z. De Ferranti, Engineer.

3, Adelphi-terrace, W.C., March 3, 1891.

### South of England Telephone Company (Limited).

An extraordinary general meeting of this Company will be held at Winchester House, Old Broad-street, London, E.C., on Monday next, March 16th, at two o'clock in the afternoon, when the subjoined resolutions will be proposed. In the event of such resolutions being passed, they will be submitted to a subsequent general meeting for confirmation as special resolutions, under the Companies Act, 1862, viz.:—

(1.) *That the agreement submitted to this meeting, and expressed to be made between this Company and the National Telephone Company (Limited) for the amalgamation of the two Companies, by a transfer of the business and property of this Company (with certain exceptions) to the National Telephone Company (Limited) be, and the same is hereby, approved.*"

Digitized by Google

"(2.) *That with the view of giving effect to the above-mentioned agreement and in order to enable the Debenture stock and shares to be allotted there, under, as part of the purchase consideration, to be distributed among the members of this Company, this Company be wound up voluntarily under the Companies Acts, and that Mr. Thomas Abercrombie Welton be, and he is hereby, appointed liquidator for the purpose of winding up its affairs and distributing its property.*"

"(3.) *That, pursuant to the 161st section of the Companies Act, 1862, the liquidator be, and he is hereby, authorised to carry the said agreement into effect, and to receive the Debenture stock and shares agreed to be allotted, and the cash payable thereunder, and to distribute the same among the members of this Company.*"

The above-mentioned agreement can be inspected by the shareholders at the offices of the Company.

---

The following circular has been addressed to the shareholders :—

"I beg to call your attention to the enclosed notice convening an extraordinary general meeting of the Company, to be held on the 16th instant, for the purpose of considering an important proposal for the sale of this Company's property to the National Telephone Company (Limited), and to pass the necessary resolutions, if approved, relating thereto.

"Shareholders who have attended the general meetings of this Company for the past few years will not be unprepared for this announcement.

"The terms of the proposed sale are as follows :—

"The National Telephone Company to take over the business of this Company as from November 1, 1890, together with all assets and liabilities. The profits of the business for the six months prior to the above date to be at the disposal of the shareholders of this Company.

"The purchase consideration payable by the National Company consists of :—

"(1.) 12,000 fully paid ordinary shares of the National Company, carrying the dividend accruing on April 30th next.

"(2.) Four and a-Half per Cent. Debenture stock of the National Company for £70,000.

"(3.) Interest at 6 per cent. per annum on the paid up amount of the Preference shares from November 1, 1890, until such date as the Debenture stock is issued.

"(4.) The amounts paid in advance of calls on the Preference shares, with interest, from November 1st last, at 5 per cent. per annum, until date of repayment.

"The Debenture stock is equal to the amount called up (£3. 10s.) on the 20,000 Preference shares, while the 12,000 ordinary shares of the National Company would on a *pro rata* distribution give one share of £5 for 25 ordinary shares of this Company of £1 each.

"The immediate advantage of this arrangement is obvious. The dividend on one £5 ordinary share in the National Telephone Company last year was 6s., as against 2s. 6d. on 25 £1 shares in this Company.

"The Board have the greatest confidence in recommending this proposal for your acceptance. FRED. L. ROBINSON, Secretary."

---

## The British Tanning Company (Limited).

An extraordinary general meeting of the shareholders of this Company was held on Tuesday at Winchester House, Old Broad-street, E.C., (at which Mr. H. Horny presided) for the purpose of considering and, if deemed advisable, approving a Bill in Parliament to render valid certain letters patent for the improved process and apparatus for tanning by electricity.

The SECRETARY (Mr. H. Hodges) read the notice convening the meeting.

The CHAIRMAN said: I regret that our chairman cannot be present to-day, but he is unavoidably prevented. You have heard the reason why we call you together. This is really only a formal meeting ; it is a special meeting required by the Committee of the Houses of Parliament, because, as I shall explain further to you, we have been applying to the Houses of Parliament for a Private Bill. At the last ordinary meeting, which was held on December 17th, you heard that we had a lawsuit going on against parties who had a similar process to our own. This came on in the Courts in the middle of January, and the result was unfavourable to us. The position that we occupy at the present moment is that by the decision of Mr. Justice Romer our patent is not valid in this country. To get this invalidity removed and make our patent again valid, we have taken the opinion of our solicitor and find there are several ways in which we could do it. We found that the best and the cheapest way to do it was to apply to Parliament for a private Bill. In saying the cheapest way, I mean that it will not cost us anything, because we have given notice to the vendors that they are liable to put our patent once more in a valid position. I have been over to Paris to see the vendors, with the result that they agree that this litigation to put your patent in a valid position is to their account, and they have given guarantees that the expense will be borne by them. Therefore, I think the proposal the Board of Directors is going to put before you should meet with your full approval, as it is to your interest to see that your property is in a right and valid condition without costing you anything. I have now to move,—

"*That the Bill now read, entitled, 'An Act for rendering valid certain letters patent to Eugene Worms, of Paris, in the Republic of France, and Jean Balé, of the same place, for improved process and apparatus for tanning by aid of electricity,' be and the same is hereby approved, subject to such additions and variations as Parliament may think fit to make therein.*"

Mr. QUINTIN seconded the motion.

The SOLICITOR (Mr. Birchall) having read the short title of the Bill,

Mr. PARKER-RHODES thought if the patent could be recovered by Act of Parliament, those who sold the worthless patent to them should be at the cost of proving that patent good for the sum they asked, £40,000. Let them go to Parliament and do all that was necessary, and not leave it to the shareholders, who had bought their shares on the understanding that it was a good property. The Chairman had said that he had been to Paris and seen the vendors, who had given him guarantees that they would bear the cost of these proceedings in Parliament. It would, in his opinion, cost the Company some £2,000 or £3,000 to proceed with this Bill, as they must prove that they had some justification for petitioning Parliament, and they must do that through counsel and through special solicitors. Was the vendors' guarantee in cash? He thought the Directors were doing a very serious thing in applying to Parliament over such a small matter as this when the Court of Chancery had decided against them, and he should protest against any action being taken in connection with this proposed Bill before Parliament.

Mr. WATSON asked what would be the result with regard to the shareholders if Parliament did not pass the Bill?

Mr. PARKER-RHODES said if this resolution was carried all those who were in favour of it would be taken as having given their consent to go to Parliament, and would lose their claim against the Directors for having bought a worthless patent. He then moved that the Bill be not approved.

A SHAREHOLDER said, if the Bill is not proceeded with the Company must be left without a patent, and must be wound up, and what little money was left would be thrown away in costs.

In reply to a SHAREHOLDER the CHAIRMAN said the Bill was in the House of Lords within the last day or two. In reply to Mr. Watson's remark, if the Bill was not passed their position would be the same as to-day, because they would have power to go to the higher courts. They could go to the Court of Appeal within a year, and they had already told the vendors in Paris that they held them liable. He hoped, however, that they would be successful in obtaining the passage of the Bill.

PATENT

# SILICIUM BRONZE AND SILICIUM COPPER WIRE.

The best for overhead Telephone and Telegraph Lines,

AND ALL ELECTRICAL PURPOSES.

Hard Drawn High Conductivity Copper Wire.

ROLLED AND DRAWN PHOSPHOR BRONZE.

PHOSPHOR BRONZE · VULCAN · PHOSPHOR · DURO METAL

PHOSPHOR BRONZE BEARINGS, BUSHES, AND OTHER PARTS OF ELECTRICAL MACHINERY

*SOLE PROPRIETORS of the British, Indian and Colonial Patents,*

THE PHOSPHOR BRONZE COMPANY (Limited),

*87, Sumner Street, Southwark, London, S.E.*

WIRE AND SHEET MILLS: BAGOT STREET, BIRMINGHAM.

Digitized by Google

Mr. QUINTIN said the Directors were so satisfied with the guarantee for the costs, that they had agreed to personally guarantee the shareholders against any expense in this respect.

The CHAIRMAN then put the amendment to the meeting, and it was lost, the original resolution being agreed to *nem. con.*

The proceedings then terminated.

## The Direct Spanish Telegraph Company (Limited).

The following is the report and accounts of the Directors for the half-year ended December 31, 1890, to be presented at the general meeting of shareholders, to be held at Winchester House, E.C., on Tuesday, 17th inst., at 2 o'clock:—

1. The accounts for the half-year ended December 31, 1890, show, after providing for Debenture interest, a balance to the credit of profit and loss of £6,597. 19s. 10d.

2. The traffic receipts show an increase of £1,612. 6s. 7d. as compared with the corresponding half-year of 1889.

3. The working expenses are £221. 3s. 4d. in excess of those for the corresponding period of last year.

4. The Company's cables and the land lines in connection with them have continued in good working order throughout the half-year.

5. The London-Bilbao section of the Company's system has been duplexed with excellent results, and is now able to carry a largely increased traffic. The cost of establishing the Duplex (£886. 15s. 1d.) has been paid out of the revenue for the half-year.

6. Of the balance of profit and loss, £2,500 have been put to reserve fund (which now amounts to £23,051. 14s. 8d.), leaving a balance of £4,097. 19s. 10d. Out of this amount the Directors recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference Shares, and a dividend at the rate of 6 per cent. per annum, together with a bonus of 1 per cent. (both free of income tax) on the ordinary shares, thus making with the previous half year's dividend a total distribution of 7 per cent. for the year on the ordinary shares. This will admit of a sum of £566. 10s 8d. being carried to the "Contingencies Account." The dividend warrants will be issued on April 1, 1891.

7. Sir James Anderson and Mr. Etlinger are the Directors retiring by rotation and offer themselves for re-election. The auditor, Mr. H. R. Duke, retires and offers himself for re-election.

## NEW COMPANIES REGISTERED.

**ASPINALL'S ENAMEL (LIMITED).**—Registered by Wilson, Bristows, and Co. (Limited), 1, Copthall-buildings, with a capital of £125,000 in £10 shares. Objects: To acquire the business of a paint and enamel manufacturer heretofore carried on at New Cross, Kent, by Henry Edward Aspinall, in accordance with an agreement, made February 24th, between Henry Edward Aspinall of the one part and James Graham, on behalf of the Company, of the other part, and to carry on generally the business of paint and enamel manufacturers, colour grinders, drysalters, &c.

**BURGESS AND CO. (LIMITED).**—Registered with a capital of £15,000, in £10 shares, to be issued as Preference or ordinary shares, as the Directors may determine. Objects: To acquire the business now carried on at Trowbridge, Wiltshire, under the style of Burgess and Co., and to carry on the business of manufacturers of and dealers in electrical apparatus and appliances, &c.

**MOBBS AND CO. (LIMITED).**—Registered with a capital of £13,000, in £10 shares. Objects: To acquire the business now carried on at Northampton by Henry Mobbs, and to carry on the businesses of civil, mechanical and electrical engineers, and general iron and brass founders in all their branches.

**UNITED STATES POWER SYNDICATE (LIMITED).**—Registered with a capital of £50,000 in £10 shares. Objects: To purchase the sole rights of manufacture and sale in the United States of Priestman's and Hume's patents relating to hydro-carbon engines, and to carry on in the United States the business of makers and dealers in electric and motive power and lighting, mechanical engineers, &c.

**NEW COMPANIES REGISTERED DURING FEBRUARY.**—Among the Companies registered at Somerset House during the month of February were the following:—

| | Capital. |
|---|---|
| Aspinall's Enamel, Limited (£10 shares) | £125,000 |
| Burgess and Co., Limited (£10 shares) | 15,000 |
| City of London Electric Lighting (Pioneer) Company, Limited (£50 shares) | 100,000 |
| Mazapil Copper Company, Limited (£10 shares) | 50,000 |
| Mobbs and Co., Limited (£10 shares) | 13,000 |
| Rubber Trust Syndicate, Limited (£100 shares) | 10,000 |
| Tewkesbury Agricultural and General Engineering Company, Limited (£10 shares) | 100,000 |
| United States Power Syndicate, Limited (£10 shares) | 50,000 |

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The Directors of this Company have declared an interim dividend of 3s. per share, or at the rate of 6 per cent. per annum free of income tax, for the quarter ended December 31, 1890, and payable on the 25th inst. The books of this Company will be closed from the 18th to the 24th inst., both days inclusive. The traffic receipts of this Company for the week ended March 6th amounted to £6,613.

**CADOGAN ELECTRIC LIGHT COMPANY (LIMITED).**—A meeting of shareholders held on the 2nd inst. confirmed resolutions passed at a meeting on the 13th ult, that the Company be wound up, and that Arthur Greenwood, 16, Great George street, Westminster, mechanical engineer, be liquidator, with authority to sell the business of the Company to the New Cadogan and Belgrave Electric Supply Company (Limited), or to any other company.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended March 7th amounted to £731.

**COMMERCIAL CABLE COMPANY.**—This Company announces a quarterly dividend at the rate of 7 per cent per annum, payable on April 1st.

**EASTERN TELEGRAPH COMPANY (LIMITED).**—This Company announce the payment, on the 14th April next, of interest of 3s. per share, less income-tax, being at the rate of 6 per cent. per annum on the Preference shares of the Company for the quarter ending March 31st, and the usual interim dividend of 2s. 6d. per share on the ordinary shares, free of income-tax, in respect of profits for the quarter ended 31st December last. The register of transfers will be closed from the 7th to the 14th April, both days inclusive.

**GREAT NORTHERN TELEGRAPH COMPANY.**—The traffic returns of this Company are as follows:—Receipts in February, 1891, £20,600; 1st January to 28th February, 1891, £41,600; corresponding months, 1890, £39,400; corresponding months, 1889, £42,000.

**LIBIOLA COPPER COMPANY (LIMITED).**—At the third annual general meeting, held on Monday, it was resolved that a dividend of 6s. 6d. per share for the year ended December 31st, be declared, and that the interim dividends paid on 18th June and 15th September of 2s. per share respectively be considered as part thereof, and the balance, 2s. 6d. per share, be paid on and after the 31st inst.

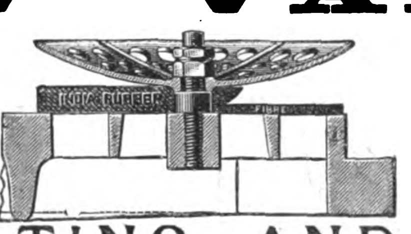
**ORIENTAL TELEPHONE COMPANY.**—The Directors of this Company have resolved, subject to final audit of the accounts, to recommend to the shareholders a dividend at the rate of 2½ per cent. per annum for the past year on the entire paid-up capital of the Company, which dividend, being payable only to the ordinary shareholders, is equal to 3½ per cent. on their shares.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ending March 6, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £5,349.

**CRICKET.**—The cricket club connected with the firm of Messrs. Girdlestone, Tatham, and Co. will hold its second smoking concert at the Swallow Assembly Rooms, Swallow street, Piccadilly, W., this (Friday) evening. The chair will be taken at eight o'clock by Mr. J. O. Girdlestone. From the programme, with a copy of which we have been favoured, a pleasant evening should result.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

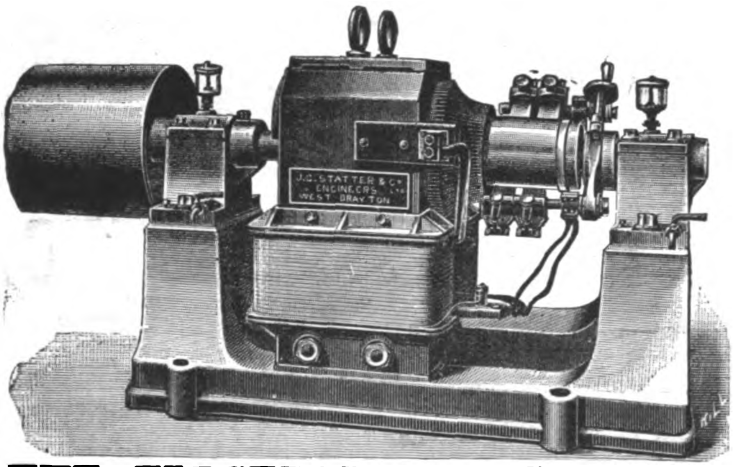
# IMPROVEMENTS IN DYNAMOS



# STATTER-BRUNTON

## DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 670.—Vol. XXVI. FRIDAY, MARCH 20, 1891. Price Fourpence.

## NOTES.

The speaking quality of the London and Par s telephone line of which a detailed description will be found in another column, fully justifies the promises of its designers. On Wednesday we had an opportunity of conversing with Paris. Room No. 90, on the second floor of the General Post Office, until recently the office of Mr. J. B. Chapman, is fitted, along one wall, with a number of telephones of different patterns, some selected by the English engineers and some by the French. On first listening, with a receiver at each ear, there was an absolute silence. We naturally supposed that the line was temporarily switched off, and expected to hear a click followed by the usual buzzing and gurgling and then by a faint Punch-and-Judy-like voice. But this silence was the normal state of the line, and a voice was soon heard with the utmost clearness and very fair volume. We inquired whether Mr. H. R. Kempe was there, and he came to the telephone at the Paris end, and during a short conversation the tones of his voice were most faithfully reproduced and perfectly recognizable. The simplicity of the arrangements and the unmistakeable recognition of the voice recalled the electrophonoscope at South Kensington, and Mr. Preece was asked by a visitor whether the line did not terminate in a neighbouring room. Mr. Kempe's voice could not have been more easily distinguished if he had been speaking from the laboratory in No. 8, where we last saw him. It is, indeed, remarkable to think that this grand result is obtained with a battery power of three Leclanché cells.

The daily papers have all been explaining that the design of the cable is based upon the K. R. law. K., we thought, stood for electrostatic capacity. This is also sometimes called inductive capacity, but the daily press unanimously call it capacity for induction. It has been asserted on purely theoretical grounds that self-induction is essential in telephone lines to prevent the higher vibrations from being extinguished to a greater degree than the lower tones. Mr. Preece has most consistently stuck to the principle laid down by him at the Royal Society in February, 1887, and has used every effort to *abolish* self-induction. Whatever may be the scientific explanation, the line is an emphatic success, both as to volume of sound, which probably depends on the resistance, and as to the clear individuality of the tones of the speaker, which is due to the more complex properties of the line.

At the meeting of the London Electric Supply Corporation on Friday the Chairman dealt minutely with the accounts, and urged as a good excuse for their somewhat discouraging aspect the scale and novelty of the Company's operations. The London Company, in common with other new enterprises, has had to buy its experience, and owing to various causes, most of which have been beyond its control, the purchase price has proved abnormally high. With ordinary good fortune Mr. Forbes may reasonably hope to have a more cheerful tale to tell next year, by which time the many obvious advantages attendant on high pressure distribution from an "eccentric" station may be expected to be more apparent in the accounts. It is with great satisfaction that we note the cordial support given to Mr. Ferranti from the Chair. With the bugbear of an unsatisfactory balance-sheet ever before him some impatience on the part of the Chairman would not have been altogether surprising.

The following summary of the financial side of the question may be of interest. The authorised capital of the London Electric Supply Corporation is 1¼ million sterling, of which more than £700,000 has been paid up. The total expenditure since the present Company's formation amounts to nearly £650,000, so that there is an unexpended balance of about £60,000. During the past year no less than £143,000 was spent, the chief items being mains (£77,000), plant at Deptford (£33,000), transformers (£9,000), meters (£3,000). The total expenditure in round figures under these headings is as follows:—Mains £121,000, plant at Deptford £102,000, transformers £36,000, meters £4,800. The revenue account exhibits a remarkable equilibrium, the expenses balancing the receipts to within £19. 14s. 3d. The total receipts for 1890 were £28,704. 9s. 11d., the current sales (by meter and contract) realising just on £26,000, about two-thirds of the current having been sold by meter.

It appears that the difficulties which have arisen in connection with the Boy Messengers Company and the District Messengers Company, and the prominence with which these have been brought before the Press and before Parliament have aroused the Postmaster-General to a sense of the obligation which rests on him, either to allow this most useful service to continue, or to provide a substitute through his department. He promises that by Wednesday next "a large staff of messengers will be always on hand" at "all the principal post-offices in London," and "at a smaller actual cost than

Digitized by Google

would be possible under the schemes of the Boy Messengers and District Messengers Companies."

We have frequently made use of the services of the latter, and realise the great difference between the convenience of being able to summon the messenger by the mere turn of a handle, and of having to go out to the nearest post-office to seek him. Some years ago there was an outcry against the inhumanity of chimney-sweeping by climbing boys, and a philanthropist invented a brush fastened to a rope. On being asked how the rope was to be placed in the chimney, he admitted he had not thought of that difficulty, and suggested that it would be best to send a lad up the chimney with it. Similarly, the subscribers to the Messenger Companies will still need some one to go and fetch the messenger, and will be deprived of the very convenient means now at their disposal for summoning a cab, a policeman, their own doctor, or a fire engine, to say nothing of a special fire extinguishing apparatus, which on one occasion, at least, succeeded in extinguishing the fire before the engine arrived. Will the State undertake any of these useful offices?

THE rejection by Mr. HANBURY'S Committee of what may be called the City and South London Railway Extension Bill was a foregone conclusion from the moment that its promoters persisted in their determination not to make a "physical junction" with the existing line from King William-street to Stockwell. The reasons adduced for this course, namely, the expense and the fact that the trains which it was proposed to run on the new line would not fit the 10ft. tunnel of the City and South London Railway were not likely to weigh against the enormous public disadvantage of a break 150 yards long in the much-wanted line from Islington to Clapham.

THE London County Council's Bill for dealing with overhead wires, a summary of which is to be found in our issue of January 30th, has passed the Select Committee of the House of Commons, but in a very emasculated condition. To put the matter briefly, the Bill in its original form gave the County Council authority to make bye-laws with regard to the erection, supervision, registration, and removal of overhead wires; empowered that body to remove aerial lines into subways where these existed and were convenient; to appoint uniformed inspectors with power of compulsory entrance at reasonable hours on to private property to inspect wires, and to make charges for identification and supervision. In the Bill as it now exists all mention of subways, charges and uniformed inspectors armed with compulsory powers is struck out; drastic excisions due, no doubt, in a large measure to the clever and in many ways convincing arguments of the National Telephone Company.

IN accordance with a resolution of the Chelsea Vestry passed in the autumn, their surveyor, Mr. HIGGENS, has recently drawn up a voluminous report on overhead and underground wires, &c. Mr. HIGGENS'S report forms an excellent epitome of the law on the subject, and contains several useful suggestions. Electricity supply companies are, as a rule, so much more sinned against than sinning, that it is quite a novelty to find that they are entitled to do something which the Vestries cannot prevent, and something which distinctly tends to raise the rates. Mr. HIGGENS points out that the junction boxes, &c., which are now so frequently met within London, are provided with iron covers which only in some few instances are filled in with material similar to that of the surrounding pavement. The result is that asphalte pavements, which *might* last ten years, will probably require renewal in less than five. The surveyor to the Chelsea Vestry not unreasonably wants compulsory powers in this matter.

A MEMORANDUM and précis of correspondence between the Board of Trade, Messrs. Crompton and Co., the Brush Company, and several other firms, on the Overhead Wire Regulations, have been printed by the London Chamber of Commerce, and the subject will be further discussed at the meeting to-day. There appears to be but little doubt that the real difficulty will soon be recognised. Major CARDEW admits that "the material need not possess a high specific resistance. Five megohms is as good for the purpose as 5,000." In case of cracks in the covering, he wants a thickness of insulating material greater than the sparking distance. This he puts at one-sixteenth of an inch for 2,000 volts. Finally, he requires some proper mechanical protection to resist abrasion. Mere piling on of india-rubber seems to be a very poor way of fulfilling these requirements, which ought to be easily met.

SOME months ago we published an important experimental investigation by Prof. RYAN dealing with the character of the variations in current and magnetism which occur in a transformer at different parts of the alternation, the losses due to hysteresis, eddy currents, &c., being shown by curves deduced from the observations. This week, MR. SYDNEY EVERSHED, in continuing his articles on the magnetic circuit of transformers, gives the first of a series of curves which are very similar to those previously published by Prof. RYAN. They were, however, obtained by an entirely different method and without reference to them in any way. We understand that the construction used to obtain the "indicator diagrams" was devised over two years ago. Publication was, however, delayed till the present time, in order that a thorough series of tests on iron might be made, with a view of obtaining data from practice.

A CORRESPONDENT writes us as follows on the Paper read last week before the Society of Arts by Mr. NEWMAN LAWRENCE and Dr. HARRIES, an abstract of which has appeared in our columns:—"I cannot but think that the authors of the Paper were somewhat unfortunate in their choice of the experiment by which they sought to demonstrate the cataphoric action of electrical currents; and that the facts adduced in support of this and other theories put forward by them were crude, even for a Society of Arts audience. The 'indifference, suspicion, and conservatism' of the medical profession was made much of on Wednesday evening; but medical men can hardly be expected to accept without considerably more proof than

Digitized by Google

was forthcoming, the statements that 'very probably life does not exist without electricity,' and that the health of the body is '*to* a large extent dependent upon electricity.'"

**Technical Instruction Bill.**—This Bill, as amended, was considered and read a third time in the House of Commons on Thursday last week.

**The "Electric."**—The accumulators on board this pinnace are by the Electric Construction Corporation, and not, as stated by us last week, of the Epstein type.

**Bradford.**—The question of adopting electric traction on a new tramway line about to be laid down in Bradford is being considered by a committee of the Town Council.

**The Junior Engineering Society.**—A numerously attended excursion of this Society took place on Saturday, 7th inst., when the Boiler Works of Messrs. Maudslay, Sons and Field, at East Greenwich, were visited.

**The Hermite Processes.**—The Hermite processes of electric bleaching and sewage purification are to be worked in France by the Société Française d'Exploitation des Procédés Hermite, whose offices are at 4, Rue Drouot, Paris.

**University College, Bristol.**—The Council of this College will, in May, nominate to one of the science scholarships offered by the Commissioners of the 1851 Exhibition. Further details will be found in our advertisement columns.

**Direct Spanish Telegraph Company.**—We are informed that the telegraph office of this Company, at No. 74, Gracechurch-street, is now again in direct communication with Bilbao and Madrid, and there is no delay in the transmission of telegrams to Spain by that route.

**A Telephone Association for London.**—Steps are being taken to form an Association with the object of securing lower telephone rates and a double-wire system in London. We are informed that the Association has already received an encouraging amount of support.

**Long Distance Electric Lighting.**—The old Breton town of St. Brieux (Côtes du Nord) is to have the first electric lighting station in France on the Thomson-Houston alternate current system. The generating plant is situated at a spot 15½ miles from St. Brieux. The installation will be inaugurated on Easter Sunday.

**Exeter.**—At the last meeting of the Town Council it was decided to obtain a Provisional Order, and lease it to the Exeter Electric Lighting Company with powers of resumption at the end of 21, 28, or 35 years, on special terms, the company's charges to be reduced in proportion to their profits over 5 per cent. per annum.

**International Electrical Exhibition at Toulouse.**—An International Electrical Exhibition will be held at Toulouse during the present year. The exhibition will be open for a period of four months, from the 15th May to the 15th September next. Full particulars may be obtained by applying to the Secretary of the Exhibition at Toulouse.

**Magnetic Meteorology.**—Some few months since the Abbé Fortin announced that he had discovered a system for predicting the weather by the movements of the magnetic needle, and an instrument of his design was, therefore, placed under test at the Observatory in the Parc St. Maur. Since it has been installed at the Observatory no movement whatever of the needle has been observed.

**The Diminution of "Chattering" on Overhead Circuits.**—A grooved washer of vulcanized indiarubber has recently been brought out by Mr. C. Dexter Barker, of Turnmill-street, E.C., to diminish "chattering" on telegraph and telephone wires. The washer is inserted into the groove of an ordinary insulator, and the wire bound round this elastic cushion instead of round the hard surface of the insulator.

**The "Amber."**—We note with satisfaction that the boats of the Eastern Telegraph Company's cable steamer "Amber" did good work in rescuing the drowning emigrants from the "Utopia" when she sank in Gibraltar Bay on Tuesday evening after colliding with H.M.S. "Anson." The electric search lights of the Fleet are also reported to have been employed with great effect, enabling many to be saved who would otherwise have been drowned in the darkness.

**London Chamber of Commerce.**—A meeting of the Electrical Trades Section Committee will be held at Botolph House, Eastcheap, at 1.30 p.m. to-day. The following are the agenda:—(I.) To receive the reports of the sub-committees on:—1. Overhead wires; 2. Telephone clauses; 3. Board of Trade form of accounts. (II.)—To consider the desirability of co-operation between the Telephone and Electric Light Companies, for the purpose of placing wires underground in future.

**An Organ-Blowing Plant.**—A recent issue of the *Electrical World* of New York contained an illustrated description of a motor plant installed in one of the prominent Brooklyn churches for blowing the organ. The motive power is furnished by a small Perret motor, belted directly to the crank shaft that operates the bellows. Attached directly to the body of the bellows is a rod that operates a regulating switch. As the bellows fills, the motor is made to run more and more slowly, and *vice versâ.*

**The Saunderson Arc Lamp.**—Mr. A. Apps informs us that he is no longer connected with the Saunderson patents for arc lighting. We regret to hear this, as Mr. Apps promised us full particulars of the system. Dr. Hopkinson reported that the use of volatile hydro-carbon in the arc was advantageous. Prof. Silvanus Thompson, on the other hand, said in his lecture before the Society of Arts on March 6th, "The introduction of all known foreign substances whatsoever into the carbon pencils of the arc is found to lower the intrinsic brilliancy." Total illumination and intrinsic brilliancy are not the same thing, and we should like to hear if Mr. Saunderson has met with success in his experiments.

**The Edinburgh Exhibition.**—The liquidator of this Exhibition has issued a circular stating that a first dividend of 13s. 4d. per pound will be paid to those creditors whose claims have been admitted. Preferable debts had been paid to the amount of £2,710. 16s. 3d., and the ordinary claims lodged amounted to to £42,215. 4s. 8d. The subscriptions to the guarantee fund amounted to £26,569. 7s., and of that sum there had been received £25,594. 7s. The total receipts, including drafts on cash credit, were £102,539. 18s. 10d.; and the total payment, £101,083. 16s. 5d. There was a balance in hand on November 15th of £1,356. 2s. 5d. The sums received from exhibitors for space amounted to £12,974. 9s. 7d.; music and entertain ment cost £12,053. 2s. 6d.

**The National Telephone Electrical Society.**—This society is still progressing. A short time ago Mr. A. C. Cotterill, the district manager, described his anti-induction apparatus lately patented, and Mr. Wicker, from Sheffield, gave a short lecture on the "The Action of the Transmitter and Receiver." On Friday, February 27th, Mr. P. Loftus, Chief Construction Engineer, gave a very interesting and instructive lecture on "Construction and Renewal of Telephone Lines," illustrated by diagrams. Mr. Loftus also explained an improvement of his own for leading in subscribers' lines. The lecture was very much enjoyed, and there was a large attendance. Last Friday two papers were given by Messrs. Lloyd and Bailey on "Magnetos and their Connections," which led to a very interesting discussion on the different kinds of switch-hooks.

**The Gordon System of Electric Traction.**—The experiments carried out at Messrs. Merryweather and Sons, Tramway Works, Greenwich, on behalf of the Gordon Electric Car Syndicate, are said to have given encouraging preliminary results. The track has closed conduits, and the general idea of the system is a series of contacts actuated by means of an automatic magnet in a box placed in the ground every hundred yards or so—about 16 to a mile. The preliminary trials have been made in all sorts of weather, and with very severe tests, such as flooding the whole track of 70 yards with water, working in snow, fog, and so forth. The working pressure is 250 volts and the current 30 amperes. It is to be hoped that the system will shortly be applied to a complete tramway line in order to verify, under ordinary working conditions, the satisfactory results shown by experiment.

Digitized by Google

**The National Telephone Company and its Border Subscribers.**—With regard to our Note under this heading last week, we are informed that the facts of the case are as follows: —When the National Company came into the Galashiels district, some five years ago, the telephone subscription was fixed at £10, with a verbal understanding that when the patents expired a substantial reduction was to be made. In January last the rentals were reduced all round by 30 shillings. The subscribers, however, expected something more sweeping, and thought £6 a reasonable figure. The result of this difference of opinion, and of negotiations with the Mutual Telephone Company, has been that all the subscribers in the vicinity of Galashiels have, with one or two exceptions, withdrawn from the National Company's system. The Mutual Company have made an offer to introduce an exchange, the subscription to which will be about £6 per annum.

**Adelaide.**—The Brush Electrical Engineering Company, having written to the Adelaide City Council, offering to lend them some electrical plant for the purpose of making experiments with regard to the lighting of the city, the matter was referred to the Electric Lighting Committee. The Committee have reported as follows:—"With reference to the offer of the Brush Electrical Engineering Company to lend the Corporation, for the period of six months, one Brush arc dynamo and 55 arc lamps, free of cost, upon certain conditions, the Committee directed the City Surveyor to place himself in communication with the agent for the Company in Adelaide (Mr. Grant) with a view of obtaining the fullest information as to the number of lamps, engine stations, &c., it would require to light the whole of the streets with electricity. The Town Clerk was also directed to obtain all the information possible from any other company who, it might be thought, might be willing to tender for lighting the streets with electricity."

**Electric Traction on the South Staffordshire Tramways Company's System.**—Speaking at a recent meeting of this Company, the Chairman, Mr. W. J. Carruthers-Wain, stated that he had recently returned from a long tour of inspection in America, where cable and electric tramways were in extensive operation, and he was much satisfied with the way in which things were worked out there. He had one or two letters from shareholders who could not attend but who wished their views to be known, and those views came to this, that they recognised the impracticability of making a steam tramway pay in a district like that worked by the Company, and they urged the adoption of some other mode of traction. For his own part he should like to see a cable tramway, but where the population was so limited, a cable line was no good, so that it would be an excellent thing if the authorities could be made to see the advantage of overhead wires. He trusted the authorities were sufficiently intelligent and liberal-minded to accept the suggestions he had made with regard to this matter. He had inspected the line to see what was possible to be done with regard to electric working, and was in hopes of receiving a favourable proposition from the local authorities in regard to it.

**Telegraphing Extraordinary.**—During the recent unprecedented fall of snow in Devon and Cornwall, the Porthcurno station of the Eastern Telegraph Company found its landline communications with the rest of the island interrupted by a barrier of snow extending over half those counties, and varying in depth from 2 or 3 to 25 feet. The cables, however, remained intact, and by their aid frequent and rapid communication was held with the Company's London station by way of Lisbon, Gibraltar, Malta, and Marseilles, a distance of over 9,000 miles, urgent service messages being frequently exchanged within the space of a few minutes. It fortunately happened that the Eastern Company's direct line from London to Marseilles through France was, notwithstanding the weather, in excellent electrical condition, and by this route wonders of telegraphy were performed. In one working day of 23 hours 24 minutes no fewer than 1,558 messages were exchanged between London and Marseilles, being an average of 67 messages per hour, many of them very lengthy, and the majority composed of difficult code words, or cypher. When it is considered that this was accomplished by hand working only, over a simplex wire nearly 9,000 miles in length, composed of aerial, submarine, and subterranean lengths, it will probably be regarded as one of the most extraordinary feats of telegraphy on record.

**Machine Stoking.**—The following statements are taken from a Paper recently read before the Institution of Civil Engineers by Mr. J. F. Spencer:—The efficiency of a machine stoker as a smoke preventer is due to its uniform careful firing. With regard to economy of fuel, this may result from two distinct causes. First, the use of a cheaper coal, either too dirty for, or the heat units of which cannot be fully utilised by, hand firing. Secondly, the more perfect combustion due to a uniform supply of fuel, and the automatic and progressive manufacture of carbonic acid. With reference to the economy from the use of a cheaper coal than is possible with hand firing, the testimony is overwhelming, and is rarely contested; but it is not so generally known that, owing to the more perfect combustion in machine stoking, the cheaper coal realises also a higher evaporative duty per pound of fuel. Machine stoking also tends generally to an increased and more uniform evaporative duty, and of this there is a large amount of evidence available. Economy of labour may be and is realised by machine stoking, as the system permits the automatic supply of fuel to the hoppers. The approximate total number of furnaces fitted, and now working, with machine stokers is, however, only 15,120. This represents about 8,000 boilers, out of an estimated total in the United Kingdom at the present time of 140,000, or only 5·7 per cent., and it has taken nearly 70 years to achieve this limited success.

**Prof. Elihu Thomson's Pioneer Experiences.**—In his address on "Pioneers' Day" at the recent meeting of the National Electric Association at Providence (R.I.), Prof. Elihu Thomson gave the following interesting account of his early experiences:—Recounting my own experience in electric lighting, I may say that I built a small dynamo about 1876 to run an arc light. It was a success, and it led to the construction of other dynamos. When I came, however, to the commercial part of the business, which began in 1878 or 1879, I found that there were many difficulties to overcome, and not the least of these difficulties was the getting of steady power to run the machines. The first Thomson-Houston three-coil armature machine intended for commercial use was capable of running from four to eight lights in series. I carefully examined every inch of the wire, and insulated the whole thing myself. Our first machine was put up in a bakery in Philadelphia, where it was used all night, and it was rather tenderly nursed by us. Sometimes we were up all night tending to this baby, and under conditions which were not altogether agreeable in the summer, as there is a good deal of waste heat in a bakery. The temperature was sometimes as high as 140 deg. After running these machines some time a Company was organised, which is now the Thomson-Houston Electric Company. It was organised in a modest way in New Britain, Conn. I became electrician of this small Company, and the apparatus was made in New Britain in an old basket shop. This was the beginning of our experiences. We soon got into another shop and began the construction of apparatus for commercial use. After we got into operation our difficulties were not, by any means, over. We had to develop all sorts of devices. We had to overcome conditions constantly arising to discourage us. When one thing was accomplished we were met by other reverses. The Brush Company saw our beginnings of success and tried to buy up a majority interest in our little Company in New Britain, apparently for the purpose of entirely swallowing us. Subsequently, however, in the same year, certain parties in Lynn purchased a majority interest in the stock, and what was the American Electric Company of New Britain started operations in Lynn. The Brush Company, as you are probably aware, has been swallowed up by us, the infant they tried to swallow. Such is fate. We have the firmest confidence in the expansion of the electrical industries. We are absolutely certain that the business is going to be greater and greater as time goes by. We have calls now for machines and dynamos up to 500 and 1,000 H.P., where a few years ago we thought it an unusual thing to have 100 and 200 H.P. machines, and it looks very much as though in the near future machines of much larger capacity would be demanded for the work of installation.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 536.*)

§ 34. Our investigations have led us to the conclusion that in order to compare the merits of two transformers it is practically useless to compare their full load efficiencies, for the worst transformer is reasonably efficient at full load; all we need do is to determine the energy losses, and of these the constant waste constitutes a criterion of efficiency. This, in brief, is the contention advanced originally by Mr. Swinburne in his British Association Paper, read in 1889. Indeed, many of the results independently arrived at in the present articles are stated, or rather concealed, in Mr. Swinburne's Paper, and may be unearthed by those possessed of more patience than the present writer. Most of the tables in the Paper are valueless for purposes of ready comparison, the amount of the drop in volts at full load having apparently been left to chance.

We will now examine a little more closely the nature of the constant losses in transformers, and for this purpose it will be convenient to construct diagrams showing the phase relations and approximate forms of the curves of induction, exciting current, eddy currents, and electromotive forces, when a transformer is run with its secondary circuit open.

§ 35. Before a diagram can be drawn, it is necessary to know the form of the wave of impressed E.M.F. at the terminals of the primary coil. In attempting to treat transformer problems analytically, it has been the invariable practice to assume that the E.M.F. wave followed a simple periodic law. Because, according to Fourier, *any* function whatever can be expressed by an *infinite* series of sine or cosine terms, the mathematical clothiers, alluded to in § 1, after an invocation addressed to the mighty powers of Fourier's theorem, calmly cut down the infinite series to one solitary term, and then find that the primary and secondary current waves (and the induction wave also sometimes) are one and all simple sine functions of the time. Such a trifle as the possible effect of hysteresis in altering the shape of the waves must give way before the powers of analysis, and the theory of transformers resolves itself into transcendental trigonometrical transformations which more or less completely mask the real phenomena involved in electrical transformation.

§ 36. But a new era is dawning, and we are gradually coming to recognise the virtue and necessity of stating the unknown laws connecting such phenomena as magnetic force and induction in iron for example, in the form of a curve which simply gives the observed relation under certain specified conditions. Why attempt to make an empirical formula fit the curve when we have the curve itself? The disastrous effects resulting from the ancient practice of constructing an elaborate formula to fit the observations, and then practically destroying the observations, are familiar to all engineers who refer to their Molesworth. To pack the results of any observations whatever into an empirical formula ought to be statutory offence. Having entered a protest against the Fourier theorem bogey and empirical mathematics, it must be confessed that the sine function is not to be despised, and when kept within proper bounds makes an excellent servant. In drawing transformer diagrams we shall first assume the E.M.F. wave to be a simple sine function of the time; next, that it is a plain zig-zag; and finally, that it is constant in value while alternating periodically in sign.

§ 37. Armed with some squared paper, a slide rule, and the cyclic **B H** curve (Fig. 9) corresponding to a maximum induction of 5,000 gausses, let us draw a "no-load" diagram for the low-induction closed transformer No. 2. It is best in choosing the horizontal scale to make a complete period correspond with some convenient whole number of squares, irrespective of the true length of period, the latter being usually an incommenusrable portion of a second. The maximum value of **B** being known, the curve connecting **B** and time is readily plotted, assuming for the moment that it is a sine function. Next work out the maximum value of the counter E.M.F. in the primary. Since $\mathbf{B}_t = \mathbf{B}' \sin 2\pi F t$; **B'** being the maximum induction, the counter E.M.F. will be $N A \frac{d\mathbf{B}}{dt} = N A \mathbf{B}' 2\pi F \cos 2\pi F t$, and its maximum value is of course $N A \mathbf{B}' 2\pi F$. This value being plotted at the epoch corresponding to $\mathbf{B} = 0$, the remainder of the curve is easily filled in by taking four or five values for $E' \sin \theta$. This is readily done if the slide rule gives sines, and if not the natural sines of, say, 10°, 30°, 50°, 70°, and 80° may be written down from a table and kept at hand. Instead of plotting the counter E curve having a *negative* maximum when **B** is passing through zero from negative to positive, it may be plotted as that component of the impressed E necessary to exactly balance the counter E (Fig. 10). Now, refer to the **B H** curve, and from the known mean length of the induction path in the core and number of turns in the primary coil, calculate the value of the necessary exciting (or magnetising) current for, say 1,000, 2,000, 3,000, 4,000, and 5,000 gausses. Owing to the hysteresis there will natnrally be two values of $C_p$ for each value of **B**, and care must be taken to plot them in the right order—that is to say, plot them as they occur in going round the cyclic **B H** curve counter-clockwise. The curve so obtained is marked X

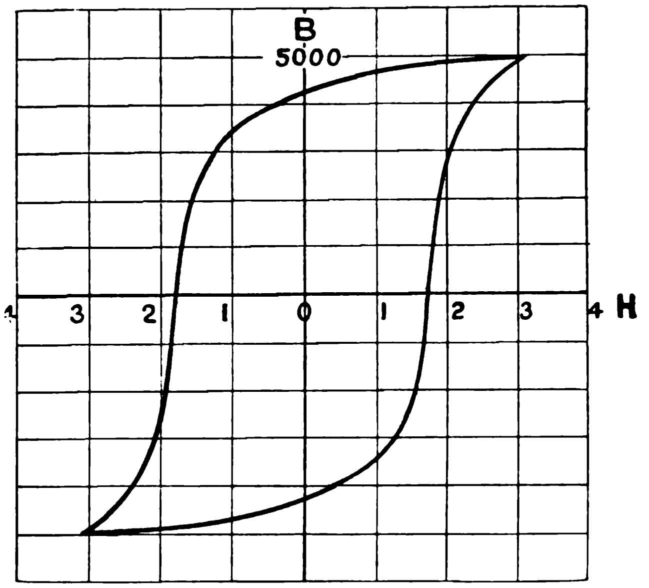

FIG. 9.—Cyclic **B H** curve from charcoal iron, taken between + and − 5,000 gausses. **B** and **H** in C.G.S. units.

in Fig. 10, and we shall in future call it the X component of the exciting current. The vertical scale to which the exciting current is plotted should be large enough to give a bold curve; it is, of course out of all proportion to the scales chosen for E and **B**.

There remains to be found the additional exciting current required to neutralise the demagnetising effect of the eddy currents in the core. As the waste of power due to core eddy currents has already been calculated, we might find the required current by dividing the power by the E.M.F., but this easy way of arriving at the result does not direct attention to the manner in which eddy currents reduce the effective magnetising force, and it will be preferable to give in this place a rough method for ascertaining the average value of the demagnetising effect of eddy currents in thin laminæ.

Referring once more to Fig. 2, and remembering the expressions found for the E.M.F. in and resistance of an elementary path in the section of the lamina, we find the current in it is $\frac{\dot{\mathbf{B}} s^2 x l dx}{\rho r^2}$, and consequently the magnetic force within the element being $\frac{4}{10} \pi C \, d\mathbf{H} = \frac{4\pi}{10} \frac{\dot{\mathbf{B}} s^2 l x dx}{\rho r^2}$, where $\dot{\mathbf{B}}$ must be expressed in volts and $\rho$ in ohms. If this expression is integrated from $x = x$ to $x = r$ we shall have the value of **H** just inside

Digitized by Google

the elementary path P Q due to all the eddy current outside it. Call this $\mathsf{H}_x$ and

$$\mathsf{H}_x = \frac{2\pi \dot{\mathsf{B}} s^2 l (r^2 - x^2)}{10 r^2 \rho}.$$

What is required is the average value of H over the whole section of the lamina, and to get this the surface integral of

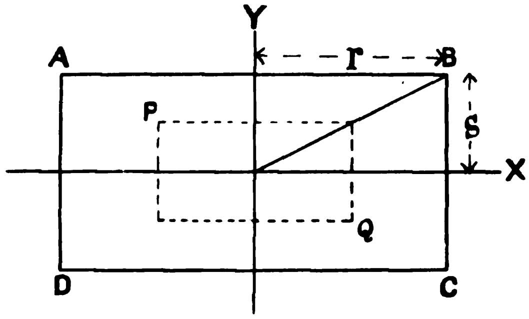

Fig. 2.

H must be taken from $x = 0$ to $x = r$, and the result divided by the whole area of section; we have then an average value of H, which, if applied in the form of a current entirely outside the lamina, would diminish the H due to the current in the primary coil by very nearly the same total amount as does the neutralising current must flow in a circuit round the whole core—in short in the primary coil.

§ 39. On performing the integration mentioned in the last paragraph, we find the average eddy current H over the whole section of a lamina is $\frac{\pi \dot{\mathsf{B}} t^2}{40 \rho}$ per cm. in length of core, and it is a maximum when $\dot{\mathsf{B}}$ is so. $\dot{\mathsf{B}} = 5000 \times 2\pi F \cos 2\pi F t$, as we have already seen, and its maximum is $5000 \times 2\pi F = 2{\cdot}2 \times 10^6$, but as we are throughout working in volts, amperes, and ohms, it must be divided by $10^8$ and maximum $\dot{\mathsf{B}} = \frac{2{\cdot}2}{100}$ volts (per sq. cm. of core).

When this value is inserted in the equation for the average eddy current H, we find that the maximum reached by this average H is ·43. Being so small no great error can be introduced by the fact that we took a rough average value throughout the section of a lamina. The maximum current required in the primary coil to produce a positive H = ·43 is found from the relation $\frac{4\pi N C'}{10} = {\cdot}43 \times 147$, where C′ is the maximum of C, and 147 is the mean length of the induction path in the core. On working out we find

$$C' = {\cdot}0225 \text{ (amperes)}.$$

This value is to be plotted on the diagram at exactly the same epoch as the maximum counter E, and the whole wave of the

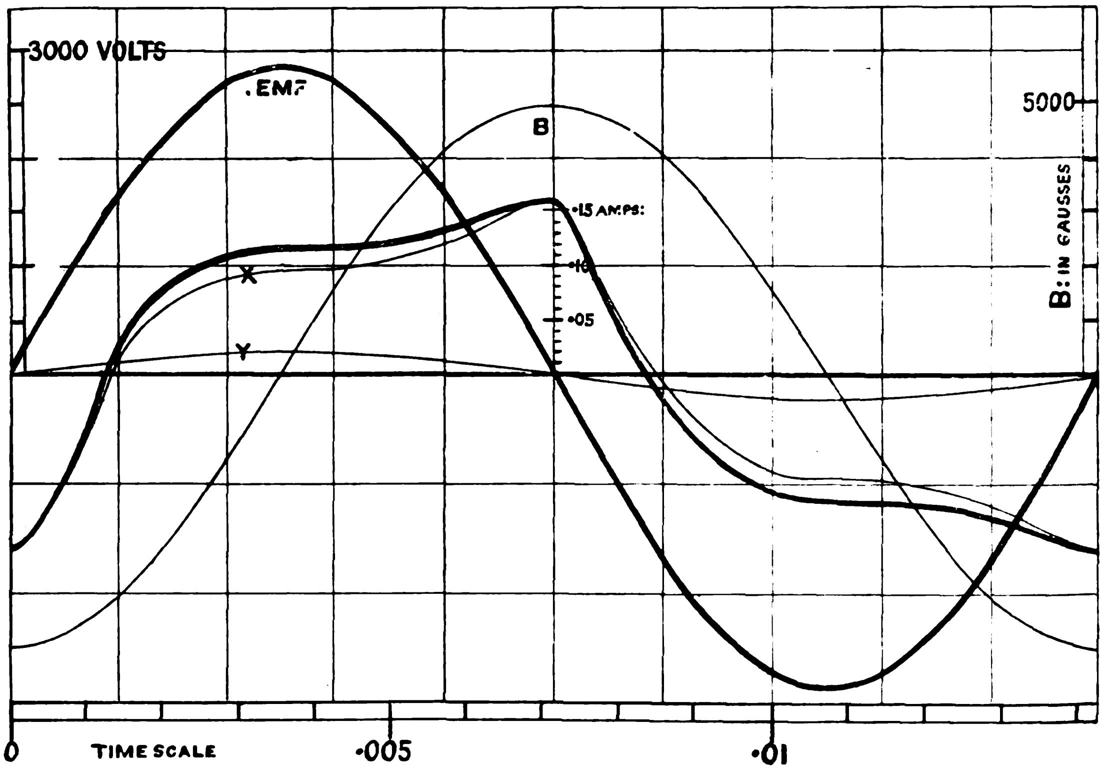

Fig. 10.—No. 2 Closed Transformer, excited by sine E.M.F. Output = 0.

B = Induction density in core.
X = Current in primary coil to magnetise the core.
Y = Current in primary coil to neutralise effect of eddy currents in core.
$c$ = X + Y = total exciting current.

actual distribution of currents in the lamina. In short the lamina may be supposed to be made up of an inner section or core of non-conducting magnetic substance, surrounded by a thin non-magnetic conductor in which all the eddy currents occur. In this simple case it is quite evident that the H due to the eddy current would be uniform over the whole section of the magnetic stuff; and the eddy current would be cophasal with the E.M.F. ($\dot{\mathsf{B}}$), which is its cause; for there is no other changing induction besides that involved in $\dot{\mathsf{B}}$, to throw the current out of step. All that is necessary to annul the effect of the eddy current is to provide an equal total current round the lamina in the opposite direction—that is, in the same direction as the main magnetising current but cophasal with the counter E.M.F. This is true of each lamina in the core, so that the anti-eddy current, as it may be called, is easily filled, is by working out a few values from the current equation C = ·0225 sin $2\pi F t$. The wave is marked Y in Fig. 10, and we may call it the Y component of the exciting current.

§ 40. The diagram now contains a complete account of the whole exciting current considered as two separate currents for distinct purposes; X to carry the core through the requisite cyclic change of induction, and Y to neutralise the demagnetising force of the eddy currents, so that X may have fair play so to speak. In Fig. 10 X and Y are added together to form one curve, C, which is the whole exciting current; it is by no means a sine function of the time nor is it possible in an iron cored transformer to make it so, if the impressed E and B waves are simple sine functions; it is not cophasal with either

Digitized by Google

E or B, so that, although it implies waste of power by reason of its not being in step with B, the power cannot be found by measuring E and C separately and multiplying their product by the so-called cosine of the "angle" of lag. The expression angle of lag, so freely used by writers when treating of alternate currents, has no meaning when applied to the exciting current of transformers there being no point on the wave from which lag is to be measured. If the time between maximum E and maximum C is called the lag, then it is exactly a quarter period, and the result would be *no* power; if, on the contrary, the time between $E=0$ and $C=0$ is taken to be the lag, the formula E C cos (angle of lag) will make the power far larger than it really is. The true waste power can be readily found from the diagram by integrating E C throughout a half-period and dividing the result by $\frac{1}{2}$T. This process will be illustrated after the zig-zag and alternating constant E diagrams have been discussed.

§ 41. The only remaining items to be noticed are the counter E in the primary coil, due to stray induction in the air between the core and the turns of the coil, and the loss of volts due to resistance of the primary coil. The stray induction being wholly confined to an air path wastes no power; it requires work to magnetise air of course, but unlike iron, air gives all the energy put into it back to the circuit again when demagnetised. The stray induction threading the primary coil causes a slight additional counter E.M.F. in it, but it will be understood that the stray B due to the exciting current must be negligible compared with the whole induction in the core. The core being worked at a low induction density will have an average permeability perhaps two thousand times greater than air, so that if the air path had the same area and length as the core the total stray induction and the counter E due to it would only amount to $\frac{1}{2000}$th of the core induction and its counter E; in fact the additional counter E due to stray induction caused by the exciting current might amount to one volt, as against 2,000 due to the core induction. When the transformer is loaded the stray induction is increased of course, and at full load, when the load current is 3·75 amperes, the total current in the primary is 30 or 40 times greater than the exciting current, and the counter E due to stray induction would be 30 or 40 volts, or 1·5 to 2 per cent. of the total E.M.F. It is this loss of volts which is sometimes spoken of as the drop due to "self-induction"; putting aside the negligible one volt drop due to the exciting current the "self-induction" drop is proportional to the load just as the resistance drop is, and the loss of volts due to the two causes together is usually spoken of as *the* drop due to load. The loss of volts due to the resistance of the primary may be just calculated in order to realise how utterly insignificant it is at no load. The diagram (Fig. 10) gives ·162 amperes as the maximum exciting current; the resistance of the primary coil is 7·6 ohms, so that the maximum value of C R is less than 1·25 volts, an amount which is invisible on the diagram. This is an important point to remember in dealing with the effect of the irregular shape of the exciting current wave on the E.M.F. and load current waves, for evidently the wave of C R would be the same shape as C (being only C multiplied by the constant R), and if it were drawn on the diagram and added to the counter E.M.F. wave in order to find the complete impressed E.M.F. wave at no load, the latter would not be a simple sine wave, being distorted by the addition of the irregular C R wave. But the latter is not only absolutely invisible on the diagram, but is really so small that it makes no appreciable distortion in the impressed E wave, and consequently if the counter E is a sine wave the impressed wave must be also.

§ 42. The fact that C R is so exceedingly small shows that for any reasonably well designed transformer having a core of even moderately good iron, the irregular shape of the exciting current wave will not affect the form of the impressed E.M.F. wave which may therefore in every practical case be obtained by differentiating the induction wave, whether the latter is capable of analytical expression or not, and conversely the induction wave may be obtained from integration of the E.M.F. wave. When the curve of impressed E.M.F. is a sine function, the induction wave is of course a cosine which can be expressed as a sine function. If the impressed E.M.F. wave departs ever so little from a simple sine law, the induction wave alters its shape in a corresponding degree but opposite sense. The next two diagrams will afford a good illustration of this remark.

---

NOTE.—If the reader will refer to § 27 (p. 535) he will find a rough method described by which the exciting current for a Hedgehog was calculated, and the statement made that the values so obtained agreed very closely with the currents actually required by Mr. Swinburne's Hedgehogs. The writer congratulated himself a little too soon on the accuracy of an estimate made on the basis of some dimensions for Hedgehog transformers kindly supplied by Mr. Swinburne, for owing to a misunderstanding by which radius of "Hedgehogging," centimetres, diameters, and inches became inextricably mixed, it turns out that a large over-estimate was made; No. 3, as an open transformer (Fig. 7), would only require about 1·4 amperes and not 1·95 as stated. Similarly No. 2 (Fig. 8) would require considerably less than 1 ampere exciting current. The reduced exciting currents would make very little difference to the efficiencies given in tables 12 and 13, but a slight modification of No. 2 will be made in a future article, as its efficiency may be raised to 90·5 per cent. by cutting off nearly half the spherical ends, without increasing the exciting current beyond 1 ampere.

## TRANSFORMER DISTRIBUTION.

BY G. L. ADDENBROOKE.

There has for some time been a general feeling in electrical circles that the celebrated Paper by Mr. Crompton on alternating *versus* continuous current distribution of electrical energy has become a matter of past history, and that the improvements which in the interval have taken place in transformers, and in the means employed for distributing energy by means of alternating currents, warranted the raising of the same issue afresh.

On learning the title, therefore, of Mr. Swinburne's Paper, there was a good deal of curiosity felt as to the manner in which he would treat the question, and what issues he would raise. If Mr. Swinburne has not gone "the whole hog,' in the design of his own transformers, he certainly has done so in the scope of his Paper. This Paper reviews the whole field presented by alternating current distribution, and the different appliances employed in connection with it, and the general effect is to leave a bewildered impression in the mind that there is something generally wrong with the methods pursued at present. Any single one of the sub-headings into which Mr. Swinburne divided his Paper would have been amply sufficient to give scope for an interesting communication raising sufficient points to provide material for an important discussion extending over several evenings.

In the present article it is my intention only to deal with what are called Transformer Sub-stations. This subject is of itself a very extended one, and, therefore, to bring it at all into shape, the best way of treating it will, I think, be to take examples and deal with them separately.

Let us in the first place review briefly the present position of matters, that is to say, the state of things which now exists when a district is served by a Central Station working on the alternating current system and furnishing electrical energy, to be used chiefly in the form of light, the district to consist of shops, public buildings, and private residences in about the average proportions.

The first fundamental fact which we have to take into consideration in such a case is that the number of lamps installed on the circuit will be usually at least double that for which current is demanded at any one time; that is to say, simply, that never more than half the total number of lamps on the circuit will be in use at once. Let us suppose, as is more or

Digitized by Google

less the case at present, that there is a separate transformer in each house. Now, although the number of lamps on the whole circuit alight at once will never be more than half that installed, yet it can never be assumed that the total number of lamps installed in a house, shop, or public building will not be in use at once on some particular occasion. It is therefore necessary to install converters in each house of sufficient capacity to take the total number of lamps for which that house is wired; that is to say, briefly, the maximum capacity of the transformers installed on the central station circuit will be double that in actual use at any one time.

Coming now to the transformers themselves, a great many not by any means accordant tests have been published on the efficiency which such transformers give at their maximum load. The average capacity of transformers installed in English houses will certainly not be, as a rule, less than 2,000 watts; at the same time this is about the smallest size transformer which can be made to work at a high rate of economy. As a rule now, in the class of lighting which is being done in London, the average size of the transformers is considerably above this; but if electric lighting is to be extended into the suburbs and to be used in provincial towns, such an average size of transformer as this would not be greatly exceeded.

In transformers of this size, and of fair design, it is doubtful if an average maximum efficiency of more than 95 per cent. can be assumed, but for the purposes of this article I shall assume that an average maximum efficiency at full load of 96 per cent. is obtained. Further, in order to facilitate dealing with the matter, it will be sufficiently accurate to assume that this loss of 4 per cent. of the maximum efficiency of such transformers is a constant one; that is to say, that 4 per cent. of the maximum efficiency of the transformer is being lost by hysteresis and in resistance in keeping the transformer fully magnetised, whether or not it is doing work on the secondary circuit; and that this loss continues the same as *related to the maximum efficiency* whatever the load on the secondary of the transformer may be.

By dealing with the matter in this way, one arrives at a sufficiently accurate basis for all ordinary calculations, while avoiding the many vexed questions as to the action of transformers which still exercise the minds of those who have experimented and gone most fully into the various actions which take place in them.

Let us suppose that such a Central Station as above indicated has been established on the alternating current system, and is in running order, and that it is necessary to keep the pressure on all its mains during the whole of each 24 hours. During the whole of each day, therefore, four per cent. of the maximum capacity of the total number of transformers installed will be continually wasted, and since the capacity of the transformers installed will be at least double of that for which energy is required at any one time, we shall have during the whole day a continual loss averaging 8 per cent. of the average maximum current sent out from the station.

Now the tabulated returns sent out from Central Stations, which have already been in operation for more than a year, show that their current output does not average much more, taking the whole year through, than about 2½ hours of the average maximum daily output. Comparing the loss in the transformers, which is 8 per cent. spread over the 24 hours with this, it is obvious that the loss in the transformers equals (8 × 24), or 192 per cent. of the average maximum current for one hour. That is to say, there is a loss of current between the switch room and the secondary circuit of the transformers which, on an average, equals the average maximum station output for two hours each day. This is equivalent to saying that, from the losses taking place in the transformers alone, very little more than 50 per cent. of the alternating current generated in the station actually reaches the secondary circuit. In fact, it will hardly be out of order to say that, under such circumstances, the average efficiency of an alternating current system is not much above 50 per cent.

Now this is a very serious state of things; and although, even under such circumstances, it is possible to supply alternating currents profitably, at a fairly low rate of cost per unit, yet it is evident that, even putting on one side all possible improvements in boilers, engines, and alternating current dynamos, which class of improvements may be said to be common not only to alternating currents, but to every other system of electric lighting, there is still great room for improvement in this single item of transformer distribution alone.

Such was the state of things when Mr. Crompton compared the economy of a Central Station on the alternating current system with that to be anticipated from the use of direct currents. It is a state of things to which the advocates of alternating current distribution have not been blind from the very first, however little may have been said by them upon the subject; but, at the same time, it is one that everyone has felt might easily be remedied in a great measure, as soon as the Electric Light was more generally adopted, and when groups of houses, situated within moderate distance of each other, were all being supplied with electric current.

Obviously the first and simplest way in which economy may be effected is by grouping several houses or shops together on the secondary of one transformer of considerable capacity; by this means two electrical advantages are secured. In the first place a large transformer is more economical in working than a smaller one, that is to say, the percentage loss in magnetising it is less. In the next place, it is a practical certainty that the full number of lamps in all the houses supplied from the transformer will never be required alight at once. Consequently, it will be practicable to install a transformer of considerably less size than would be necessary for running all the lamps installed at one time; and so the average loss on the whole circuit will be reduced from, let us say, 8 per cent. to something like 6 per cent., that is by one-quarter, or 25 per cent.

Any little extra expense which might be incurred for longer secondary mains in such a case would be more than counterbalanced by the diminished cost of the single larger transformer, as compared with several small ones, and by the fact that it would be only necessary to install one primary pair of cut-outs, one primary switch, and one earthing device, instead of several. Companies working in London and the provinces have already adopted this improvement in many instances where the conditions were favourable.

But further and still greater economies may be attained by grouping the transformers in what are now called Sub-Transformer Stations. Such Transformer Stations have the immediate advantage over the system last mentioned, that by their means it is possible to reduce the transformer capacity to about that required for the maximum current supplied, which will only be half that of the total number of lamps installed, and operated from each sub-station. The average loss in the transformers is therefore at once reduced from eight per cent. of the average maximum current supplied by the station to four per cent.; and there is this further gain, namely, that with such large transformers as would be required for operating such sub-stations, the losses in magnetising, &c., would probably not average more than two per cent. of the maximum efficiency; while there is good reason to suppose that these losses might with care be reduced to less even than this extremely low figure.

Here, then, at once putting all other considerations on one side, is an enormous theoretical gain, but this is by no means the whole gain which may reasonably be anticipated and calculated upon if such transformer sub-stations are established and properly operated. Since the heavy working load is only on for a few hours each evening, it would not as a rule be necessary for a large transformer to be in circuit with the mains for more than six hours per diem, and probably even this period could be very materially reduced with a little care. At other times a transformer with a capacity of not more than about one-tenth that of the large transformer would be amply sufficient for all the lighting done on the secondary circuit. The losses in such small transformers established in sub-stations situated at moderate distances from each other over the area of supply would be so small that, for our present purpose, it is hardly necessary to estimate them.

Consequently, by this method of using Sub-Transformer Stations, and by employing small transformers to do the work during the day and night when the load is light, and a large one for the evening hours when it is heaviest, what may be

Digitized by Google

called the transformer efficiency of an alternating current system of distribution will be raised from not much above 50 per cent. to at least 85 and probably 90 per cent. Such being the theoretical aspect of the question, it now remains to consider how such a system could be carried out in practice, and how in first cost, and subsequent maintenance, it compares with the present methods, either of using high-tension alternating currents and establishing transformers in each house, or in using continuous currents, supplemented by secondary batteries, or any of the other means with which electricians are familiar.

*(To be continued.)*

## ELECTRO-MAGNETIC REPULSION.*

BY PROFESSOR J. A. FLEMING, M.A., D.SC., M.R.I.

*(Concluded from page 571.)*

§ 10. We must now pass on to study shortly another class of actions, namely, deflections and rotations produced by electro-magnetic repulsion on highly conducting discs or rings. If the conducting ring or disc which is presented to the alternating pole is constrained by being fixed to an axis around which it can rotate, the action may reduce to a deflective force. Here, for instance, is a flat disc fixed on a transverse axis. On presenting this disc to the pole, the disc is prevented by its constraint from being repelled bodily; so it does the next best thing it can, it sets its plane parallel to the lines of magnetic force, and gets into such a position that the induced currents in it are reduced to a minimum. On this principle, before becoming acquainted with Prof. Elihu Thomson's original work, I devised a little copper disc galvanometer for detecting small alternating currents.

§ 11. More interesting than the deflective actions are those which result in the production of continuous rotation in highly conducting bodies placed in an alternating field. This electro-magnet in front of me, and which has come from Prof. Elihu Thomson for the purposes of this lecture, consists, as you see, of a nearly closed circuit divided iron core wound over with a coil (Fig. 10). The ends of the iron circuit are provided with copper bars, which embrace and cover portions of the polar terminations of the magnet. When the magnet is excited by a

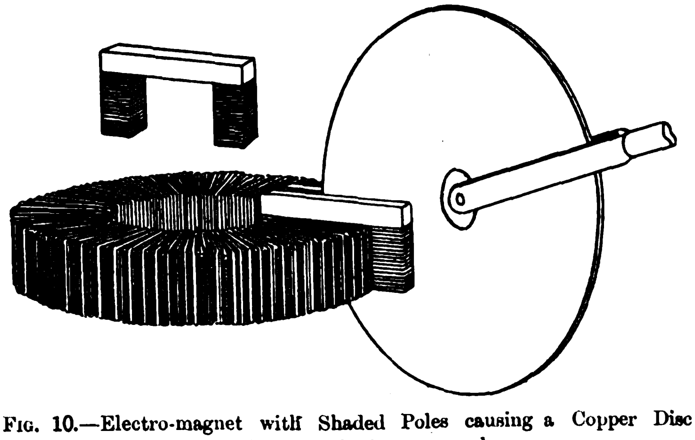

FIG. 10.—Electro-magnet with Shaded Poles causing a Copper Disc placed between the jaws to revolve.

periodic current, these secondary circuits become the seat of powerful induced secondary currents. Taking in hand a large copper disc pivoted at the centre and held in a fork, we hold this wheel so that part of the disc is inserted between the jaws of the electro-magnet. Immediately, rapid rotation is produced. The reason is not far to seek. The alternating field induces, both in the closed coils and in the neighbouring portions of the disc, induced currents; these tend to cause the parts of the conductors in which they flow to be pulled into parallelism, and if the polar coils are so placed as to partly shield the poles these attractive actions act unsymmetrically on the disc and pull it continuously round. The action is, perhaps, better illustrated by a simpler experiment. If we hold a pivoted copper disc (Fig. 11) symmetrically over an alternating pole, the action of the pole is one of pure repulsion on the disc, which, however, causes no rotation in it. When a copper sheet is so placed as to shield or "shade," as Prof. Thomson calls it, part of the magnetic pole, currents are induced both in the fixed plate and in the movable one. The fixed disc shields part of the other from the induction of the pole, and hence causes the induced currents in that plate and disc to be so located that they are in positions to cause continual attraction between one another and continuously pull round the movable disc into fresh positions, so creating regular rotation. This principle of "shading" a pole is employed in constructing the polar coils of the magnet used in our experiment a moment ago, and the experiments present us with a form of self-starting alternating-current motor, although not perhaps a very efficient one in the technical sense. This principle of "shading" a portion of a conductor from the inductive action of the pole, and so causing the eddy currents in it to be located in a portion of its surface, and to cause attraction between that conductor and the shading conductor, is capable of being exhibited in various ways. We place on this copper plate a light hollow copper ball, and support it in a little depression in a copper plate. Holding the arrangement over the alternating magnet, the ball begins to spin round rapidly when the magnet is excited. This rotation is caused by the continual attraction of the eddy currents induced in the fixed plate and in that part of the ball which is not shielded from the pole by the plate. We may vary the experiment, and exhibit many more or less curious and amusing illustrations of it. If we float these copper balls in water (Fig. 12), and place the glass bowl containing them over the alternating pole, the interposition of a copper sheet between the pole and the balls causes the latter to begin to spin in a highly energetic manner.

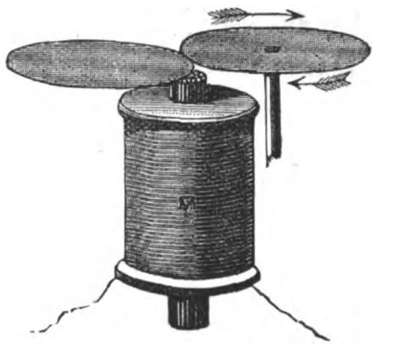

FIG. 11.—Revolution of a Shaded Copper Plate held over an Alternate Current Magnetic Pole.

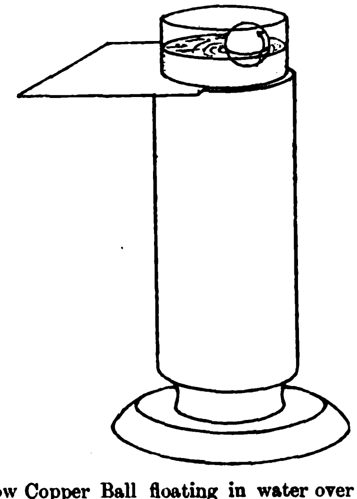

FIG. 12.—Hollow Copper Ball floating in water over an Alternate Current Electro-magnet, and caused to revolve by the interposition of a "shading" plate.

* A discourse delivered at the Royal Institution of Great Britain on Friday evening, March 6, 1891.

Digitized by Google

§ 12. Prof. Elihu Thomson has invented a novel form of electro-magnetic gyroscope (Fig. 13). We have now suspended over the alternating magnet a gyroscope of the usual form. The wheel of the gyroscope is made of iron, and the tyre of the wheel is a thick copper band. Immediately the magnet is energised, the gyroscope begins to rotate with great rapidity over the pole. In this case the unsymmetrical disposition of the eddy currents in the copper band around the wheel is sufficient by itself to cause the rotation to occur. The phenomenon which, however, lies at the bottom of all these effects is that the self-induction of the secondary circuit causes the eddy currents to be delayed in phase behind the magnetising field, and hence to persist into the period of reversal of that field, and so produce the repulsion between the primary conducting circuit and that part of the secondary conducting circuit in which the eddy currents are set up.

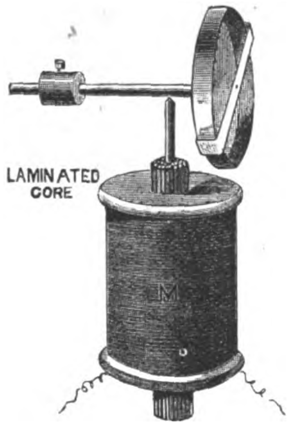

Fig. 13.—Electro-magnetic Gyroscope revolving over the pole of an Alternate Current Electro-magnet.

One more experiment in this part of the subject, before we pass on to some other developments of it, shall be placed under your notice. Returning to the use of the electro-magnet, in which the iron circuit is all but complete, we find that when a highly-conducting disc is put between the closely approximated half-shielded jaws of this electro-magnet, and an alternating current employed to excite it, the conducting disc is held up in

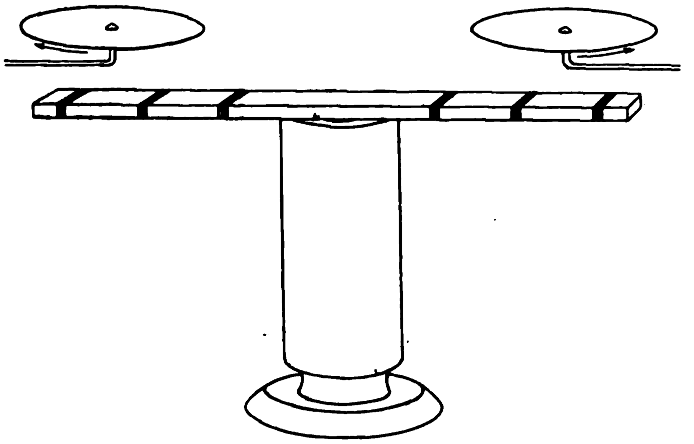

Fig. 14.—Alternating Magnetised Iron Bar causing revolution of two iron discs held near its extremities.

the air gap by reason of the electro-magnetic attraction set up between the disc and the shielding polar plates. If, however, the disc has a relatively poor conductivity the attraction is not nearly so marked. A good or bad silver coin can be discriminated thereby, because the good silver coin has conductivity enough to be the seat of powerful induced currents but the bad coin has not.

§ 13. Closely akin to the foregoing, but rather less easy to explain, are the rotations in copper and iron discs which can be caused by the approximation to them of a laminated iron bar alternately magnetised. These actions have been carefully studied by Prof. Elihu Thomson, and applied by him and others in many practical devices. Across the top of this electro-magnet we place a long bar of laminated iron with the plane of the lamination vertical (Fig. 14). This bar is throttled at intervals by copper bands, which form small closed secondary circuits upon it. We excite the magnet, and hold near the bar an iron disc capable of free rotation; it begins to rotate rapidly, as you now see. Not only can this be done with a laminated bar throttled by conducting circuits, but even a solid bar of hard steel will serve the same purpose, and a couple of steel

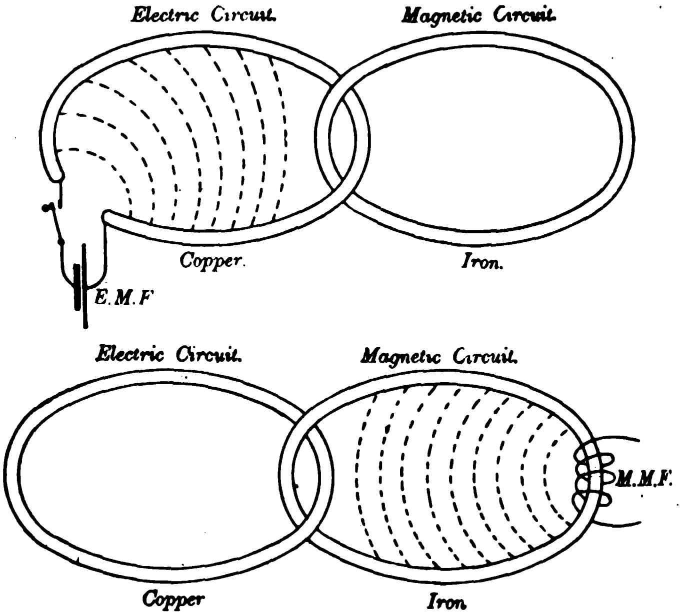

Fig. 15.—Diagrams illustrating the symmetry in relation between Electro-motive Force and Electric Current, and Magneto-motive Force and Magnetic Induction.

files placed across the poles can cause rapid rotation in pivoted discs of copper or of iron held with their edges close to the bars so alternately magnetised. To elucidate this remarkable action, we must revert for a moment to some fundamental facts. Here are two paper rings interlinked, one red, the other of blue paper (Fig. 15). Let the red ring stand as a symbol for a copper or conductive circuit. Let the blue ring stand for an iron or magnetic circuit. If we introduce into the conductive circuit an impulsive or alternating *electromotive*

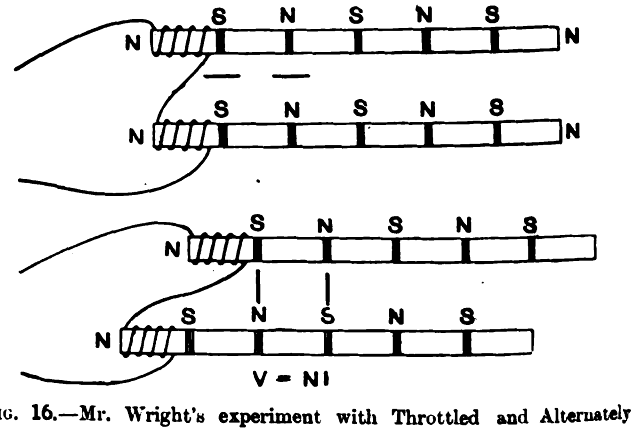

Fig. 16.—Mr. Wright's experiment with Throttled and Alternately Magnetised Bars.

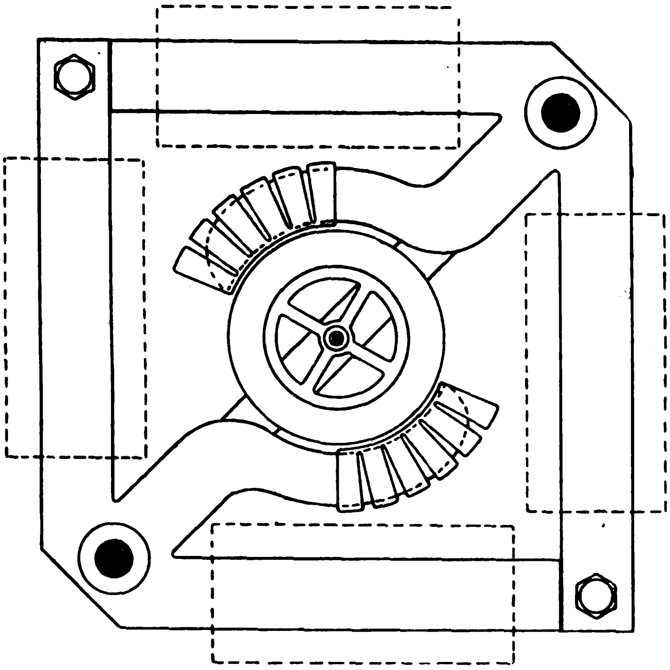
*force*, we are well aware that the interlinked iron circuit, by increasing the self-induction of the conductive circuit, hinders the change of current strength in it by introducing a *back electromotive force* of self-induction. Consider now the iron circuit. If we introduce into that magnetic circuit an impulsive or alternating *magnetomotive force* by interlinking it with some turns of a magnetising current, the effect of the copper or conductive circuit, which is linked with the iron or magnetic circuit, is similarly to introduce a *back magnetomotive force* into the magnetic circuit by reason of the magnetic field set up by the secondary current generated in that copper or conducting circuit. In other words, the secondary current induced in the copper circuit by any change in the magneto-

Digitized by Google

motive in the iron circuit is in such a direction that it operates to oppose that primary magnetomotive force, chiefly, however, at the spot where the copper circuit passes round the iron. The general result may be stated to be that the action of the interlinked copper circuit is to cause the magnetic induction in the iron circuit to leak across through the air and partly to escape passing through the secondary circuit. This escape of induction is called magnetic leakage, and the induced current set up in the closed secondary circuit is the cause of this magnetic leakage. There is a symmetry in the relations of magneto-motive force and the magnetic induction and electromotive force and electric current, and we can, as Faraday pointed out long ago, make the symmetry complete, if we suppose the two interlinked magnetic and electric circuits immersed in an imperfectly conducting medium. If, then, we throttle a magnetic circuit such as a laminated iron bar with copper coils closed upon themselves, and place a magnetising coil at one end, the closed conducting circuits hinder the rise of magnetic induction in the bar; in other words, they give it what may be called *magnetic self-induction.* If the source of magnetism is a rapidly-reversed pole, the consequences of this delay or " lag " in the induction is that a series of alternating magnetic poles are always travelling with retarded speed up the bar, and these may be considered to be represented by tufts of lines of magnetic force which spring out from and move laterally up the bar. If the bar is not laminated and not throttled, the eddy currents set up in the mass of the bar itself act in the same way, and operate to resist the rise of induction in the bar and to delay the propagation of magnetism along it. Hence we must think of such a throttled bar when embraced by a magnetising coil at one end as surrounded by laterally moving bunches of lines of magnetic force, which move up the bar. Each reversal of current in the magnetising coil calls into existence a fresh magnetic pole at the one end of the bar which is, as it were, pushed along the bar to make room for the pole of opposite name, which appears the next instant behind it. When an iron disc is held near such a laminated and throttled bar, these laterally moving lines of force induce poles in the disc which travel after the inducing poles, and hence the disc is continually pulled round. If the disc is a copper disc the laterally moving lines of magnetic force induce eddy currents in the disc, and these, by the principle already explained, create a repulsion between the pole and the part of the disc in which the eddy currents are set up.

§ 14. The progression of alternate poles along a bar can be investigated by means of an experiment due to Mr. A. Wright. Two laminated straight iron bars (Fig. 16) are throttled at intervals with secondary circuits, and have wound on one extremity a magnetising coil. The two bars are placed near each other and parallel. The coils are so connected that the poles at any instant in the ends of the two bars are of similar name. An alternate current is sent through the coils joined in series. Under these circumstances a series of alternate poles of similar names run up the bar parallel with one another. A small, soft iron needle hung at any place between the bars sets itself parallel to the bars because at any instant poles of similar names are abreast of one another at any spot in the length of the bars. If, however, we shift one bar lengthways backwards or forwards through a certain distance so as to bring opposite poles abreast of each other throughout their journey up the bars, we shall find a position such that the soft iron needle will set at right angles to the bars when hung at any point in the space between them. The distance by which we have to shift the one bar backwards of the other to effect the change is evidently half a magnetic wave length, and knowing the frequency of the alternations we can readily arrive at a measure of the velocity of propagation of these alternate poles in the bar. This velocity is evidently numerically equal to the product of the frequency and wave length so obtained.



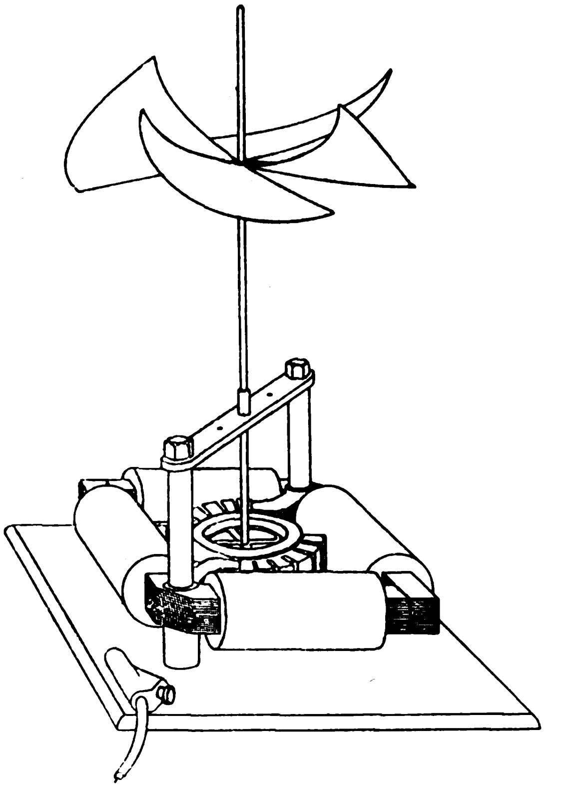


Fig. 17.—Plan and General View of Ferranti-Wright Self-starting Alternating Motor working a Fan.

§ 15. A very pretty application of the above principle has been made in the electric meter of Messrs. Ferranti and Wright for measuring alternating currents. Before me stands one of these meters. It consists of a pair of vertical electromagnets, with laminated iron cores, and each magnet bears at the top a curved horn of laminated iron which is throttled by copper rings. These curved horns, springing from the magnets, embrace and nearly touch a light iron-rimmed wheel, free to turn in the centre. The actions just explained drive the wheel round, when the magnet coils are traversed by an alternating current. The iron wheel carries on its shaft a set of mica vanes, which retard the wheel by air friction. Under the opposing influences of this retardation and the electro-magnetic rotation forces, the wheel takes a certain speed corresponding to different current strengths in the magnetic coils, and hence the total number of revolutions of the wheel in a given time, as recorded by a counter, serves to determine the total quantity of alternating current which has passed through the meter. A motor (Fig. 17) working a fan is also here exhibited, the operation of which depends on the same facts. In the case of

Digitized by Google

the motor the iron-rimmed wheel has its tyre clothed with copper sheet to aid the action.

§ 16. The rotation of iron discs can be shown also by means of a badly designed transformer. If a closed laminated iron ring (Fig. 18) like the one before me is wound with a couple of conducting circuits, such an arrangement constitutes a transformer. If these two circuits are wound on opposite sides of the iron ring, the previous explanations will enable you to perceive that the arrangement will be productive of great magnetic leakage across the iron circuit. In designing transformers for practical work, one condition amongst others which must be held in view is to so arrange the conductive and magnetic circuits that a great magnetic leakage of lines of force across the air does not take place. If, however, this leakage exists, it indicates that the secondary circuit is not getting the full benefit

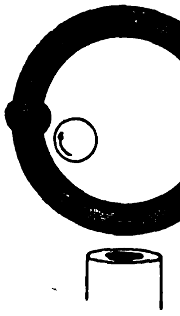

FIG. 18.—Magnetic Leakage across a Throttled Iron Ring, causing rotation of an iron disc placed near the Secondary Coil.

of the induction created by the primary. To detect it we have merely to hold near the iron circuit a little balanced or pivotted iron disc, and if it is set in rapid rotation, as you observe in this case, it indicates that there are laterally moving lines of magnetic force outside the iron, which have escaped from the iron in consequence of the back-magneto-force of the secondary circuit.

§ 17. Time would fail me if I were to attempt to enlarge on the practical applications of the scientific principles which these experiments disclose to us. They are a fertile field both for the investigator seeking to add to the sum total of existing knowledge, or to the inventor in search of applications in elec-

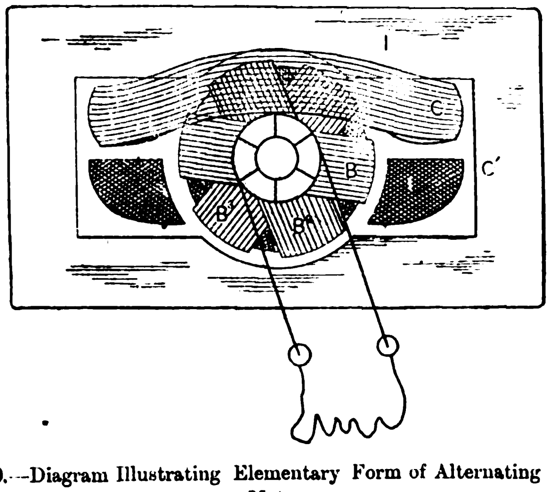

FIG. 19.—Diagram Illustrating Elementary Form of Alternating Current Motor.

trical technology for such acquired facts. Ingenious minds, and that of Prof. Elihu Thomson foremost amongst them, are busy in seeking to turn these facts to account in the construction of alternating current motors.

One of the simplest of these is shown in principle in the diagram now on the screen (Fig. 19). The coils C are traversed by an alternating current, and are placed on either side of a drum armature wound over with three sets of insulated wire coils, the terminals of the coils coming to insulated sections of a commutator. The functions of this commutator are to keep one coil, B, on short circuit during the time when it is in such positions relatively to the field coils C that the induced current in the closed coil causes it to be repelled by the field coils, and as each successive coil on the armature becomes in turn the active coil, rotation is kept up. A motor, made by Prof. Thomson, based on these principles, but with some additions, is on the table, and on turning the current into it it speedily starts and gets up considerable speed. The details of the actual construction are a little less simple than in the diagram shown, because the motor is made to start by sending the external current into the armature by means of a commutator and brushes. When, however, the proper speed is attained, the armature coils are automatically short-circuited, and the motor continues to run in virtue of the current induced by the field magnet in the armature coils. This is by no means, however, the last word said on this portion of the applications, and I think we may shortly look to Prof. Thomson to give us further and more perfect methods of utilising these facts in the construction of self-starting alternating motors.

§ 18. For the opportunity of exhibiting to you this evening these remarkable experiments, I am personally indebted to Prof. Elihu Thomson, both for constructing and sending the apparatus we have used. Part of these appliances have now an historical value, and have been presented by him to the Royal Institution. For the use of the rest, I desire to record my obligations and thanks. Illustrative as these experiments are of important facts in connection with the use of alternating currents, they have a special value at the present time. In the opening year of next century, when we celebrate the centenary of the first practical production by Volta, in 1801, of the electric current, we shall find ourselves in the presence of the fact that almost every large city is ramified by a subterranean network of copper conductors for the distribution of electric energy as a necessary of modern life; and although it may be dangerous to express too confident a view on the direction which the progress of electrical invention may take, yet it does not seem improbable that the alternating current will be doing a considerable share of that work. It is, therefore, not only as a contribution to a comprehension of the vagaries of these alternating currents that the phenomena we have shortly studied are worthy of attention, but also as being, perhaps, the avenue of approach to a further possession of valuable knowledge, enlarging our views, and capable, without doubt, of being minted into the current coin of useful and ingenious applications.

ERRATA.—On page 570, Fig. 7, of our last issue, the words *attractive impulses* and *repulsive impulses* should be interchanged, the large shaded hummocks representing the repulsive impulses.

## THE LONDON-PARIS TELEPHONE LINE.

The establishment of telephonic communication between London and Paris, the progress of which has been recorded from time to time in our columns, is now an accomplished fact, and has proved a most unqualified success, highly creditable to all concerned.

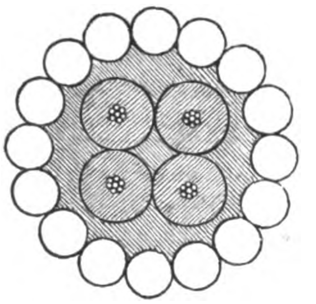
The route for the English landline runs along the South Eastern Railway to a point near Sidcup, and thence by road and rail through Swanley, Maidstone, and Ashford to the cable-house on the beach at St. Margaret's Bay, between Dover and Deal. The English landline is of copper, and weighs 400lb. to the mile. It has a resistance of about 2·25 ohms per mile at 60 deg. Fahr. It is supported on creosoted wooden poles, 70 yardsa part, by means of double-shed porcelain insulators about 25 feet above the ground. The going and returning wires of each circuit are twisted spirally round each other all the way, exchanging places at each cross-arm, the spiral being completed by each wire regaining its normal position at every fourth pole—that is to say, every 280 yards. The buzzing effect of induction has been reduced to a minimum. A Wheatstone automatic transmitter, working at fast speed on one of the circuits, can just be heard in the telephone upon the other circuit. The telephone at present employed is the Post Office form of the Gower-Bell apparatus, but Hunnings, Berliner, Ader and other instruments are being tried. The French landline is similar in construction to the English

Digitized by Google

line, except that only one circuit is run at present, and the copper wire weighs about 600lb. a mile. Its length is about 204 miles, and the speaking with the D'Arsonval apparatus employed in France is also excellent. There are, unfortunately, no less than seven kilometres of underground line in Paris. This is constructed on the Fortin-Hermann system, and is insulated by wooden beads impregnated with paraffin.

The connecting cable, which is the joint property of the two Governments, was designed by Mr. Preece, and contains four separate conductors (*see* Figure), two for each circuit. Each conductor is a strand of seven pure copper wires, weighing 160lb. per nautical mile, with a resistance of 7·478 to 7·632 ohms per knot at the testing temperature of 75deg. Fahr. It is covered with three alternate layers of Chatterton's compound and guttapercha, weighing 300lb. per knot. The total weight of each core is, therefore, 460lb. to the knot. Its insulation resistance from the wire to the water is not less than 500 megohms per knot after lying in water at a temperature of 75deg. Fahr. for 24 hours before the test, and after the conductor has been electrified for a minute. The capacity does not exceed 0·3045 microfarads per knot. The cores are twisted spirally round each other in a strand, so as to change places like the land wires; and to silence the cross talk as much as possible the opposite wires are meant to form part of the same circuit. The stranded cores are served with tanned hemp, and on this cushion is laid a spiral sheathing of 16 galvanised iron wires, each 0·28in. thick, with a breaking stress of 3,500lb. Clark's coating of mineral pitch and sand protects the whole.

The K.R. or product of the capacity into the resistance of the entire line from London to Paris is estimated at 5,300. Theory shows that good articulation begins to fail when the K.R. exceeds 10,000 for an overhead copper wire and 8,000 for



Section of the London-Paris Telephone Cable.

an underground or underwater line. The cable was manufactured by Messrs. Siemens Brothers, under the supervision of Mr. Mittelhausen, general manager of their works, and Mr. F. Jacob, their chief electrician, as well as the Post Office engineers.

On Monday, the 9th inst., as we informed our readers last week, the laying was begun. Preparations were made early in the morning for landing the shore end at Sangatte, where the "Monarch" had been lying for several days. The shore end being landed, the "Monarch" immediately started paying out towards St. Margaret's Bay. At first there were no signs of an approaching storm. A drizzling rain, however, soon began to fall, and the breeze freshened, but it was not until towards three o'clock, when ten miles of cable had been paid out, that the gale came on, and the water became rough, and a blinding snowstorm swept over the vessel. At length it was decided to anchor until a lull in the storm should reveal the land. The cable was fastened and the anchor rattled out soon after 4 o'clock. The snow cleared about 5 o'clock, and it was then discovered that the "Monarch" was lying off St. Margaret's Bay, about a mile from the shore, and eastward of the cable hut. An attempt was made to lift the anchor and pay out all the cable, but the strong tide, aided by the wind, had driven the cable foul of the anchor, and after a fruitless attempt to clear, the anchor was slipped with 14 fathoms of chain. It was now a quarter past 8 at night, and very dark, but the "Monarch" paid out the rest of the cable to avoid cutting it, and buoyed the end well off the shore to the east of St. Margaret's Bay, about 20 minutes past nine. She then ran for the Downs, where she anchored soon after 10 o'clock. Next morning a strong easterly gale prevented further operations. Wednesday was not much better. Thursday was fine, and after picking up the cable from the buoy, as we mentioned last week, she proceeded to clear it from the lost anchor. The cable was coiled four times round the anchor, and could only be released by cutting out the damaged part. This was done, the anchor and chain being recovered, and the end of the cable buoyed. On Friday nothing could be done owing to the high wind and sea; but on Saturday morning the cable was picked up and some five miles re-laid, so as to clear a bight in the Calais-Dover line. The "Monarch" finally arrived off St. Margaret's Bay about twenty minutes past three in the afternoon, where she anchored 1,000 yards away from the landing-place. A raft was speedily formed with the lifeboats, and the shore end landed. The end was hauled ashore by the sailors at ten minutes past six, and twelve minutes later brought into the cable hut. St. Martin's-le-Grand was immediately called up, and the good news announced. Three cheers were given at the Post Office and in the hut, and those from London sounded so lustily that it was declared they had split the drum of the telephone. The end of the cable was then stripped and the sheathing filed off, the rasping of the file being plainly heard in London. The cores were then pared, and the cable connected to a Morse apparatus, by which the hut was put in communication with Sangatte. The French electricians there telegraphed a "hurrah for the telephone," and the work was done.

It was arranged that no telephonic communication should be held between London and Paris until the French engineers arrived in London, and on Tuesday the first words were spoken by M. Amiot. At 4.15 p.m. he addressed his colleagues in Paris, his first words being "Hallo, hallo!" Mr. Graves, Mr Preece, and others afterwards spoke through the line. A formal inauguration took place on Wednesday, when the first message transmitted was one from the Prince of Wales to M. Carnot. An exchange of congratulations then passed between Mr. Raikes and M. Jules Roche. At the Paris Central Telegraph Office, Lord Lytton, Mme. Roche, M. Reinach, M. Broquisse, and M. de Selves were present with M. Roche. Mr. Raikes spoke from his room at the Post Office. Finally, in the afternoon the members of the Press conversed with Paris.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, March 20th.**

LONDON CHAMBER OF COMMERCE.

*1.30 p.m.* Meeting at Botolph House, Eastcheap, of the Electrical Trades Section Committee.

PHYSICAL SOCIETY.

*5 p.m.* Ordinary Meeting. Papers to be read: (1) "The Theory of Dissociation into Ions and its Consequences," by Mr. S. U. PICKERING, F.R.S. (2) "Some Points in Electrolysis," by J. SWINBURNE. (3) "The Variation of Surface Tension with Temperature," by A. L. SELBY, M.A. (4) "On Magnetic Proof Pieces and Proof Planes," by Prof. S. P. THOMPSON.

INSTITUTION OF MECHANICAL ENGINEERS.

*7.30 p.m.* Ordinary General Meeting.

**SATURDAY, March 21st.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "The Forces of Cohesion," by Lord RAYLEIGH, F.R.S.

**MONDAY, March 23rd.**

SOCIETY OF ARTS.

*8 p.m.* Cantor Lecture IV. 3. "Photographic Chemistry," by Prof. R. MELDOLA, F.R.S.

**TUESDAY, March 24th.**

INSTITUTION OF CIVIL ENGINEERS.

*8 p.m.* Ordinary Meeting. Paper to be read and discussed: "On the Reception and Storage of Petroleum Oil in Bulk," by W. T. H. CARRINGTON, M. Inst. C.E.

**WEDNESDAY, March 25th.**

CHEMICAL SOCIETY.

*8 p.m.* Anniversary Meeting.

OLD STUDENTS' ASSOCIATION.

*8 p.m.* Ordinary General Meeting. Paper to be read: "Coals, Coalmines, and Coalmining," by ALBION T. SNELL, Member,

Digitized by Google

# The Electrician.

**Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny**
**Editorial, Publishing, and Printing Offices:**
**SALISBURY COURT, FLEET ST., LONDON, E.C.**
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher,* "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "Coutts and Co" *All other letters to be addressed to the Editor.*

*All letters intended for insertion in* "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of* "THE ELECTRICIAN" *commence in May and November.*

## SUBSCRIPTION RATES

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## GOOD FRIDAY.

**In Good Friday Week "THE ELECTRICIAN" will be published on Thursday Morning (March 26th) instead of on Friday (March 27th).**

**Contributors, Correspondents, and Advertisers are requested to take note, and to forward their communications as early as possible, but not later than Tuesday night in Good Friday week.**

## "EXACT" SCIENCE.

Two statements were made in the course of the discussion on Mr. SWINBURNE'S Paper at the Institution of Electrical Engineers last week which were more epigrammatic than is usual on such occasions. Mr. KAPP said that no mathematical assertion was of much use without a practical application underlying it; and the author of the Paper remarked in the course of his reply that nothing was so misleading as experiments carried out with a view of proving a theory. There is a temptation, in attempting to convey a good deal in a few words, to use expressions which, instead of being merely comprehensive, are rather too strong or too sweeping. The first speaker would of course readily admit the great intrinsic value of analytical reasoning, and the immense ultimate value to engineers of the powerful methods which it supplies. Pure science does not seek to be utilitarian; its disciples take up a physical problem now and then as a peg on which to hang their wondrous web of symbols, but its purity is their pride. The other speaker would of course qualify his statement if pressed, for a very large proportion of all experimental work is carried on to investigate or to support some assumption or hypothesis; and the exact difference between supporting a hypothesis and proving a theory is difficult to define.

From one aspect these two statements may be taken as being opposed to each other. The one deprecating abstract theorising if not attended by tangible results, and the other slighting objective evidence as untrustworthy support for sound reasoning. But the author of the first remark is better known for his mathematical work than for any extensive records of experiments; while the other is daily engaged with tests, and on this particular occasion was dealing largely with the results of his own experiments and with those of other

Digitized by Google

manufacturers. On the other hand, it would be conceded at once that a mere record of a phenomenon, or, indeed, of a fact—if we may make the distinction—with no theory or explanation to accompany it, is but a very meagre contribution to knowledge, and cannot be admitted as having any scientific import. The value of experiments can hardly be over-estimated, though it is well to bear in mind the errors into which it may lead anybody who has preconceived notions and who is rather attached to them.

Bacon made a distinction between learning and knowledge, though we do not know if he gave an exact definition. "Let us seek the dignity of knowledge, . . . we may not seek it by the name of learning; for all learning is knowledge acquired." Learning in fact is the higher and wider, and knowledge, included in it, is the particular. Speaking of Mathematic in the Advancement of Learning, he says, "For it being the nature of the mind of man, to the extreme prejudice of knowledge, to delight in the spacious liberty of generalities, as in a champain region, and not in the inclosures of particularity; the mathematics of all other knowledge were the goodliest fields to satisfy that appetite." Generalisation is the first step as a rule from knowledge to science. Galvani's first observation of the stimulation of the frog's limb was an isolated fact. It merely roused his interest; he experimented at first blindly and then systematically, and thus started the great science of dynamic electricity. There are many mere calculators who can wield the potent tools of their subtle art and can attack a knotty problem without perhaps having seen one of its kind before, and by sheer skill in their trade they will crack its shell and serve up the kernel of fact, with perhaps a garnish of formulæ, but sometimes, happily, in such a shape that the plain man may have some chance of making use of it. And there are not a few experimentalists who potter on and poke about in their particular corner of science with all the industry and with all the aimlessness of the ant. Now and again they light on something interesting or useful, but for the most part their work will have to be overhauled by an abler hand, or perhaps some keener mind will re-discover and develope the truths that they have half observed.

Difficulties begin when a combination is effected, and two of the prominent stumbling-blocks are imperfect data and erroneous reasoning. Edison, for example, observed some tiny sparks many years ago and described how they could be produced between wires in a darkened box. No known electrical theory would explain them. Speculations were made about an etheric or odic force. The unfortunate names were repellant to most minds, for we are chary of welcoming to "new forces"; they are generally associated in our minds with table-turning. But there is no doubt now, that Edison had accidently made a Hertz resonator, his keen eye detected the sparks, but the reason for them lay too deep, and the precise nature of the circumstances were not understood. Several unhappy inventors, on the other hand, have observed that a glow lamp is not instantaneously extinguished when the current is broken, and have proposed to light a number of lamps in rapid succession with the current required for one, taking, as every engineer strives to take, a mean advantage of the laws of nature. These men were guided by reasoning which, unfortunately for them, was false reasoning.

A sad amount of time is wasted by these two stumbling-blocks. Where a man is working alone, he may thus waste years like Jacobi with his crude motors. But the scientific societies of to-day undoubtedly do a great service, both by bringing to light work that is actually in progress, and by encouraging discussion. Faults of reasoning do not often meet with criticism until the results to which they lead are found to clash with others, and then comes the value of discussion. A case of this kind is before us at present in connection with the losses in transformers. In the course of his series of articles on Magnetism, Prof. Ewing alluded (*Electrician*, vol. xxv., p. 169) to the influence of speed on magnetic hysteresis. He says that experiments are wanting to show whether speed has in general any material effect. For very small cyclic changes the magnetic changes depend largely on the speed, but "there does not appear to be anything like so serious a dependence on speed when the magnetic changes are considerable." With small changes there is magnetic viscosity. He quotes the calorimetric measurements of Warburg and Hönig, showing two-thirds the heating effect for reversed magnetism. Tanakadaté found the heating for quick cycles to be equivalent to about 80 per cent. of the slow cycle value. "He observed, further, that the heating effect was practically independent of the frequency of the reversals when that was varied between the limits of 28 and 400 cycles per second."

One of the topics of conversation in the electrical community to-day is the simple statement which has been put forward as to the decrease of hysteresis in the iron core of a transformer when the load increases. As far as we are aware, the explanation was not concealed in the mathematics of the Paper in which it was published. The first Paper at the Physical Society on February 27th contained a mysterious sentence which hints that the authors "have reason to believe that the magnetising value of an ampere-turn varies." This would appear to be connected with the other statement, but it cannot be said to explain it. The Vice-President of the Institution, who was in the chair last week, firmly declined to afford the smallest clue to an explanation. He alluded to the work of Prof. Roiti and others to the probable diminution of hysteresis with high frequencies, and to the conclusion which they had arrived at, viz., that the iron losses in transformers were negligible. But the point of peculiar interest, as to the relation between the loss and the load, still remains as an assertion. The course is unusual, but it has this to be said for it. Prof. Ayrton's Paper was presented to the Physical Society, and it is obviously there that it should be discussed. This loss, hitherto unaccounted for, was predicted by Mr. Mordey some years back, and was thought by him to be revealed in experiments made nine or ten months ago. He, too, modestly disclaims any obligation to offer an explanation. "Give you a reason on compulsion? If reasons were as plenty as blackberries, I would give no man a reason on compulsion." After the meeting came explanations. Differences of phase of currents, demagnetisation by the primary, waves of magnetism running round the core and neutralising each other, sheets of magnetism soaking inwards one after the other, but no very sound or confident proof. In Prof. Ryan's Paper (*Electrician* vol. xxiv., p. 264) a table is given, showing a decrease of hysteresis loss from 96·1 to 69·7. An accompanying diagram shows "loss by hysteresis, &c," apparently falling with these limits. A determination of the hysteresis on a slow cycle, by Dr. Sumpner's modification of Prof. Ewing's method, gave a *smaller* loss. Prof. Ryan suggests that the hysteresis falls off on account of the mechanical vibration of the iron. If this be so, there should be less loss in a noisy transformer than in a silent one. If this be the explanation, it is at the same time satisfactory and disappointing. Satisfactory, because it is well known that mechanical shocks decrease hysteresis, and we need not throw over any theory of magnetism; and disappointing, because some new scientific truth was expected. The matter

Digitized by Google

is like the "Ferranti effect," of trifling importance practically, but of great interest theoretically, if it is to affect magnetic theories. Hysteresis is treated as a residuum, and is, after all, of nearly the same order as the errors of observation. It is, in fact, the petty cash of the balance-sheet.

This one item must surely be cleared up soon; in its present stage the matter is very incomplete. Recent Papers have raised many perplexities. The alternate-current transformer has not been long with us. JABLOCHKOFF hinted at it, GAULARD-GIBBS gave it to us, FERRANTI tried it, somebody proposed putting them in parallel instead of in series, manufacturers experimented with some caution and no little secrecy, and here we are to-day in the midst of a conflict which touches the very root of the matter.

## THE ELECTRIC CURRENT AND ITS LAWS.—IV.

BY JOHN T. SPRAGUE.

(*Continued from p. 577.*)

§ 30. If we were examining the electric current systematically, it would be natural to commence at the "source;" but for present purposes it may be better to consider first the phenomena of the "variable" periods at closing and opening the circuit. It is from these that the new notions about the current itself take their rise.

Fig. 3 represents what occurs. The horizontal line A G is the period of a current's duration. The vertical line A E may

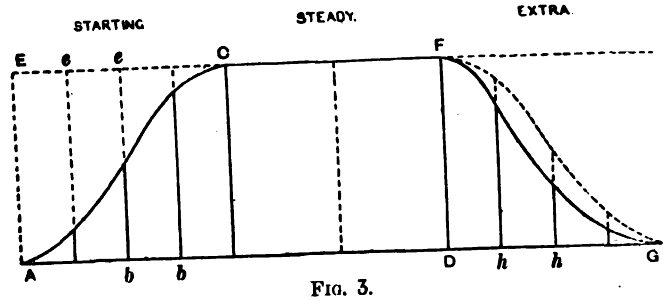

FIG. 3.

have several relations; it may be the E.M.F or "voltage" of the source; or (which is the thing which underlies voltage) it may be "energy." The other vertical lines are the measures of "current," the ordinates which give the curve of current A C F G; c C and D F being the full current due to the voltage of the source and the ohmic resistance of the circuit; b b the ordinates of the initial variable period, and h h those of the terminal variable period. This latter period is the "extra" current period, the true circuit being supposed to be broken at the time D.

§ 31. Any process which takes time, however short, must necessarily be developed gradually, and be describable by a curve. The curve A C is that of the growth of the current up to its full strength; the form of this curve and its length depend upon the conditions which favour or retard the generation of the full current. In the case of electric currents the retarding conditions are found in § 17, p. 576. They are due to certain stresses which must be produced before current can be set up at all, and which involve an absorption of energy from the source. I will defer their special examination till each comes before us in turn, and only indicate them now, viz., static electric stress (§ 17 *d*) and pressure (*e*), these being really the charging of a condenser; (*d*) the magnetance of the circuit, which has some analogies to the charge of a condenser, in that it is a storage of energy in producing some kind of stress. There is another temporary call upon energy, in the "inertia" of the conductor. Think what we may of the nature of current, it can hardly be doubted that it involves a motion of some kind in the molecules of matter; something accompanies it of the nature of friction, which results in the production of heat. This involves inertia, the same thing which resists every mechanical motion, and needs a temporary greater energy to produce than is required to sustain action; and this does not produce heat, but momentum.

§ 32. It will be necessary later on to include all these in one conception of the initial "stress storage" of energy which retards the development of current. Looking at Fig. 3 we may now consider the lines *b b* as representing energy expended *in the conductor*, while their dotted continuations *e e* represent the energy stored in producing stresses, chiefly *outside* the conductor.

§ 33. Inertia implies momentum, and stresses can do work. When the supply of energy from the source is stopped at D, this stored energy returns into the conductor, from which the stresses were created and sustained by the constant stress within it which produces the current; as a consequence identical with what we find in mechanics. This energy appears as momentum, replaces the "source," and maintains a continued current till it is gradually exhausted, when the circuit is opened.

It now becomes internal energy and heat. But the space within the curve F G can never be equal to that outside the curve A C, because all the energy cannot return; some is always retained in magnetism, which results in "hysteresis," Foucault currents, and so on; and even an electric stress in any medium dissipates some energy. I have shown this by the dotted curve F G, which corresponds to A C. The space between the two curves represents this wasted or lost energy; but it should be clearly understood that my curves are ideal and arbitrary. I use this representation to convey ideas, not the exact facts of any particular case.

§ 34. The kind of curve is familiar enough of late; but I wish now to turn it to a purpose that I do not remember to have been utilised before.

*Frequency* is a very useful term for the periodicity of make and break, or of alternation of current, which has now established itself; and if the reader will make a copy of Fig. 3, fold it on itself at the middle dotted line, and slip this into a slit in a card, he will see all that is concealed in a good many pages of mathematical symbols in various papers about variable periods, oscillations, and electrical wave transmission.

By drawing in, and so eliminating the middle part, we alter the "frequency" of the current shown; and when we make the lines C c and F D coincide, we come to a pure wave, the crest or amplitude of which equals the full power of the source. Now this is the lowest proper frequency to be used when the alternating effects are wanted, and the proper frequency when it is intended to fully saturate a magnet.

§ 35. But continue the process, *increase the frequency* without altering the conditions of inductance and magnetance. Now we have the very results before us, which are described by Dr. O. Lodge in his admirable experiments about lightning conductors; we have a lower and lower "current" in the conductor; but we have a higher discharge of energy into the external space, with less facility for its return into the circuit. Here, I think, we may find the truth about the Hertz experiments. They involve successive impulses of energy into space outside the conductors, in such manner and time as to produce waves of induction (not waves of electric transmission), and these find an outlet for the energy which is not given the opportunity of return to the circuit, an action different from, but comparable with, that of the condenser of an induction coil.

§ 36. It is a digression, but I must here explain what I mean about these so-called electric waves. Every musical note has its rythmic interval, which we call its wave length, its periodicity. Take a church bell, for instance, and let us suppose its vibrations to be 400 per second. This is its sound wave period, which we may call A. Now let that bell be struck four times a minute; at each blow a wave of sound will issue, at a periodicity of 15 seconds. Now this may be called a wave of sound, but it is not a sound wave length or period. We may call it B; in this case it is really a recurrent addition to the amplitude of the true sound waves, but no one would complain of the fact being described as successive waves of sound.

Digitized by Google

Perhaps the true combination of the two would be a wave of 15 seconds, with its outline broken into ripples of $\frac{1}{400}$ of a second, each ripple being a true sound wave with rising and falling amplitudes generating the wave of impulse. Now what I mean is, that the electrical waves, of which we have heard so much lately, are not electrical waves analogous to the sound waves A. They have nothing to do with the nature of electric transmission. But they may be called waves of electricity, if we only knew what that means, or, more truly, waves of electric induction. They are analogous to the waves of sound B, merely mechanical incidents, produced not by electricity, but by an artificial periodicity controlled by the conditions of the experiments—mechanical, not electrical waves.

§ 37. Returning now to Fig. 3 and the interpretation of § 35, we may find at once the explanation of the phenomena discussed on several occasions by Sir W. Thomson, and particularly in Papers "On Alternate Currents in Parallel Conductors," abstracted *Electrician*, XXV., pp. 510 and 512. He says (§ 7, II.) :—"When the period is very small compared with 400 times the square of the smallest diameter (400 times the sectional area is more consistent with questions of conductance) multiplied by its magnetic permeability and divided by its electric resistivity, the current is confined to an exceedingly thin surface stratum of the conductors." At all events, it is so small that a very thin stratum will conduct it. Fig. 3 shows why it is small.

§ 38. The statement that it is confined to the surface stratum is, I think, derived from mathematical considerations; but by-and-bye I will give a physical reason why it should be expected to be so. Meanwhile, this is one of the reasons given to show that the energy comes from outside, and under these conditions only just enters the skin of the conductor to propagate the current there. Well, the reasons I will give will show why only this skin current is produced by energy transmitted *within* the conductor.

§ 39. Mr. Heaviside, speaking, p. 388, of the phenomena of a commencing current, and the theory that its origin is from outside the skin of the conductor, says "very few (if any) non-mathematical electricians can understand this fact; many of them neither understand nor believe it." Well, I believe it, and think I understand it, and had already said in reference to it, p. 340, that I would try "to show that there is a better way" to explain it than inventing an action from outside the conductor. My views as to the relation of electricity to the structure of matter and that energy becomes electrical energy only by the agency of a completely closed circuit involve the commencement of the process at the surface of the conductor, and action first externally; the propagation of current in the conductor, being a gradual progressive action in both directions in the conductor, of course "gradual" relates here to time in millionths of seconds. All the facts are as readily explained in this view as on Mr. Heaviside's, and I have no doubt mathematicians would be able to show that either theory is equally adaptable, like the action at a distance, or by a medium which Clark Maxwell says are the same as to mathematical treatment.

Both views of necessity must work from the facts, but in the opposite way. According to the new views, as explained by Mr. Heaviside, p. 389, "the battery or other source of energy" (to save words I shall always speak of "the source") "acts upon the dielectric primarily—that electrical conductors act rather as obstructors, except that they guide the electromagnetic waves along definite paths in space." I maintain that the source transmits energy only into the conductor, but the conductor exerts forces all around, as well as along it; that the characteristic of the force called electricity (which is the marriage of matter and energy, neither alone) involves the setting up of two actions, induction or stress and conduction or transfer of energy.

§ 40. *Induction* precedes *conduction* in genesis. This is not an assumption or hypothesis, nor is it an explanation of any thing in itself, though its consequences may explain much. It is purely a statement of a general fact in nature, for induction is a *stress*, conduction is a *flux*, and of necessity, a flux must be preceded by a stress.

We separate substances into classes, as possessing inductive and conductive capacities; but no such absolute distinction really exists, except as to degree. Induction must occur in copper as well as in gutta-percha, only it breaks down and becomes a conductor (as, indeed, gutta percha does) directly sufficient energy is available. But still the distinction does exist, and is enormous practically; and it is quite clear that the distinction is one of "structure" of matter. Good conductors are elements, metal and carbon, and of simple molecular structure. The next great stage in classification, electrolytes, though more complex in ultimate structure, are still very simple in primary structure, they can break up into two radicals, which to the chemist's mind correspond with the atoms of elements.

Inductors are much more complex in structure, or, as sulphur, are capable of taking variable molecular structures.

Now we know that, given a sufficient stress, that is E.M.F. or voltage, every inductor breaks down; we can generalise from this, and see that until stress rises to a fixed degree, and until all possible stress-bearing matter is charged to that degree, the energy of a "source" will be wholly expended in producing stresses.

§ 41. Current will only be propagated when, and so far as, all stresses are satisfied; therefore, of necessity, the current in a conducting wire can only rise to its normal degree gradually, and reach that degree gradually along the length of the conductor. In fact, if we look at the conditions of Fig. 3, we shall see that there will be a current curve travelling along the wire A G, which will be like the curve A C turned over, and producing gradually the full current strength.

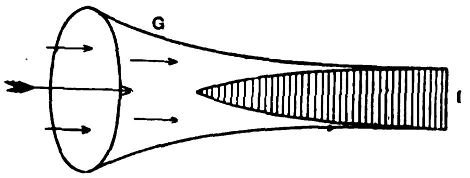

FIG. 4.

Common sense, without the aid of mathematics, will see at once that this progressive wave of propagation must begin at the surface of the conduits, because the leakage of energy is from the conductor into outer substances in which stress is to be set up; it is also evident that a corresponding internal curve of current must exist within the conductor, its elements turned towards the surface, to reach the outer induction circuit, and only taking up the whole of the conductor when the energy is left free to act wholly within it.

Putting these two self-evident ideas together, we see the advancing current must be at first confined wholly to the mere skin of the conductor; and when the frequency is great, we have of necessity no other current generated, as shown §§ 34 and 35. Fig. 4 will show this idea, though prepared for another use later on.

(*To be continued.*)

**The Action of Electric Currents on the Human Eye.**—Prof. Dubois, of Berne, says *Nature*, has been lately studying the physiological action of electric currents and discharges, and he has some interesting observations on the human eye, which, it is known, has luminous sensations under the action of galvanic currents. Sudden variations of current strength, especially at making and breaking the circuit, produce flashes. With a moistened plate at the nape of the neck, and a pad on the eye, a slight flash was distinctly perceived even with a Leclanché cell, giving about 1·20 volt and ·04 milliampere. Raising the current to ·5 milliampere, the observer could tell which pole was applied to the eye. On the other hand, the retina responds much less readily to discharges from condensers or induction coils. Not till a capacity of 0·037 microfarad and a pressure of 21 volts was reached, was a true retinal flash perceived; and not even with 10 microfarads were the durable sensations characteristic of the two poles produced.

## NALDER'S BALLISTIC GALVANOMETER.

A good deal of inconvenience sometimes attends the use of the ordinary form of control magnet in a galvanometer This arises from its being really required to perform two distinct

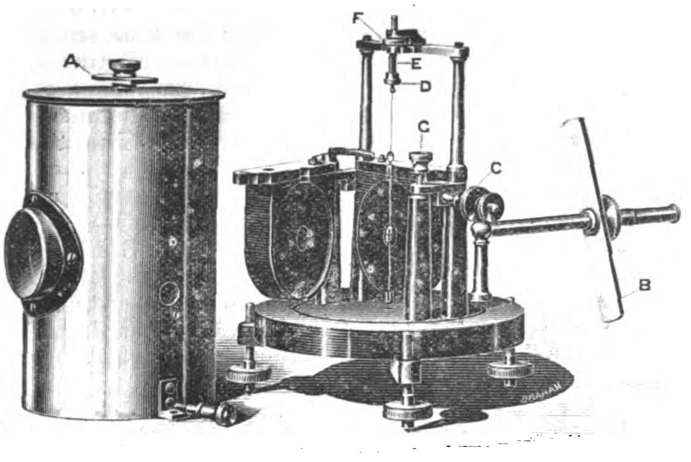

FIG. 1.—Nalder Ballistic Galvanometer. General view, with case removed

functions; first, to alter the strength of the field acting on the needle system; and, secondly, its direction, the former determining the sensitiveness of the instrument and the latter the zero position of the needle. When altering the one it is difficult to avoid altering the other, and the inconvenience becomes the greater the slower the swing. The form of control we illustrate above (*see* Fig. 1) was suggested by Dr. R. Mullineux Walmsley, of the Heriot-Watt College, Edinburgh, who wished to more or less avoid this double effect of the magnet. The usual one is replaced by the much smaller one, A, as fixed on the top of the case, and which can be turned round, but not raised or lowered. By it the spot is first brought to zero. The combined field of the earth and A are then diminished (or increased if a quick swing is required) by turning the tail magnet B on its shaft, or bringing it nearer or further off; but it will be observed that, from the symmetrical position of this magnet with respect to the needle system, when thus moved or turned, it merely alters the intensity of the field without interfering with its direction. Any slight shifting of zero which may occur, due to want of absolute symmetry, is adjusted by a very slight movement of A.

FIG. 2.—Nalder Ballistic Galvanometer. Details of Needle System.

Messrs. Nalder Brothers and Co, of 16, Red Lion-street, Clerkenwell, have applied this method of control to ballistic galvanometers. There are one or two details about this pattern that may be noted. The whole coil is supported on ebonite pillars, and the terminals screw into plates in these after the cover is on, passing through holes in the latter, which are closed by sliding ebonite plugs, C, to keep the dust out when the instrument is not in use. The front coil is hinged so that the needle system is left clear in case a new fibre is required. The attachment for the fibre, D, is free to turn on the end of the rod, E, so that torsion can be taken out; D itself is threaded, and raised or lowered by the nut F, but has a longitudinal slot in it in which a pin works, so that the rod cannot turn round. The second connection to the front coil is through the clamping screw G, which holds the coil in place when closed. In Fig. 2 the needle system with its heavy bell-shaped magnets is shown in detail.

## THE KINGDON INDUCTOR DYNAMO.

This machine is one of the revolving keeper type. The coils, which correspond both to the armature coils and to the field magnet coils of an ordinary alternating current dynamo are fixed, while the revolving wheel carries a number of laminated masses of iron or keepers, which, by their motion, continually change the direction of the lines of force in the iron cores of the armature or secondary coils. The magnets of the dynamo are built up of a number of stamped iron plates of the shape shown in the diagram, and bolted between two stout circular cast-iron frames divided horizontally along the centre line, so that the top can be lifted off and the wheel taken out. The lower frames are bolted to a stout cast-iron bed-plate. The keeper wheel is of exceptionally strong mechanical construction, and consists of 16 keepers, which are constructed of a number of soft iron plates, insulated from one another, and bolted between two stout steel plates mounted on a hub, keyed on to the main driving shaft. Between the keepers and steel plates are two brass rings, which tend to magnetically insulate the keepers from one another. The field magnet or primary poles are permanently magnetised by the current from a small exciter. The intermediate poles have their polarities constantly changed as the keeper wheel rotates. When the keeper wheel or (inductor wheel, as the inventor calls it) has rotated through one thirty second of a revolution the secondary poles will all have their polarities changed, and alternating currents are accordingly generated in the coils with which they are wound. There are no brushes or rubbing contacts, all the coils being fixed.

This dynamo, designed by Mr. J. A. Kingdon, is in use at the Kidsgrove Works of Messrs. Woodhouse and Rawson United, and is wound with one set of coils for supplying incandescent lamps direct at 105 volts; another set is wound with high potential coils for transformer circuits; while a third set is used for arc lamps.

Two machines of similar though slightly different design have been supplied by the Company, and erected at the Woking Central Station. These are wound for 30 amperes at 2,000 volts, and are coupled direct to triple expansion engines. Their periodicity is 70; the inductor wheel is 4ft. 6in. in diameter. The resistance of the eight primary coils connected in series is 2·7 ohms, and of the eight secondary coils 1·8 ohm. The total weight of each is about $7\frac{1}{2}$ tons.

## ST. PANCRAS VESTRY ELECTRICAL EXHIBITION.

The Electrical Exhibition now being held at the St. Pancras Vestry Hall is intended to afford an opportunity to the inhabitants of that district to inspect fittings and switches, &c., and thus enable them to judge of the effective appearance and many other advantages of the electric light which their enterprising local authority will soon be in a position to supply. The Exhibition is of a very complete character, and the large number of lamps at the prettily decorated stalls form an attractive *tout ensemble*.

The current is supplied from a temporary plant erected in a shed near the hall, and consists of a 100 H.P. Marshall semi-portable boiler with extra long fire-box, working under 140lbs. pressure, and provided with a feed-water heater with copper tubes and Worthington pump, and a 80 H.P. Willans engine, coupled direct to a 48 unit Goolden dynamo. This machine was intended to run 400 amperes, at 120 volts, but has been delivering close on 500 amperes very comfortably, without a sign of sparking. There is in addition to the above plant a 20 H.P. Parson's steam turbine. The whole of the plant was erected in four days by Messrs. Sharp and Kent, in the midst of the severe snowstorm of last week. Although it is greatly to the credit of this firm that work of so substantial a character should have been accomplished in such a short time, it is to be regretted that the promoters of the Exhibition should have allowed such a short time for the erection of the plant.

Digitized by Google

One of the first objects of interest in the exhibition is a sample of the mains which are to be laid in the St. Pancras district. These consist of copper strip, as used by the St. James Company and others, supported on wide porcelain blocks, mounted on galvanised iron fittings. Distance pieces of porcelain are bolted at intervals, keeping the strips parallel and straight. Designers of central stations have already shown some originality in the construction of chimney shafts, and here we find a remarkable water-cooling apparatus, constructed of corrugated iron sheets, slung on to the chimney at a height of about 40 feet from the ground. Stand No. 3 is occupied by the recently established firm of Messrs. Miller and Woods, of Gray's-inn-road. Mr. Miller

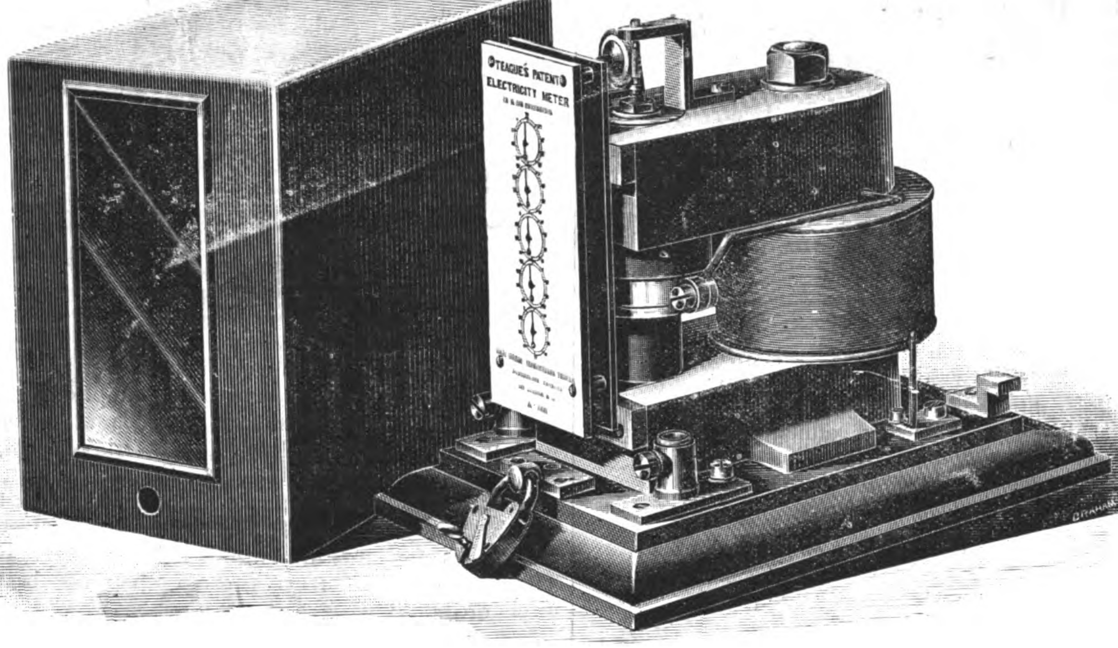

Fig. 1.—The Teague Meter

has a capital ammeter and voltmeter, containing but a very few grains of iron, and the internal arrangements are such that the scale may be either uniform or spread out, the former being used for ammeters and the latter for voltmeters. This firm show an Oerlikon arc lamp, which is one of the very few which will run, if necessary, direct upon a storage battery without the intervention of a resistance. An effective fitting is shown at this stall, hung by a short length of the new flexible metallic tubing, which seems very well adapted for this purpose, being much more substantial than a ball and socket joint. A good assortment of instruments, keys, &c., is exhibited by John Muirhead and Co. The Acme Electric Works make an excellent show, including the Teague watt meter, the Perry twisted strip voltmeter, Ayrton and Perry

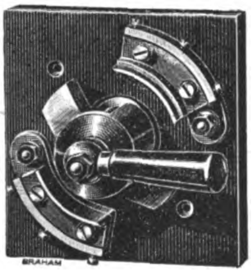

Fig. 2.

combined magnifying spring voltmeters and ammeters, and a number of improved Cockburn quick break lock switches. The Teague meter (Fig. 1) consists of a horse-shoe electromagnet and a hollow revolving cylinder or drum inserted in an annular space bored near the pole. The series current enters at the bottom by the axis of the cylinder, which projects into a mercury trough, passes thence to the top, radiates by the cap of the cylinder to the exterior, and passes down to another mercury trough. The improved Cockburn quick break lock switches are now constructed on an entirely new principle, the amount of spring necessary to ensure the ends of contact brush bedding firmly on the terminal plates being obtained by the flexibility of the brush itself (Fig. 2), which is constructed of extremely thin rolled copper. The terminal plates are segments of a circle, being made adjustable, and by means of screws can be so arranged as to compensate for considerable wear on the brush. At the end of the room the General Electric Company have a number of Aron meters and other fittings, and next to them is the stall of Messrs. Rashleigh, Phipps and Dawson, who show a collection of fittings and give a prominent place to their patent glass bead ray diffuser. This consists of a number of strings of glass beads, threaded on a wire. The beads are in graduated sizes, tapering upwards, and enclose

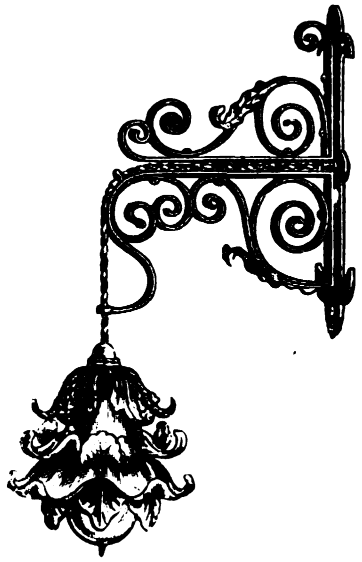

Fig. 3.—Bracket Pendant for Incandescent Lamp (Benham and Froud).

an ordinary electric lamp in a flexible sheath. The arrangement will be admired by those who like clear cut glass on a lamp. Fitting, as the diffuser does, close to the bulb, it takes very much less space than the ordinary cut-glass shade of the preserve jar type. The idea, however, is not altogether new, as we saw something of the kind nine years ago. The new Ferranti meters are shown on an adjoining stand, together with a double

Digitized by Google

pole switch adapted for 2,400 volts. This has a parallel sliding motion, the distance of the break being six inches and the distance between the mains being the same. Messrs. Wake and Sanders have a very fine show of specimens of mica, including large sheets of the quality termed "ruby," and some exceptionally large and clear specimens from Australia and Madras. Messrs. Osler and Co., Strode and Co., Benham and Froud (*see* Fig. 3), Paterson and Cooper, Woodhouse and Rawson, and other well-known firms, are also exhibiting fittings and accessories. One of the most attractive stands is that of the comparatively new firm of Mr. Richard Crittell, of Baker-street, W. Amongst the metallic work shown by them are some very handsome specimens of iron work. Messrs. Drake and Gorham show some specimens of their new D.P. battery plates, both formed and unformed. This plate consists of narrow strips of lead placed horizontally and burned together at the ends, and formed in the old Planté style. At the same stall clear moulded glass cut-outs are shown.

The General Electric Power and Traction Company, which has a prominent stall in the centre of the room, the Keys' Company, and Messrs. A. B. Gill and Co., make a praiseworthy attempt to fulfil the request of the promoters in supplying examples of the domestic applications of electric power, and show washing machines, mangles, air-fans, and hat brushing machines driven by miniature motors. The Keys' Company show a number of switches of a pattern which we understand is largely used in Germany (Fig. 4). The moving part is constructed like an ordinary door bolt. The bar is pressed back by a spring, but may be held forward by a catch. When pressed forward it makes contact between the two lugs on a split copper ring. This ring encloses an ordinary Edison screw

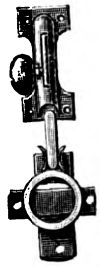

Fig. 4.—Bayonet Bolt Switch.

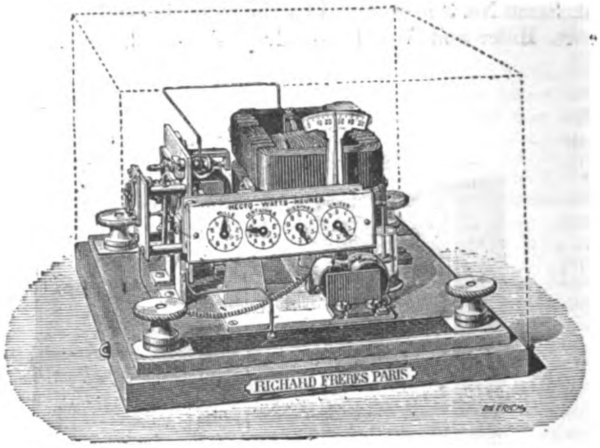
cut-out. The contact would not be very good, except for the fact that there is both a sliding and a turning motion. It takes up very little space and looks neat. Finally, the Executive Committee have not forgotten to provide something in the nature of mild amusement, such as telephonic "auditions," and a far-reaching, ever-moving search-light on the roof.

The promoters and the Executive Committee of the Exhibition have succeeded in getting together a decidedly creditable display, and we are not surprised to learn that the Exhibition has proved sufficiently attractive to warrant it being kept open beyond the originally fixed period of one week.

## RICHARD FRÈRE'S ELECTRICITY METER.

Richard's meter belongs to the class of intermittent integrating apparatus. The meter is composed of four principal parts —a clock, a wattmeter, an integrating mechanism, and a counter train. The clockwork is entirely independant of the instrument, can be removed and replaced without in any way interfering with the lighting, or giving trouble to the consumer. The clock is wound up at regular intervals of 15 seconds, by a shunt current passing for $\frac{2}{100}$ of a second. The wattmeter consists of a dynamometer composed of a coil of wire or ribbon; inside this a fine wire coil is mounted on a spindle, and the pull is balanced by means of a counter weight. The spindle is provided with a clutch, and is allowed an end play of 2mm. The clockwork makes a contact, which allows the shunt-current to pass through the fine wire coil and an electro-magnet in series with it. The inertia of the armature, being less than that of the fine wire coil, the armature acts first, and disengages the clutch, then the fine wire coil adjusts itself, and a hand upon the spindle indicates the watts passing. Five seconds later the clockwork is automatically rewound, and the wattmeter circuit being interrupted, the clutch engages, and the wattmeter in returning to zero turns it through a certain angle. Ten seconds later, the wattmeter being disengaged, another measurement is made. The counter train, therefore, shows the sum of all the measurements.



The power expended in these meters is said to be less than 20 watts, and they start with a consumption equal to $\frac{2}{100}$ of their capacity. Such meters may be used for measuring both the charge and discharge of batteries, a polarised armature being arranged to cut a resistance in or out, this resistance being proportional to the difference between the charging and discharging in volts. The meter then registers differentially, going forwards in charging and backwards in discharging. The index ought to return to zero when the battery is fully discharged.

## TRANSFORMER DISTRIBUTION.*

BY J. SWINBURNE.

DISCUSSION.—AUTHORISED ABSTRACT.

Before the commencement of the discussion Mr. SWINBURNE showed three of his Hedgehog transformers, having outputs of 2,000, 3,000, and 120 watts respectively. The primary of the first was wound for a pressure of 1,000 volts at a frequency of 130, that of the second for 2,480 volts at 70 periods. The third was intended for street lighting. He said he anticipated a lively discussion on the subject of open *v.* closed-circuit transformers, and in order that a better comparison might be made he hoped speakers would give all details of the patterns to which they referred. As a word of warning to those who intended to criticise the "Hedgehog," he remarked that, like the Scotch thistle, its motto was "*Nemo me impune lacessit.*"

Mr. ESSON said the Paper would be regarded as a most important one, for it served to rectify certain errors which had recently crept into the

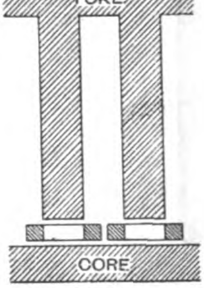


Fig. 1.

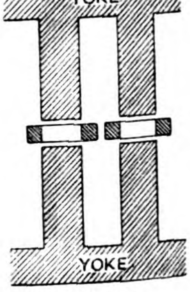

Fig. 2.

consideration of alternating-current machines. The discussion on Mr. Mordey's Paper left things in a very unsatisfactory state, for no figures were given by which the offered explanation of the experiments could be confirmed or confuted, and at the close of the discussion the author himself admitted that some self-induction was necessary for successful parallel working.

* Paper read before the Institution of Electrical Engineers, February 19, 1891.

Digitized by Google

The question of how much was needed was not at all clearly understood, for Mr. Swinburne said that coreless armatures had not sufficient, and Mr. Mordey thought that because his armature had no iron core it had practically no self-induction. Now it is known that both were wrong, and that armatures without iron may have self-inductions quite comparable with those of cored armatures. He then pointed out that the classification of armatures into those having iron cores and those without had led to misconception, and showed that the chief differences between, say, a Siemens or Ferranti alternator and those of the Lowrie-Parker or Westinghouse form are, first, in the position of the air gap, and, second, that in the cored armatures part of the iron forming the magnetic circuit moves, or is utilised to lay the generating coils on. Diagrams 1 and 2 were shown to illustrate these differences. Speaking of Mr. Swinburne's armature-reaction theory, he said Dr. Hopkinson included armature reactions in his term "self-induction," and remarked that it would be difficult to deal with self-induction as exhibited by alternators without including these reactions. Dr. Hopkinson had also stated what should be the value of this self-induction. Mr. Swinburne, however, objected to the treatment on the ground that the harmonic law did not hold, yet he gave no hint as to how the magnitude of the reaction-effect was to be estimated, nor any indication of a law that did hold. With the author's objections to complicated high-pressure networks he heartily agreed, having himself made similar observations in the discussion on Mr. Crompton's Paper three years ago. He also believed it better to use 1,000 volts instead of 2,000, but failed to see any advantage in feeding parallel machines into common bars, and then isolating the supply circuits by feeding them through transformers. On the subject of transformers he remarked that the true efficiency was the ratio of the useful energy supplied by the secondary during lighting hours to that put into the primary in the 24 hours, and that upon this ratio the efficiency of the system mainly depended. Coming to the examination of Mr. Swinburne's figures for the efficiency of the closed-circuit type, he found this efficiency rather understated. Taking a 50 lighter tested by Prof. Ayrton some three years ago, its efficiency at half load was 90 per cent., whilst the loss with open secondary was 53 watts. Now supposing this to work at half load for only four hours out of the 24, its all-day efficiency comes out 69 per cent.; whereas Mr. Swinburne made out the efficiency of a modern closed-circuit transformer to be only 51 per cent. He thought all would

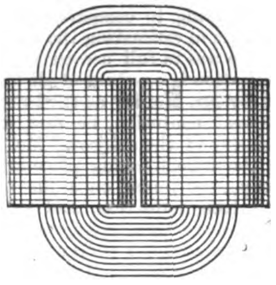

FIG. 3.

agree that it was of great importance to make the "all-day efficiency" as high as possible, but doubted whether Mr. Swinburne took the best way of doing this. For if the Hedgehog transformer be cut in two and made into a closed-circuit one resembling Fig. 3, the watts spent in hysteresis would not increase by more than 66 per cent., and if the loss in the Hedgehog is only 13·5 per cent., the 66 per cent. increase would give 22·5 for the loss in the closed-circuit transformer, instead of 120 as given in the Paper. Making this correction, the "all-day efficiency" of the closed-circuit converter came up to 80 per cent., and by redesigning it this could be further increased. It therefore appeared that there was little to choose between them. In conclusion he pointed out that in 1885 Messrs. Gaulard and Gibbs, at his suggestion, closed the magnetic circuits of their transformers, thus making them resemble Fig. 3. Messrs. Ganz and Co. experimented on a similar form in 1884, and after trying several types had again returned to it, thus showing that no great advance had been made on the shape he suggested some six years ago.

Mr. MORDEY said he did not propose to touch upon the first part of the Paper, as he thought he could best utilise the time at his disposal by confining himself to one definite subject. On alternators he did not at present wish to add anything to the practical contribution that two years ago he had given on the subject. On many of the minor points of distribution he agreed with Mr. Swinburne's conclusions; but from its present interest he thought the design of transformers was the most important subject dealt with in the Paper, and to that he would confine himself. It was interesting to notice that the author had arrived at his present conclusions by a zigzag path, as was seen by a reference to the *Journal* for 1888 where in the discussion of a Paper by Prof. Forbes, Mr. Swinburne said:—"I notice a slip where Prof. Forbes said that some transformers would be more efficient if the iron circuit were open. As I fell into the same error myself, I may point out that the waste of energy is $\int I\,d\,H$," and so on. He (Mr. Mordey) would first sum up the author's present grounds for preferring open circuit transformers. They were (1), that iron was wasteful, hysteresis loss heavy and continuous; (2) that losses were easily ascertainable by calculation only, from $C^2R$ in the conductor, and by Ewing's or Hopkinson's curves for hysteresis (which the author said was constant for all loads), and by calculation for the eddies; (3) that these phenomena in iron and the action of transformers being understood fully—that only "phenomenal iron" could improve closed circuit transformers; (4) that tests of closed-circuit transformers by various observers, showing high efficiency, were wrong, as such efficiencies did not agree with the author's calculations; (5) that the magnetising current was large even in the closed-circuit type. He thought all these conclusions were wrong. On the question of these losses, Mr. Mordey said that careful tests were needed to decide the points, rather than calculations. Many independent observations on closed, circuit transformers by various methods, such as the Calorimeter method used by Prof. Ayrton and others, the "Split Dynamometer" method devised by Mr. Blakesley, &c., had shown the efficiency to be very high. The method he had himself devised and alluded to in 1889, viz., finding the steady temperature to which the transformer was raised when working at a known output, and then determining the loss by applying, with direct currents, sufficient power to maintain this temperature, led to similar results. Recent tests of a 6 kilowatt transformer of his own design by the latter method gave the loss on open circuit as 110 watts, and at full load 206 watts, of which 176 are accounted for by $C^2R$ in the copper. This left only 29 watts for the iron losses at full load, whereas at no load they amounted to 110. On calculating the theoretical iron loss from Ewing's curves it came out at 180 watts at the magnetisation employed. These results showed that as the loss in the copper increased the iron losses diminished, and that conclusions based on the assumption that the iron losses were constant, and could be calculated from Ewing's curves were erroneous. On the basis of the above tests, the efficiencies at various loads of the particular transformer were calculated to be as follows, the first and last being determined by experiment, the intermediate filled in by calculation:—

**Table I.**—Mordey Transformer.

| | Efficiency. |
|---|---|
| Full load. | 96·7 |
| ¾ | 96·2 |
| ½ | 95·1 |
| ¼ | 92·1 |
| ⅛ | 86·7 |
| 0 | 1·8 % loss. |

At no load the total loss was 1·8 per cent. of the full output, and the apparent loss (viz. C × V) 3·1 per cent. the lag between E.M.F. and current (determined simply from the ratio of the true to the apparent waste), which gave the cosine of the angle of lag therefore being 53deg. and 54deg. On the important subject of "all-day efficiency," which Mr. Swinburne stated to be very low in closed-circuit transformers, Mr. Mordey gave the following numbers as relating to the transformer above mentioned, which was one of the Brush Company's ordinary type.

**Table II.**

| Full load for 4 hours (20 hours idle). | | | All day efficiency. |
|---|---|---|---|
| ¾ | " | " | 86 |
| ½ | " | " | 82·7 |
| ¼ | " | " | 68·6 |
| ⅛ | " | " | 52·6 |

He remarked that the small difference between the steady temperature of some of his transformers working at no load and at full load was noticed by him in 1889. For instance, in one case this rise of temperature was 43°F. at no load, whilst at full load it was 48°F. only. From this observation one could infer that either the transformer was very inefficient, or that the loss in the copper was very small, or that some other explanation was needed. Now he knew that neither of the first two suppositions was correct, hence the necessity for some other explanation. Just before the meeting Prof. Ayrton had shown him some tests of one of his transformers, made by Blakesley's method. These tests, conducted by Prof. Ayrton, confirmed his own, and as an instance of this he gave the following numbers, which he said were taken from several pages of concordant figures.

**Table III.**

| Frequency. ∿ | Watts. | Iron losses (watts). | Efficiency. |
|---|---|---|---|
| 210 | 2,363 | 3 | 94·1 |
| " | 907 | 69 | 90·4 |
| 100 | 2,638 | 21 | 93 |
| " | 2,425 | 18 | 93·8 |
| " | 849 | 69 | 90 |

These tests, together with many others made by disinterested observers, all pointed to the conclusion to which he had been led, viz., that the losses in the iron decreased with the load. He submitted that these results, if correct, upset every one of the author's conclusions. But even if Mr. Swinburne's contentions were true, the low "plant efficiency" obtained would seriously interfere to prevent the practical use of transformers constructed in accordance with his views. The author confessed to three-tenths of the plant being required to supply the magnetising current, but said that closed-circuit transformers required two-thirds as much, which latter was by no means the case. The use of condensers would reduce this great disadvantage of open-circuit transformers, but it must be remembered that condensers would also reduce the small disadvantage of closed-circuit transformers. If satisfactory condensers could be obtained (and he congratulated the author on the progress he seemed to have made in that direction) he thought the outlook for closed magnetic circuits was better than ever. The best plan of all, however, was to make apparatus, so that it could be left to work in its simplest form.

Mr. CROMPTON thought the results of his own tests on transformers would confirm Mr. Mordey's observations, but they also enabled him to

Digitized by Google

contradict some of the statements made by that gentleman. In the first place the number of hours required for transformers to attain a steady temperature was much greater than Mr. Mordey would have us believe, for he (Mr. Crompton) had kept them running 30 hours, and still the temperature was not constant. He had also kept both a "Hedgehog" and a closed-circuit transformer of equal output on for 20 hours, the final temperature of the former being 120°F., whilst that of the latter was 212°F. His experience with the Hedgehog type in the lighting of Chelmsford had been satisfactory. Referring to "all-day efficiency," he said most people speak of the efficiency of transformers being 90 per cent. at half load, as if this was their normal working condition. This load was far above the average, even during lighting hours. It might be approximately right for shops and other places where the probable load was readily ascertained, but for private houses it was much too high. Taking the case of a customer whose lighting bill, at 8d. per unit, amounts to £20 a year, he said such a house would require a 50 to 60 light transformer, and the average consumption throughout the year would be 70 watts. The transformer would thus be working on an average at one-sixteenth its full load. It was curious to notice that in the transformer mentioned by Mr. Mordey (*see* Table III.) the iron losses at light loads were about 69 watts, and thus the yearly efficiency would come very near indeed to 50 per cent., the number he gave three years ago. He would have been glad if Mr. Mordey had given the statistics of some of the transformer stations with which he was connected in the shape of the ratio of energy paid for to energy sent out from the station. This, he said, was the important point, and at present it appeared that transformer plants were using about two and a-half times as much coal per unit sold as direct systems. All this extra coal, he submitted, was spent in heating the transformers. Banking transformers and distributing at low pressure would diminish this loss; but after all, what did this come to? Simply that you put down a high-pressure line, with its expensive insulation and a transformer at the end of it, whereas with continuous currents a rather heavy feeder with cheap insulation was all that was required. Transformers, he said, were not so easy to manage as was imagined, and were in this respect not much better than secondary batteries. On the question of "storage," he could not agree with Mr. Swinburne's opinions, for in stations subject to uncertain load, the employment of accumulators to the extent of 20 or 30 per cent. of the total output enabled the working expenses to be reduced immensely. In his opinion, the reason why storage is not used in America was that the loads were fairly steady, and a satisfactory storage cell was not to be had there.

Mr. ADDENBROOKE remarked that Mr. Swinburne was under a wrong impression when he stated that probably no existing company intended changing their system of supply, for he (Mr. Addenbrooke) well remembered that when Mr. Ferranti took out his first patents for transformers the subject of sub-stations and low-pressure distribution was thoroughly appreciated by the inventor. At that time, however, it was impossible to found sub-stations, but it had always been the intention of Mr. Ferranti, as well as of the House-to-House Company, to adopt this system whenever they could. The cutting out or in of transformers at such stations could be effected either automatically or by hand on the lamplighter principle, and with either method a difference of 1 or 2 per cent. in the efficiency of the transformers would be a matter of little importance.

Mr. EVERSHED regretted that the diagrams belonging to the Paper were not issued with the proofs, for without them it was very difficult to follow the reasoning. He described as admirable the explanation of how alternating dynamos act as motors, and said the action was much easier to understand on the armature-reaction theory than by the older ideas about self-induction. Referring to the compound machines mentioned on slip 7, where the magnets are excited by a redressed alternating current, he inquired how the sparking could be got over? On slip 8 the author said cast-iron magnets would not respond quickly to armatured reactions; but he (Mr. Evershed) failed to see why this should be so, for the high specific resistance of the iron would prevent Foucault currents almost as well as laminated wrought iron. In conjunction with Mr. Vignoles he had made many experiments on the loss by hysteresis in different samples of iron, and had never found a sample give more than 25 per cent. more loss than Ewing's specimen; only one sample gave this value, and it was an ordinary bar taken out of a smith's shop. In most cases the losses are about 5 per cent. more than that found by Ewing. On the subject of efficiency of transformers, he said Mr. Swinburne had not taken a good design of closed circuit converter with which to compare his "Hedgehog." [Mr. Swinburne here remarked that in his British Association Paper he had given the best proportions of copper and iron for the closed-circuit form; but in this Paper he had taken an average of the various forms in the market.] Mr. Evershed said that to be anything like a good design there should be much more copper in it, about 2,000 turns in the primary instead of the 400 given. This would reduce the iron loss to 40 watts instead of 120, and the exciting current would be reduced to ·08 instead of ·3 amperes required by the open circuit-type. Nevertheless, if good condensers could be obtained, the large exciting current would not be a serious defect. The subject of open *versus* closed-circuit transformers had occupied his attention for some time, and he found that if you cut the iron circuit of one of the latter form its efficiency was increased. Such being invariably the case, he said, Why not "go the whole hog or none," and do away altogether with the iron core? Recently he had worked out the dimensions of a ten horse-power transformer made on this plan, and found that at a frequency of 70 it would require two tons of copper. If, however, the frequency was raised to 210, the weight was reduced to 200 lbs., and the saving resulting from the absence of a core amounts to 20 per cent. per annum on the cost of the transformer. Difficulties might be experienced in making alternators for such high frequencies, but so far as coreless transformers were concerned high frequency was decidedly advantageous.

The discussion was then adjourned until Thursday, March 12.

THURSDAY MARCH 12TH.

Mr. A. P. TROTTER said the author had been criticised for giving figures instead of facts. This criticism he considered unfair, for it was better to give figures early enough to prevent serious mistakes being made. Had Mr. Swinburne's Paper on Armature Reactions in Direct Current Dynamos appeared sooner, it might have saved others from falling into error in making large Gramme armatures for constant current machines. On the subject of transformer tests, he said the calorimeter method, to be at all accurate, involved many troublesome corrections, and would require very large vessels. The electrostatic wattmeter methods need to be tried; split dynamometers neglected leakage, and as the stray fields are quite different to what one would expect, serious errors may be introduced. Dr. Fleming's experiments at the Royal Institution illustrated how the stray fields of alternating magnets were different from those of ordinary electro magnets. In such fields copper behaved very much like iron in ordinary fields, and possibly copper filings might prove useful for exploring the waste fields of transformers. Mr. Mordey's thermometer method would, he thought, involve considerable trouble if anything like accurate results were to be obtained, for since the heat was in one case generated in the iron, and in the other in the copper, the fact that a thermometer on the iron gave the same reading did not necessarily show that the energy dissipated in the two cases were identical. To obtain reliable results the distribution of temperature should be uniform, and the isothermal surfaces parallel to a casing surrounding the transformer under test. The two latter methods curiously enough led to the result that the losses in hysteresis become less as the load increases. This he could not understand, for if, as is generally assumed, the induction is constant at all loads, he failed to see what goes on in the transformer which would explain the new fact. Since the last meeting, two valuable contributions to our knowledge of transformers had been read before the Physical Society. On the subject of the diminished iron losses at large loads referred to in one of these Papers, he would ask whether such a result was consistent with Ewing's theory of magnetism. To him it appeared possible, and even probable, that the losses with rapidly alternating currents may be quite different from those existing for slow cycles. In order to illustrate the fact that physical properties of materials depend on the rapidity of the changes influencing them, he showed by experiment that a piece or pitch, which was quite soft and viscous to steady pressures, yet transmitted the rapid vibrations of a tuning-fork like a perfectly elastic rigid body.

Mr. G. C. FRICKER, referring to comparisons of closed and of open circuit transformers, said that in estimating the loss in a closed circuit one as 120 watts, Mr. Swinburne was in full accord with writers and teachers who hold that the magnetisation is constant at all loads. This assumption was, however, challenged by Mr. Mordey at the last meeting, and he himself doubted its truth. Great confusion, he said, existed amongst recognised authorities in the theory of the subject. Mr. Kapp, for instance, in his diagram illustrating the actions taking place in a closed circuit transformer, builds up his component forces on a line drawn to represent the maximum value of the resulting induction, and in the speaker's opinion thereby begs the whole question. He also asserts that the resulting induction is in quadrature with the secondary current because this current is in consonance with the impressed E.M.F. Mr. Blakesley, starting from a different standpoint, viz., the impressed primary force, and assuming the necessary adjustment of primary and secondary currents, arrives at the conclusion that the secondary impressed force is in quadrature with the primary current. If, therefore, both Mr. Kapp and Mr. Blakesley are right, the phase difference between the primary and secondary currents is always 90deg. He (Mr. Fricker) thought one of the statements must be wrong, and asked Mr. Swinburne to point out which was correct or to reconcile the two. In view of the contradictions between recognised authorities on the theory of transformers, he thought the experimental facts brought forward by Mr. Mordey should not be lightly set aside. So far as these results would affect the comparison of closed and open circuit transformers, Mr. Swinburne might say that the open form would be equally benefited if the new view be correct. He, however, could not agree to this, for the Hedgehog required a very large exciting current, and hence the plant efficiency would be materially lower even during the hours of full load. It was difficult, he said, to conceive the mechanism which must exist within the transformer if Mr. Mordey's and Prof. Ayrton's figures be true; but, nevertheless, their confirmation would be one of the most interesting developments of electrical science. Speaking of calculations based on the sine law, he remarked that several months ago he arrived at conclusions similar to those proved analytically by Prof. Ayrton, viz., that harmonic variations were not essential to the accuracy of the resulting formulæ, and would give the considerations which led him to the conclusions in the *Journal*.

Dr. FLEMING said Mr. Swinburne had ventilated his opinions against the orthodox view of parallel working, but so far as he (Dr. Fleming) could see, he merely put forward old views under a new name. Armature reactions really meant mutual induction between armature and magnets, and, as such, their existence had always been recognised. Considerable attention, he thought, should be paid to the state of a system at a given instant, and a distinction drawn between the instantaneous inductance and the mean inductance of a circuit. Referring to Prof. Ryan's indicator diagrams for transformers, where the E.M.F. and current curves are plotted in correct relative positions, he showed how the inductance at any instant could be obtained, and expressed it by the formula

$$I = \frac{e - r\,i}{\frac{d\,i}{d\,t}},$$

$e$ being the E.M.F., $i$ the current, and $\frac{d\,i}{d\,t}$ the slope of the current curve

at the point corresponding to the instant considered. Inductances so found were, he said, periodic functions of time. On the subject of parallel working he thought little or no advance had been made since Mr. Mordey's Paper was read. Parallel working was then shown to be quite practicable, and is now largely employed on the Continent. At Leghorn several 150 H.P. alternators were perfectly in parallel. These machines have high resistance, small time-constant, and stiff field, the conditions which, according to orthodox views, are desirable. He could not agree with Mr. Swinburne that 1,000 volts station pressure was preferable to 2,000, for the cost of the mains in the latter case was only about half that in the former. The employment of 2,000 volts did not seem to be any more dangerous, for Messrs. Ganz and Co. and the Thomson-Houston Company had many stations working at this pressure, and, so far as he had observed, the 2,000 volt alternators required no more care in working than their low-pressure exciters. He doubted whether the use of low-pressure alternators and step-up transformers would be safer or more economical, for the waste in the transformers would be considerable, and their cost would probably far exceed the figure quoted by Mr. Swinburne. The chief claim made for the Hedgehog form of transformer was that it gave a more square-shouldered efficiency curve than the closed type. Whether this was so or not was, he said, not a question of calculation, but one on which experiment alone could decide. Such experiments should not be made by a wattmeter, where a fine coil and non-inductive resistance were employed, for considerable error may be introduced. Although Mr. Swinburne admitted that the Hedgehog transformer required a large exciting current, he seemed to underrate the effect of this, when a number of small transformers were connected up, for it would entail a great waste of coal and lower the plant efficiency. As regards sub-centres and low-pressure distribution, he said nothing could be more charming when writing a Paper, but when one came to devise a practical system to work under present conditions great difficulties presented themselves. Care should, however, be taken to run the feeders for supplying high-pressure distributors so that they terminate at points where sub-stations may subsequently be conveniently placed.

Mr. KAPP thought the efficiency of the Hedgehog transformer would be increased by closing its magnetic circuit, for this would reduce the exciting current, and by diminishing the magnetic resistance the lag would be increased; therefore the power would be less and the plant efficiency greater. He could not see how it was possible for an open circuit transformer, which required a large exciting current all the day, to be more efficient than a closed circuit one. The matter could not be settled by argument, and experiments must be appealed to. Speaking of sub-stations, he said he was disappointed with Dr. Fleming's view, for the system had taken great hold upon engineers. At present, however, it would be futile to build large sub-stations. Eventually a leaf might be taken out of the book of direct-current engineers, and stations to supply limited districts established; but instead of carrying coal to these stations they would convey electric energy. Distribution could then be effected much more economically, for large or small transformers could be put in or out according to the demand. He called attention to a drawing of an automatic apparatus for performing these operations which he had designed, and said a copy would appear in the *Journal*.

Mr. F. KING agreed with Mr. Swinburne about the defects of the house transformer system, but thought his estimate that the average comsumption amounted to half-load for four hours per day was rather too high; three hours half-load would be nearer the truth. Making this correction, the all-day efficiency becomes considerably less than the least figure given in the Paper. Referring to the advantages of storage, he said secondary batteries were now satisfactory things, and believed that when transformer systems could use storage, then alternate current engineers would appreciate its importance in reducing working expenses.

Mr. S. JOYCE, jun., asked whether the iron losses in transformers obtained from Mr. Mordey's and Prof. Ayrton's experiments continued to decrease with increase of load, and if they ever became zero or negative?

Major CARDEW said people's opinions differed considerably as to what was meant by sub-stations. Mr. Kapp's system was expensive, but he saw no reason why transformers should not be placed in small lean-to buildings, and used to supply several houses in the neighbourhood.

Prof. S. P. THOMPSON hailed with satisfaction Mr. Swinburne's opinion about 1,000 volts being generally preferable to 2,000. Dr. Fleming had said that the cost of the mains varied inversely as the volts. As far as copper was concerned this might be correct, but it was not so for insulation. This, he thought, varied as the square of the volts, whilst compensations, &c., might be as the fifth or sixth power.

Mr. MORDEY, replying to Mr. Joyce, said the efficiency curve rises and then falls again, whereas the iron losses fall to a minimum, and then rise with further increase of load. Many tests show the same result. On the subject of armature reactions he had experimented by isolating one coil of a 50 H.P. armature from the rest, and connecting it with a voltmeter. On varying the load from 0 to 20 amperes this voltmeter remained quite stationary, whilst the pressure of the active coils fell six or seven per cent. Referring to Mr. Trotter's objections to his thermometer method of testing transformers, he said magnetic leakage could not affect the result at all, and with care there was no difficulty in obtaining correct results.

Prof. AYRTON did not agree with the author's remarks on slip 4 about the word "self-induction" being meaningless when applied to an armature, and pointed out that the self-induction of a coil was not affected merely by its being interlinked with lines due to other magnetising forces. The self-induction of a coil meant the change of lines threading the coil due to unit current in that coil; and although its value would be affected by the presence of iron, yet under given conditions its meaning was quite definite. The transformer tests made by Mr. Taylor and himself had, he said, been attacked both because they gave a point of maximum efficiency and because they showed the loss in iron to be small at full load. No doubt Prof. Ewing and Dr. Hopkinson had shown what the losses were when iron was subjected to slow changes of magnetism; but, so far as he knew, there was no proof that the same losses occur with rapid reversals. In a number of *La Lumière Electrique* for March, 1890, Prof. Roiti had given results of transformer tests made by different methods to those employed by Mr. Mordey and himself, and had been led to the same conclusion, viz., that at moderate loads the iron losses in transformers were negligible. Three independent observers, using different methods, had thus been led to the same conclusion. Speaking of measuring power, he said Dr. Sumpner and himself had communicated to the Royal Society a new and simple method, quite independent of any assumptions as to harmonic variations or leakage, and at an early date he proposed making tests on both closed and open circuit transformers by this method.

Mr. SWINBURNE, in replying to Mr. Esson, said Dr. Hopkinson had worked out the best condition for parallel working by getting the greatest control for a small change in the lead or lag angle, on the assumption that two equal machines were in parallel; this, he pointed out, was not the condition which holds in practice. To Mr. Evershed he pointed out that there was no difficulty in redressing the main current for series excitation of an alternator, for this was done daily both by Thomson-Houston and Ganz. He then observed that though it was said that his representative closed circuit transformer was not good enough, he had repeatedly asked for particulars of a better one, but they had not been produced. Though he had done so in his British Association Paper, he was not now called upon to design closed circuit transformers for his opponents, and in his present Paper he had taken a commercial "Hedgehog" and had compared it with a commercial closed-circuit transformer. His "freezing mixture" statement, he said, was not based on Ewing's curves, for he found that, according to Ferrari's tests, the loss in the whole transformer was less than the loss by resistance, and so the iron must have actually supplied power to the circuit. The readings were taken by the "split" dynamometer method, and proved its worthlessness. Mr. Mordey's figures were, he said, shown to be inaccurate by their agreement with those of Prof. Ayrton and Mr. Taylor, which were taken by the split dynamometer method, and thus gave too high efficiency, especially at full load. Whether the iron losses become small or not at full load was, he said, of little importance to his contention, for if it be admitted that they are large at no load, his point as to the superiority of the open circuit type was proved. Any wattmeter would not give accurate results in transformer measurements, and before one is used it should be carefully checked both with direct and alternating currents on resistances and choking coils. As it was very important that people should have confidence in transformer tests, his firm would provide all apparatus for different tests to be carried out on the same transformers by all the well known methods, and he hoped a good closed circuit transformer would be forthcoming to undergo the same tests. He would be glad if Profs. Fleming or Thompson would make the tests, everything being provided for them. Mr. Kapp's and Mr. Esson's argument that a "Hedgehog" would be improved by closing the iron circuit was, he said, bad, for that would double the iron loss. The large exciting current was not a serious matter, for, although speakers had overlooked the fact, this could be supplied by condensers or by a dynamo running loose. On the subject of sub-stations, he pointed out that there was no need for buildings, for transformers might be sunk in the roadway where needed. Neither was there any necessity for automatic switches to cut transformers in and out, for, if properly designed, they could always be left on without appreciable waste.

## NOTES ON ALTERNATING CURRENTS OF VERY HIGH FREQUENCY.*

BY ELIHU THOMSON.

The interesting account of the novel experiments given by Mr. Nikola Tesla in the *Electrical World* of February 21, 1891 (see also *The Electrician*, March 6, p. 549), relating to the phenomena of alternating currents of very high frequency, leads me to make a statement of some of my own observations while working in similar directions. The highest number of alternations which I have had at my disposal up to the present is 8,000 per second, a rate somewhat below that which Mr. Tesla has obtained, but which, nevertheless, shows properties and brings about actions and results similar to those which he describes. The physiological actions of these rapidly alternating currents have been very ably investigated by Dr. Edward Tatum, some of the results of whose work I have presented in a separate communication. Mr. Tesla's experiences in relation to the static effects of these currents of high frequency are similar to those noted by myself, particularly the small surface of the condenser, which is able to transfer, or permit to be transferred, a considerable amount of energy through a dielectric, owing to the exceedingly high rate at which the changes of direction of charge are made.

The following experiment, which was tried by me some months ago, is interesting in this connection: An incandescent lamp bulb was constructed in which only a single platinum leading-in wire was used, on the end of which, inside the bulb, was mounted a single slip of carbon of two or three inches in length, it being one leg of a broken incandescent lamp filament. Two-thirds of the

* From the *Electrical World* of New York.

Digitized by Google

lamp bulb was now immersed in an outer vessel of water, leaving the single wire above the water for attachment to the source of alternating currents at one terminal, and the other terminal was connected with the outside water, which was rendered slightly conducting by salt dissolved therein. The water surrounding the lamp bulb formed, of course, an outer condenser coating, while the vacuous space and straight slip of carbon were the means for the conveyance of a charge to and from the inside surface of the bulb, which was, of course, exhausted to the ordinary vacuous condition, as found in an incandescent lamp. When an alternating potential of about 1,000 volts, and with a rate of alternations up to 5,000 per second, was applied to the carbon strip, the filament was brought to bright incandescence simply by the bombarding action of the residual gas, as in the Crooke's tubes, while, of course, no complete circuit existed, but only the condenser action of the lamp bulb allowing sufficient current to flow. At the same time the glass of the lamp bulb not immersed in the water became rapidly heated, indicating that that portion which was immersed in the water would have become equally heated had it not been subjected to the cooling action of the water itself.

The retention of the arc, as with direct currents, and the high note evolved by it have been noted from the beginning of my experiments with these high-period currents. Mr. Tesla expresses surprise that he was enabled to hear the note from an arc in which the alternations of current were more than 10,000 per second. Mr. Tesla will pardon me for calling his attention to the fact that he is taking as the limit of audition in this case sounds of from 5,000 to 10,000 complete waves per second, which is far below the limit at which sounds become inaudible to ordinary ears, cases existing in which a pitch corresponding to over 30,000 per second has been heard, according to some authorities. The cause of the persistence of the arc with very high-period alternations, as stated by Mr. Tesla, is undoubtedly the correct one, *i.e.*, that the gas stream has no time to cool between the alternations, and its variations of temperature must therefore be quite slight. The conductivity of the vapour or gas stream constituting the arc therefore remains nearly constant when the rapidity of alternations is sufficiently great.

The characteristics stated by Mr. Tesla as requisite to be possessed by machines suitable for obtaining constant current for the working of arc lights are, of course, connected with the fact that in such machines the characteristic curve indicates a drop or fall in the electromotive force developed on a slight excess of current above the normal, and on a decrease of current arising of the electromotive force to a point above the normal. It is not, however, in accordance with my experience that the undulation of the current is almost essential to the success of an arc-light system; nor do I think that properly constructed clutch lamps depend for their success, any more than do finely constructed clock-work lamps, on the presence of a rapidly varying current due to a small number of armature coils and correspondingly small number of segments in the commutator. In fact, I have run with perfect success clutch lamps in circuit with coils of such large self-induction that any but very slight fluctuations were wiped out and without introducing any particular difference in the behaviour of the lamps. It probably is true, however, that slight gentle fluctuations occurring at very moderate intervals may be of benefit in the working of clutch lamps by keeping the clutch mechanism in a state of vibration or tendency to open or close; but it can scarcely be doubted that if this benefit exists for such lamps a similar benefit would exist on the operation of clockwork lamps, as a similar fluctuation would give rise to a continual tendency in such lamps to keep the detent or escapement free enough for delicately letting go teeth for the feed; but the fact that large numbers of lamps are in use in which the feeding of the carbon either by clutch or by clockwork is under the control of a derived circuit magnet only, and that such lamps operate with the greatest satisfaction, shows that the undulations mentioned by Mr. Tesla are not necessarily a factor to be considered. In such cases the self-induction of the arc branch is negligible as compared with that of the derived circuit magnet controlling mechanism, and the fluctuations, therefore, would pass through the arc without affecting the said magnet to a perceptible degree, particularly as the potential around the arc with slightly different current strengths flowing is nearly constant. I may add that the experiments of Mr. Tesla in relation to the action of the condenser and the elevation of potential brought about by it are decidedly interesting, and point to the possibility of obtaining a pure resonance effect. This would require, however, that the periodicity of the alternations be preserved very rigidly during the experiments, and involves the production of an unvarying or perfectly constant speed in driving the generating machine, a condition not easily obtained in practice.

In making the above notes on the highly interesting and valuable account given by Mr. Tesla, I desire to state that, in whatever way my notes may appear as criticism of Mr. Tesla's views, they are not made in any unfriendly spirit, but with the desire of reaching the exact facts which it is the object of scientific investigation and discussion to ascertain.

## PARLIAMENTARY INTELLIGENCE.

### The City and South London Railway Extension Scheme.

BILL BEFORE THE SELECT COMMITTEE OF THE HOUSE OF COMMONS.

The City and South London Railway Bill, which proposes to extend the electric railway system from King William-street to Islington, came (on Friday last) before a Select Committee of the House of Commons, consisting of Mr. Hanbury (Chairman), Sir G. Campbell, Mr. F. Parker, and Mr. H. Stewart.

Mr. Pembroke Stephens, Q.C., and Mr. Rigg, appeared for the promoters, while the opponents were represented as follows:—The Gas Light and Coke Company, Mr. Pope, Q.C., and Mr. Danckwerts; Lord Calthorpe, Mr. Sanders, Q.C., and Mr. Lewis Coward; the Corporation of London, Mr. Littler, Q.C., and Mr. L. Monk; the Commissioners of Sewers, Mr. Russell Griffiths; Messrs. Rothschild and Sons, Mr. Bidder, Q.C., and Mr. Lewis Coward; the Metropolitan Railway Company, Mr. Littler, Q.C., and Mr. Worsley Taylor, Q.C. Counsel were reserved by the Vestry of St. Luke's, the Regent's Canal Company, the City and Docks Railway Company, Messrs. Cooper Brothers and Co., the Metropolitan District Railway Company, and the Union Bank of London.

Mr. PEMBROKE STEPHENS, in opening the case for the promoters, said the City and South London Railway Company were the pioneers of the system of underground electric railways in London. The proposed extension line would start from a point in King William-street, about 150 yards from the Company's Monument station, and would pass under Moorgate-street, Old-street, City-road, to the Angel at Islington.

The CHAIRMAN: It is not an actual continuation of the present line?

Mr. PEMBROKE STEPHENS said it had been thought better not to carry the proposed line into the existing terminus, but there would be a sub-way leading from the Monument Station to the proposed station in King William-street to enable passengers to pass under cover from one station to the other. The mode of construction in the case of the proposed line would be similar to that adopted on the existing line. The length of the proposed line was two miles, and there would be stations in King William-street, near Moorgate-street, in Old-street, in City road, near the Regent's Canal, and at a point a little short of the Angel at Islington. The Committee would see that the proposed line was clear away from any other line of railway, and, except for the fact that it would pass under the Metropolitan Company's railway at Moorgate-street, it would not touch any other line at all.

The CHAIRMAN: You have no provision in the Bill for workmen's trains.

Mr. PEMBROKE STEPHENS replied in the negative. They were all workmen's trains. The additional capital to be raised in order to carry out the proposed extension was £660,000 of share capital and £220,000 borrowing powers, making together £880,000.

The CHAIRMAN: Have you any clause asking for the subsoil for nothing?

Mr. PEMBROKE STEPHEN: No, sir. The Metropolitan Railway Company, in their petition, went so far as to allege that the working of the proposed line could not be effectually accomplished by electricity as a motive power. The application of electricity as a motive power, they said, was at present in its infancy, and although experiments had been made, the practical results had been uncertain and unsatisfactory; in fact, they had shown that electricity was inadequate as a sole means of efficiently working a line of railway. He (the learned counsel) was afraid that the Metropolitan Company had failed to recognise the various uses to which electricity had been put during the past few years. Certainly, the Company said, "Your petitioners are advised that the cost of working railways or subways by electricity is proportionately very much greater than the cost of the ordinary method of working the traffic of railways, and that although it is true that the South London Railway has been worked since its opening by electricity, such working has been frequently unreliable, and it will be found that the cost is far too great to permit of railways being worked by this system, even though they carry an enormous Metropolitan traffic, to be a commercially remunerative concern." What right had the Metropolitan Railway Company to trouble themselves about the success or failure of the proposed scheme? It was no business of theirs whether the Company did or did not make the line pay. Further, the Metropolitan Railway Company said in their petition: "The promoters of the Bill have inserted the provision for working the line by electricity in order to secure for the Bill a measure of public favour, and to facilitate its passing into law; and the probability is that, in the event of the line being sanctioned, the promoters, having obtained powers for the construction of their railway, will come to Parliament in a future Session for power to make use of steam, which is the only motive power that at present can with efficiency and economy be used upon railways." That was a very curious statement for the Metropolitan Railway Company, seeing last year they themselves considered whether they would not throw over steam and take to electricity.

Mr. GREATHEAD, one of the engineers of the City and South London Railway Company, said the object of the Bill was to afford to the very populous districts north of the City better facilities for travelling to the City. The generating station would be in Duncan-terrace, near the Angel.

The CHAIRMAN: Will it in any sense be a nuisance?

WITNESS: No; there are no houses near. Continuing, the witness said. the generating station at Islington would only supply the extension, and not the whole system. There would be two generating stations—one for each section.

The CHAIRMAN: If the two sections joined you would only want one generating station.

Digitized by Google

WITNESS: Well, there is an advantage in having two, because, if one failed, you will be able to use the other. The conductor will pass through the subway.

What is the distance from the Angel to the present generating station?—About five miles.

On the Central London Railway one generating station will work the whole six miles?—Yes, it is quite possible to work the proposed extension and the existing line with one generating station. It is simply a question of costs.

The CHAIRMAN: The site for the proposed generating station at Islington appears to me to be in a crowded district.

Mr. LEWIS COWARD: So it is, sir.

WITNESS, continuing, said it was proposed to work the new line in the same way as the existing line was worked. The trains, however, would be rather larger, and would accommodate more passengers. The proposed line would cause no interference with the public thoroughfares, and the excavated soil would be collected at and removed from the sites of the various stations. The total cost of the works, including the purchase of land and contingencies, would be about £458,402, and to that sum must be added £110,C00 for equipment. That equipment would enable the Company to run a three minutes' service. A two minutes' service would involve an additional outlay of £40.000 for equipment. The distance from Islington to King William-street would take from 7½ to 8 minutes. There would be no serious competition between the proposed line and the Metropolitan Company; in fact, he could not see that there would be any competition at all. The ground underlying the petition of that company was that they were afraid of further extensions.

Cross-examined by Mr. RUSSELL GRIFFITHS: The tunnels of the proposed Islington extension, the proposed Central London line, and the existing City and South London line varied in diameter.

Would not that be objectionable if you wanted to amalgamate the lines at any time?—No.

The CHAIRMAN: You will have the same gauge on these lines?—Yes.

Mr. POPE, who had just entered the room, rose to cross-examine the witness on behalf of the Gas Light and Coke Company.

The CHAIRMAN said as he was not present during the examination of the witness they could not allow him to cross-examine the witness, unless some special reason could be shown for granting him an indulgence.

After some argument between the Chairman and the members of the Bar, Mr. Pope, Mr. Littler, and the other opposing counsel left the room.

Shortly afterwards Mr. Danckwerts, who was with Mr. Pope, for the Gas Light and Coke Company, entered the room, and attempted to cross-examine the witness, but the Chairman at once stopped him.

Mr. DANCKWERTS: In the name of the members of the Bar of England I protest against such a course.

Mr. Danckwerts then withdrew.

Sir BENJAMIN BAKER, consulting engineer with Sir J. Fowler, stated that he gave evidence in support of the original Bill.

Sir G. CAMPBELL: What are the advantages of two small tunnels over one large one?—The cost of construction is about one-half less.

Then the saving of cost is the great advantage?—Yes; but you also get better ventilation. There are no serious disadvantages attached to the small tunnels, while there are a great many advantages.

Were you consulted about the break of line and the construction of a subway?—There are difficulties in the way of carrying the existing line through.

What are they?—The very great expense and the necessity of making some rearrangement of the City station, probably.

There are no physical difficulties—it is merely a question of expense?—Yes; no doubt you could do it.

The further consideration of the Bill was adjourned till Monday.

### Monday, March 16th.

The CHAIRMAN said, in the opinion of the Committee the weakest point of the promoters' case was the awkward break between the existingand the proposed lines. The Committee would require to be satisfied onthe point.

Mr. RIGG said he would bear the Chairman's statement in mind.

Mr. DOUGLAS YOUNG, land valuer and surveyor, gave evidence to the effect that, allowing for certain improvements, lands required for the service of the railway would cost £198,992. He had had experience of the depôt at Stockwell, and he was in a position to say that the working of the machinery of the depôt proposed to be established at Islington would cause no injury.

Mr. VENNER, Secretary of the Agricultural Hall Company, stated that Islington required more direct means of communication with the City, and that the proposed line would be of great advantage to those persons in the City who desired to visit the Agricultural Hall.

Mr. GRAY MOTT, the Chairman of the City and South London Railway Company, stated that the subway for foot passengers connecting the existing Monument Station with the proposed King William-street Station would be about 150 yards in length. It was not proposed to make a physical junction, so that passengers might be carried direct from Islington to the south side of the Thames. There were several serious obstacles in the way of such a junction, one being the great outlay which would be required to buy up most expensive property in King William-street. The carriages on the Islington extension would be larger than those on the existing line, so that the Islington carriages could not run over the Stockwell line, though of course the Stockwell carriages could run over the Islington line, the gauge being the same on both lines.

The CHAIRMAN: I should like to know a little more as to why you do not propose a physical junction, so that passengers might be carried right through from north to south. It strikes me that the Company are deliberately adopting a style of carriage which will make any junction in the future impossible.

WITNESS replied that they had found the carriages on the South London line rather small, and that therefore they were anxious to make those on the proposed line larger. In addition to the great cost of acquiring property in King William-street, the running of through carriages would not pay. The great bulk of the traffic was to and from the City, and not from north to south.

Mr. H. STEWART: Have you any future intentions in the way of extending your line, say from the Angel towards Highbury in the north, or westwards to King's Cross?—There is no such intention at present. Of course we cannot say what the future may bring forth, but the further you go the less likely is the traffic to prove remunerative. We anticipate a very large traffic on the Islington extension.

Mr. LITTLER asked the witness whether he had not stated that the object of the Company in promoting the Bill was not to make the line but to occupy the ground?

WITNESS replied that the promoters of the Central London Railway Company deposited a Bill in Parliament last year to take up the ground in King William-street, and it was true he had said one of the objects of the City and South London Company was to occupy the ground. Their desire, however, was to make the line, and if they got the Bill they would make it. He believed that the existing line would pay.

By RUSSELL GRIFFITHS: He hoped the proposed line would be constructed for less than £440,000 per mile. It would cost more than £225,000—the cost of the existing line—because property was very expensive in the City.

Re examined by Mr. RIGG: The existing line was not opened for traffic until December 18th, and therefore they had barely had three months' experience of its working.

You have not worked the line to its full capacity?—We have not done so yet.

Have you the means of increasing your train service without any great additional expenditure?—Yes. We do not run any trains as yet on Sundays.

You hope to do very much better by the end of the year than you have done up to the present?—Yes. We are doing better every week.

Supposing there was no subway, that the line was simply from the Angel to King William-street, would it afford valuable facilities to the public?—Yes. I do not know any district which requires such facilities more than Islington.

Sir G. CAMPBELL: Have we the least security that the line will ever be made?—You have more security than you often have.

Mr. PEMBROKE STEPHENS: Parliament has no absolute security that any line will be made. The City and South London Company, who are promoting this Bill, have paid the necessary deposit.

Sir G. CAMPBELL: This is very different from an ordinary railway. The proposal of the Company is that they shall be permitted to occupy a certain main line of streets in the City, and if we pass the Bill we prevent other people from using the ground as long as the powers last.

Mr. H. STEWART (to witness): If Parliament sanctioned it, another Company could run either above or below your line?—Certainly. We do not occupy the whole of the ground.

Mr. GREATHEAD, the Engineer, was recalled, and stated that last year the Central London Railway promoters proposed to make a physical junction with the existing City and South London Railway. The estimate for the junction was £70,000. That estimate was based on the assumption that the promoters would be able to take easements under the property. They did not contemplate having to purchase the whole of the property. Mr. Viger's estimate for purchasing the necessary property was £440,000

The CHAIRMAN: Then your main objection to having a physical junction between the two lines is the expense?—Yes.

The CHAIRMAN: Therefore your evidence is in conflict with that of Mr. Mott.

Mr. RIGG: But Mr. Mott has to find the money.

The CHAIRMAN: Mr. Mott certainly said he would not like a physical junction if he could get it at a small cost.

Mr. RIGG (to witness): If you had to make a physical junction would the cost be such as to make the line financially impossible?—I think so.

Sir JOHN FOWLER said he had no doubt the proposed line could be carried out successfully. It would, undoubtedly, carry a large number of passengers. There was no engineering difficulty in the way of the construction of the proposed line.

Do you approve of the substitution of a subway between King William-street and the Monument for a physical junction?—I do not think that a physical junction should be made, at least for the present.

Do you consider that the subway ought to be made as a temporary arrangement?—It is quite impossible to come to a decision on the point now as to whether or not there should be a junction connecting the two lines. In addition to the question of expense, there is the important point as to where the station should be made.

Do you think this line must be a continuous line ultimately?—I am not so sure of that. With the expience I have had I am not prepared to suggest anything to the Committee with regard to a junction. I would not take the responsibility of suggesting anything at the present time. I think it would be wiser to let things develop themselves.

This closed the evidence for the promoters, and the Chairman ordered the room to be cleared. On the public being readmitted the Chairman said the Committee proposed to hear the evidence against the Bill on the following day. The proceedings were accordingly adjourned.

### Tuesday, March 17th.

On the Chairman taking his seat, the counsel for the leading opponents were absent from the room. Mr. Littler, Q.C. (who, with Mr. Worsley Taylor, Q.C., appeared for the Metropolitan Railway Company), was eventually sent for, and on the learned counsel entering the room,

Digitized by Google

The CHAIRMAN said the Committee intended to adhere to their ruling with regard to counsel cross-examining witnesses. That ruling is in accordance with a resolution passed in 1861 by the General Committee on Railway and Canal Bills, which remained the standing authority on the subject. The resolution ran as follows :—" Counsel shall not cross-examine a witness, unless he has been present during the entire examination-in-chief ; and counsel shall not re-examine unless he has been present during the entire cross-examination." The Committee would regulate their procedure by the spirit, and, if necessary, by the strict letter of that authoritative resolution.

After a formal protest against the ruling of the chair, the learned counsel then retired from the room.

Mr. BIDDER announced that Messrs. Rothschild had arranged clauses for the protection of their property in the City with the promoters.

Mr. DANCKWERTS made a similar announcement on behalf of the Gas Light and Coke Company.

Mr. J. WOLFE BARRY, C.E., was then examined on behalf of the Corporation of the City of London. He stated that a physical connection between the existing line and the proposed line at King William-street was perfectly practicable from an engineering point of view, and that he thought the line ought not to be sanctioned by Parliament without such a connection. No underground railway ought to be authorised in London which did not communicate with external lines. The tunnels of the proposed line ought to be 11ft. 6in.—size of the proposed tunnels on the Central London Railway. If the tunnels on both lines were the same size there might be a junction between the two lines at a future date.

Mr. RUSSELL GRIFFITHS having addressed the Committee on behalf of the Corporation of London,

Mr. PEMBROKE STEPHENS summed up the case for the promoters. He said the scheme put forward by the promoters was admittedly a good one, and therefore he asked the Committee not to reject it because it did not include a general connection of the various systems. The Committee had passed the preamble of the Central London Railway Bill, and he did not see why they should not sanction the scheme now before them. He asked the Committee to bear in mind the enormous boon the proposed line would confer on both the districts traversed and the City itself. With electric lines from the Angel to the City and from the Monument to Stockwell he ventured to think that sooner or later science and the logic of events would bring about the desired solution.

At the conclusion of the learned counsel's speech the room was cleared. On the public being readmitted, the Chairman said the promoters had failed to make out a case for the passing of the scheme, and therefore the Bill would be thrown out.

The Bill was accordingly rejected.

## Overhead Wires Bill.*

### HOUSE OF COMMONS SELECT COMMITTEE.

On Friday last a Select Committee of the House of Commons, presided over by Mr. S. Williamson, had before them the Overhead Wires Bill, promoted by the London County Council for the control and regulation of overhead wires in the administrative County of London. There were several petitions against the Bill.

Mr. Pope, Q.C., and Mr. Freeman appeared for the promoters of the Bill, while the opponents were represented as follows :—Mr. Pember, Q.C., Mr. Moulton, Q.C., and Mr. Erskine Pollock for the National Telephone Company ; and Mr. Littler, Q.C., and Mr. Russell Griffiths for the four Inns of Court.

Mr. POPE, in opening the case for the promoters, said the Bill was one of the results of the report of the Committee appointed by the House of Commons in 1885 to consider the law relating to the control of telephone, telegraph, and overhead wires. That Committee consisted of influential and experienced members of the House, including the late Chairman of the Metropolitan Board of Works. While the Committee came to the conclusion that the risk of danger to the public from overhead wires had been very greatly exaggerated, they also expressed the opinion that the probable development of the telephonic system made it desirable that there should be some change in the law relating to the control over such wires. After dealing with the present state of the law and making certain suggestions, the Committee concluded their report as follows :—" Bye-laws for the regulation of all wires as to substance, length of span, durability and other matters for their identification and inspection should be made for the whole of London by the Metropolitan Board of Works, for provincial towns by the corporations, and for rural districts by the local authorities, in each case subject to the sanction of the Board of Trade. * * * * For the protection of the public it is necessary that there should be a ready means of dealing with every wire. For this purpose every wire should be identified, and the bye-laws should provide for the best method of identification by registration or otherwise, and for the removal of all ownerless wires. The Committee believe that such regulations as they have recommended will be abundantly sufficient." To carry out the recommendations of that Committee so far as the administrative County of London was concerned, the London County Council had promoted this bill.

Mr. HENRY LAWRANCE CRIPPS, Parliamentary Agent, stated that he had assisted the County Council in preparing the Bill. Clause 3 provided that where the Council had a subway in any street it should be lawful for the Council at any time to require the Telephone Company by notice in writing to remove into the subway any then existing wire of the Company over the street which could be conveniently placed in it, and that if any question should arise between the Council and the Company as to whether the subway was in fact convenient for the reception of the wire, or whether, having regard to the purpose for which the wire was used, it could under the circumstances be conveniently placed in the subway, the matter should be settled by an arbitrator. It was a necessary clause, and he hoped it would commend itself to the Committee. To obtain uniformity it was necessary to give to the County Council a certain control over the bye-laws and other local authorities.

Mr. RICHARD MELVILL BEACHCROFT, Solicitor, and a member of the London County Council, was then examined.

In the present Bill do you accept the decision of Parliament that the local authorities should themselves carry out the bye-laws which you and the Board of Trade finally decide ?—That is so.

One of the objects of this Bill is to prevent as far as possible wires from being taken overhead ? We hope to see the day when there will be subways through which all the wires will go.

The further consideration of the Bill was adjourned till Tuesday.

TUESDAY, MARCH 17TH.

Mr. J. WOLFE BARRY, Civil Engineer, was called on behalf of the County Council. He stated that he had advised the London County Council with regard to this Bill. The circumstances of London were special and peculiar, and therefore London required careful legislation. He thought it was necessary that the definition of the word "wire" should include "any wire, conductor, or cable, and any support or attachment thereto, any part of which is placed, or shall hereafter be placed, over any street or any part of any street." With that addition it was made perfectly clear that the words "support and attachment" enabled the County Council to deal with the posts or any other fixture to which the wires were attached. He approved of the provisions of the Bill, which enabled the County Council to call upon the various companies to remove their overhead wires and place them into the subways, and to bear the cost of registration and inspection.

By Mr. E. POLLOCK : The Bill of last year contained a general power to construct subways throughout London, but that power was withdrawn before the Bill was considered in Committee. There was no power in this Bill to make subways.

Do you think it reasonable to ask for powers to compel telephone companies to place their wires in subways when you do not ask for power to construct the necessary subways ?—Yes. I assume that they can be conveniently placed into subways.

Don't you think it would be better to postpone asking for such power until the subways have been constructed ?—No. We are dealing with overhead wires, and we say wherever they can be conveniently placed into a subway, subject to a reference to an arbitrator, then the wires shall be placed there.

Until the County Council have constructed the subways I suppose the telephone companies must go on constructing lines overhead ?—Yes, if they want to go on with their business.

Then after they have done this you ask for power to call upon them to place their wires into subways ?—Yes.

And you think it is reasonable to ask for such power now ?—Yes.

Mr. WINTERBOTTOM, Solicitor to the National Telephone Company, stated that the application of the County Council for power to call upon his Company to place their wires into subways was premature. At present the Company used copper wires, similar to telegraph wires ; but if they were compelled to place their wires into subways, they would have to incur an enormous expense. The single wire which they now used would be of no use in a subway alongside an electric wire. It would be necessary to have two wires, and these would have to be covered with an insulating material ; in fact the whole system would have to be reconstructed.

With regard to the cost of registration and supervision. However small the fees are you will be serious affected ?—Certainly. We have at present 12,000 miles of wire representing about 12,000 wires, and the wires passed through four different districts.

At a registration fee of a shilling it would cost you £2,400 ?—Yes.

Mr. COLLINS : That is supposing they have to be registered in each district ?—Yes.

Mr. PEMBER : And they will have to be.

WITNESS, continuing, said if the County Council of London had the power to send inspectors into private houses, the business of his Company would be greatly hampered.

By Mr. POPE : He did not think the wires of his Company were in any sense dangerous.

Would you represent that no bye-laws are necessary for the protection of the public against the wires of the Company ?—Yes.

Therefore Parliament passed an unnecessary provision in the Public Health Act, 1890 ?—Not at all. Every company may not be as careful as we are.

Then your Company ought to have been exempted from the Act ?—No ; we do not wish to be exempted.

WITNESS, in further cross-examination, said the County Council were trying to take away the common law rights of the Telephone Company. That was one of the reasons he objected to the proposed licence of the County Council. Such a licence was quite unnecessary. This Company were using one of the County Council's subways between the City and Westminster. In his opinion the question of the removal of the wires into subways should be postponed until the subways had been constructed, or, at least, until the County Council had the power to construct them.

Colonel R. JACKSON, Vice-President of the National Telephone Company, stated that he knew the telephone system in London which was carried on under a licence granted by the Postmaster-General. At present they paid the Postmaster-General £37,240 a-year, which represented 10 per cent. of the net receipts.

You therefore pay for this licence a very heavy tax, which of course will increase as your business increases ?—Yes.

* A summary of this Bill appeared in our issue of January 30th, p. 392.

Digitized by Google

The entire system in London is conducted by overhead wires ?—Yes.

Has there been a single fatal accident caused by the Company's wires in the Metropolis ?—Not one.

Would the removal of the overhead wires into subways be expensive ?—You cannot remove our wires into subways, but you can take down the present overhead wires and substitute new wires for them. To do that would cost hundreds of thousands of pounds. Our present system is carried on with a single wire, and, therefore, if we are ordered to put our wires underground we shall have to alter our whole system and double our wires. If we were to put a single wire into a subway with an electric light wire our system would be stopped. In fact, if we are ordered to put our wires into subways, it will cause a revolution in our system, and entail a great expense. As the County Council have not the necessary subways, we must even now go on placing our wires overhead, and we might have to do so for years to come. It would be very hard if, after this great expense, we were called upon to go to the additional expense of placing our lines into subways.

Mr. POPE said under the Bill it would be for the arbitrator to decide whether the wires could be conveniently placed into subways. If the Bill was not clear on that point the County Council would be glad to insert words to remedy the defects.

Mr. PEMBER hoped his learned friend would go further and say that the arbitrator should also decide the question as to whether the Telephone Company or the County Council should bear the expense of removing the wires. The learned counsel then proceeded to sum up the case for the National Telephone Company.

Mr. LITTLER having addressed the Committee on behalf of the Inns of Court,

Mr. POPE summed up the case for the promoters. He argued that the provisions of the Bill were very reasonable, and that none of the contentions which had been urged against them afforded any justification for the Committee altering the measure.

The room was then cleared, and on the public being re-admitted the Chairman said the Committee would postpone their decision till the following day.

WEDNESDAY, MARCH 18TH.

The Committee having deliberated for over an hour and a-half, the public were re-admitted, and

The CHAIRMAN said: The Committee have come to the conclusion that the preamble of the Bill is proved. They are also of opinion that the marginal distance of 50ft. shall stand, that the Inns of Court shall have no exemption under the Bill, that all reference to subways shall be struck out of the Bill; that Clause 8, relating to charges for supervision of wires, shall be omitted, and that sub-section 2 of Clause 13, with regard to compulsory powers of entry by inspectors, shall be omitted.

The Committee then went through the clauses, and struck out those involved in their decision.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *March* 6, 1891.

**Physiological Effects of Alternating Currents.**—Some very interesting experiments have recently been tried on the physiological effects of alternating currents of very high frequency. They were performed in the laboratory of Dr. Edward Tatum, whose contributions to this department of knowledge I have noticed more than once. Prof. Elihu Thomson placed at his disposal one of the most remarkable alternators that has been recently built. The machine had 100 armature coils, and gave a little over 8,000 alternations per second. Dr. Tatum's experiments were performed on dogs, as in his previous work, and the results were very remarkable. It was found that with a frequency of 4,500 per second the animals were more tolerant of current than at lower frequencies. For fatal results a current ten to twelve times greater was required with the high frequencies mentioned than was necessary with 120 alternations, about the usual rate in this country. Even at 300 alternations per second the amount of current required to kill was largely in excess of that at 120. In fact, Dr. Tatum's results indicated that the fatality is somewhere nearly inversely proportional to the frequency. Some experiments were made with a view of determining whether the current distribution with the high frequencies was different from that ordinarily found, but the results were negative. All this goes to show that raising the frequency in alternating systems might have a tendency to render them decidedly more safe than at present, a fact that *a priori* would be decidedly surprising.

**Electrical Development in the United States.**—Recent figures give the total number of electric light central stations in the United States as 1,718, a number considerably in excess of former estimates, and also noticeably greater than the number of public gasworks. The growth, especially through the West, in the past year has been something astonishing, and has taken place very largely in the smaller towns. The number of electric railways is, if possible, more difficult to estimate than the number of lighting centres; probably at present it is not far from 275, and rapidly on the increase. Speaking of electric railroads, it is very noticeable that the Broadway and Third Avenue-street Railway Companies in this city do not seem to be in a hurry about putting in the cable system, although the privilege of so doing was obtained some time since. It is understood that on investigation the cost of moving the complicated substructure of pipes that underlies Broadway was found to be so enormous that the stockholders revolted. Laid, as they are, without any reference to the possibility of rapid transit at any future time, the double cable conduits that would be required would necessitate a complete remodelling of the entire water, gas, steam, sewer and electric service. There would be an admirable chance for electricity on these surface lines were it not for the vicious opposition to overhead wires that has made itself felt so strongly. Mayor Grant has, however, apparently undergone a change of heart since he investigated the trolley system in Boston. It is already proposed to use the overhead system in the so-called annexed district on the upper part of Manhattan Island, and, indeed, the permits for the work have been granted. It would not be very surprising if efforts should be made to have this privilege extended. Street railway men do not seem to have much faith in the storage battery, nor in any of the electric conduit systems, and they are determined to have something better than horses.

## CORRESPONDENCE.

### THE BARKING-ROAD CARS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue, Mr. King takes exception to the figures in my letter relating to the life of E.P.S. secondary batteries on tramcars, published in your number of the 6th inst. He says that the life of the positive plates is about 400 discharges more or less, according to the degree of care in handling, giving at the same time the life of the negative plates as about 750 discharges.

Well, let us see how these imaginary life figures compare with the actual results obtained up to the present time with the service of cars on the Barking-road—that is, how they compare with the real life figures to which he takes exception. The service of electric tramcars commenced (under Board of Trade rules and police regulations) on June 14, 1889, the first complete renewals were ordered of the Electric Construction Corporation, by letter from the writer, dated January 16, 1890, and delivery of same was completed at Barking-road on March 14th following. They were at once put into service in lieu of the original batteries now worn out by 10 months' work. These second batteries continued in use until December last, they, in their turn, then being worn out with 10 month's work. This time, instead of putting in complete renewals, an effort was made to economise by replacing the positive plates only; perhaps, at the suggestion of the authority, who on inspection had found that the first batch of discarded negative plates would certainly have run for another year. The result of these partial renewals has been that last month the negatives which it was attempted to retain have had to be thrown out, and new plates put in; these third batteries are now in use. Moreover, in order to keep the cars on the road during the time the old negatives were retained, a supplementary charge every afternoon from the dynamo was necessary, which meant extra fuel burnt, overtime made, &c., and three battery charges used in lieu of two per car and per day. The life of the batteries is, then, as shown in my letter (see *Electrician*, 6th inst.) ten months, or 300 discharges, as well for the negatives as the positives, and this with good fair handling. With the actual handling and working of accumu-

Digitized by Google

lators, the writer has perhaps had more experience than your correspondent, and has been engaged on accumulator work in Paris before their introduction into England.

No experiments, crucial or otherwise, have been made with the K type plates on accumulator cars in service.

The maintenance of traction batteries up to date is, then, 2¾d. per car mile; the one penny, like the two-thirds of a penny, being purely imaginary and prospective.—Yours, &c.,

T. Frazer.

114, Broadway, Plaistow, E., March 18, 1891.

## TRADE NOTES AND NOTICES.

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891**

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The Handbook Division contains a mass of most useful information. The Directory Division consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. A large number of copies have been already subscribed for from the Colonies, the Continent, the United States, and other Foreign Countries, whilst at Home orders have been received from Local Authorities, Railway, Tramway, Mining, and other large Industrial Corporations, as well as from those for whom the Directory and Handbook is primarily compiled. The Colonial and Foreign Division will be found extensive and reliable. *Orders should be forwarded at once.*

Tenders Wanted.—Tenders are wanted for putting up and maintaining the electric light installation at Falcon Cliff, Douglas, Isle of Man, from May to September, 1891. Particulars may be obtained of Mr. F. Rowe, Secretary, Falcon Cliff Company, Villiers-chambers, Douglas.

Mr. Napier Prentice.—We are informed by Mr. Napier Prentice that he has amalgamated his business with that of the well-known firm of Easton and Anderson (Limited), of Erith and London, and that his factory and staff have been removed to the firm's works at Erith, where, in future, the manufacture of his dynamos, &c., will be carried on under his supervision. It is intended to keep a large stock of standard machines in hand for prompt delivery.

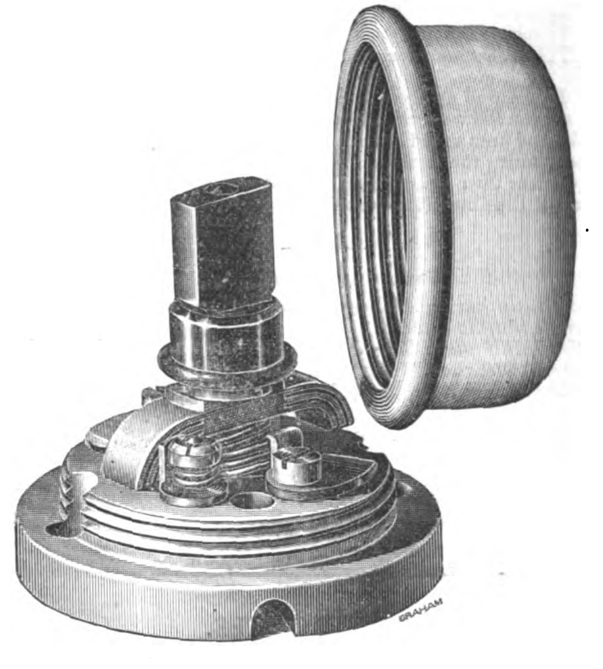
Dissolution of Partnership.—The partnership between Messrs. Fiford and Collier, trading as electricians at Bournemouth and Southampton, has been dissolved.

Messrs. McGaw and Co.—We are in receipt of an elaborately-illustrated price list of Messrs. McGaw's well-known specimens of electric light casings, mouldings, &c. The list includes mouldings, casings, pillars, and all kinds of similar accessories, and the method of printing adopted is very effective.

Messrs. F. and C. Osler.—The makers of metal and glass ware who have been tempted to turn their attention to electric light fittings, have in several cases produced more artistic work than those whose speciality lay in gas fittings, and who were quickly forced to take up electric work. The old-established firm of F. and C. Osler, who have long held a leading position as makers of cut glass, have some very artistic work at their show rooms at 100, Oxford-street. Their glass is almost exclusively brilliant cut flint, and for hall lanterns some very large pieces are employed, hanging below the ornamental metal work and not enclosed by it. The metal work of some table fittings in the French antique style is noteworthy for its excellent finish and design. For electrolier work fine brass chains are used with very graceful effect. Messrs. Osler provide a darkened room specially arranged for showing their fittings with the lamps burning.

Yacht Lighting.—The electric lighting of H.S.H. the Prince of Monaco's yacht, "Princess Alice," has been placed in the hands of Woodhouse and Rawson, United. The engine is of the single cylinder vertical type, running at from 200 to 250 revolutions per minute with a steam pressure of 150 lbs. The dynamo is coupled direct to the engine, and gives, when running at 250 revolutions per minute, current for 100 16 candle-power lamps at 135 volts, this particular E.M.F. being provided to allow of charging the accumulators. There will probably be a set of accumulators, a projector, and a submarine arc lamp for carrying on scientific observations at night.

The New Diamond Switch.—An improved switch known as the "New Diamond," has recently been introduced by Messrs. Poole and White, of 58-9, Bread-street, E.C. Although this new switch is made under the patents granted to Messrs. Poole and White for the well-known "Diamond," it is also the subject of further patents for improvements taken out by this firm. The illustration shows the switch as it is at present made in its circular form. It is made in three sizes for currents up to three, seven, and fifteen amperes respectively. The base is of porcelain, and is fitted with a screwed cover of the same material. The contact bridge has brass separating pieces between the contact pieces, thus giving greater freedom of motion to each individual spring. Instantaneous break action is assured by stout steel wire springs. The suddenness of the break is independent of the motion of the hand. These switches are constructed in a rectangular form to carry currents of from fifteen amperes to 1,000 or more if necessary.



In the larger sizes the bases are of enamelled slate and the thumb taps are replaced by lever handles. The porcelain bases and covers of the circular forms are made either in plain black or white, or decorated in design suitable for any style of mural decoration.

The Demon Water Motor.—This motor appears to be of the well-known Thirlmere type. It is made by Mr. P. Pitman, of Aubrey-road, Whittington, Manchester, in four sizes, from "a quarter man," at 1,800 revolutions per minute, to "two man" at 800 revolutions. The maker supplies castings and forgings for those who desire to make them up.

## PATENT RECORD.

### APPLICATIONS FOR PATENTS.

February 27, 1891.

3,609. E. Hartmann and W. Braun. London. Improvements in electricity meters.

February 28, 1891.

3,628. G. R. Postlethwaite. Aston. Improvements in dynamometers or force measurers.

3,629. C. D. Barker. London. Improvement of insulators.

3,643. F. J. Rowan and W. McWhirter. Glasgow. Improvements in means for holding portable electric lamps.

3,650. L. Pope. London. Improvements in electric clocks.

3,644. G. Binswanger. London. Improvements in electrical switches.

3,673. A. C. Seibold. London. Improvements in electric arc lamps.

3,675. E. Edwards. London. Improvements in apparatus for the transmission of telegraphic messages by means of direct or alternate electrical currents.

3,680. H. H. Lake. London. Improvements in electric lighting apparatus for gas burners (The Aktiebolaget Göranssons Mekaniska Verkstad Company (Limited), Sweden).

## SPECIFICATIONS PUBLISHED.

1890.

475. SACK and ZIESEL. Telegraphic, &c., communication. (Price 8d.)
2,108. WHITMORE and AKESTER. Switches for electromotors. (Price 8d.)
2,504. WYNNE. Propelling vehicles by electricity, &c. (Price 8d.)
3,276. WHALLEY. Telephonic apparatus. (Price 8d.)
4,004. BARNETT. Electric discharge paths. (Price 4d.)
4,992. GAY and HAMMOND. Recording electric measurements. (Price 11d.)
5,836. RADCLIFFE. Dynamo-electric machines, &c. (Price 8d.)
13,044. BARDONNAUT and JUPPONT. Electric lighting. (Price 11d.)
18,589. WADDELL. Electric railway signals. (Price 8d.)

1891.

83. THOMPSON (Striemer). Electric guest calls. (Price 8d.)
616. ALLISON (Ward). Carbon stick for arc lights. (Price 6d.)
624. AMERICAN ELEVATOR COMPANY (Otis Bros. and Co.) Electrical elevator apparatus. (Price 8d.)
647. LAKE (Weston). Electric measuring instruments. (Price 8d.)
649. LAKE (Eickemeyer). Electric elevators. (Price 11d.)

# COMPANIES' MEETINGS & REPORTS.

## The London Electric Supply Corporation.

The fourth ordinary general meeting of the shareholders was held on the 13th of March, at the City Terminus Hotel, Cannon-street, under the presidency of James Staats Forbes, Esq.

The MANAGER and SECRETARY (Mr. Charles B. Waller) having read the advertisement convening the meeting, the report of the Directors was taken as read.

The CHAIRMAN then said: I should like you, if you please, to follow me through the accounts, in order that the figures may reveal themselves up to date. These accounts, as you know, are rendered in accordance with the form prescribed by the Board of Trade. They are very full and comprehensive, and they do, as they are intended to do, carry forward from year to year the state of the capital and the expenditure under a great many sub-divisions. I had occasion at the last meeting (I daresay much that I said on that occasion is forgotten) to dwell at some length on the position of the Company at that moment; and I suppose that the proprietors have had sufficient interest in the business to have read what took place on that occasion. What I have to say to-day is rather in continuation of that text. Now, with reference to the accounts, No. 1 statement shows the capital, and there you see that the whole of the ordinary share capital that has been issued has been paid up —£555,000. The preference capital last year stood at £100,000, and during the year a further portion of it has been paid up. You may remember that we were in some difficulty as to how to deal with the preference shares, because, under the arrangement of the prospectus, the calls were to be made by a particular time. I explained at the meeting, a year ago, that we were not in pressing need of money, and that we thought that the circumstances of the time were such as not to make it very desirable to call up people's money when interest was at a very high rate. They themselves would be the losers of the difference between what we paid and the interest they could get on deposit for their money; but in order that there might be no ground of complaint we offered the preference shareholders the option of paying in advance, and that option has been exercised to the extent of £53,043. We have therefore now £153,043 of preference share capital paid up, and £96,957 of this capital remains to be paid up and will meet obligations incurred, or that may come on in the future. That is the end of our available assets at the present moment. Of course if that fund be exhausted you have 89,000 unissued ordinary shares to fall back on. No. 2 account does not require any observation, because we have not raised any money on loan. We are all shareholders. In the next account you come to the expenditure, and this account is pretty clear as to what has become of the money. At the end of the first column you find that at the close of 1889 we had expended £504,954, and you will see by running down the column, by analysing it, how that money went. You will see that there are 14 different items on which that amount was expended, and during the past year you will see that that outlay has been very largely increased—by no less than £143,501. If you cast your eye on the column showing the total expenditure, you will see that we had a balance to the credit of the capital account at the end of last year of £59,566. We are therefore getting extremely near the end of our tether as regards capital powers. Of course you want to know what this money has been spent upon, but you can find that out by looking at the different headings—buildings, freehold land, general construction at Deptford; plant and machinery; mains; and the purchase of the business. That, of course, is the foundation price, so to speak, of the undertaking, and this item—including the small payment shown during the past year on account of some old legal expenses—stands at £250,397. Then beyond the items I have mentioned you will notice that there are several others—transformers, meters, electrical instruments, &c. This indicates, of course, that during last year there must have been a very considerable advance in the provision of the machinery for lighting, and that is the case, as I shall be able to show you presently. We have spent, in fact, in preparation—in the progress, I hope, towards the completion of what may be called the first stage of our existence—£143,501 during the past year. The revenue account is also very explicit; and on the one side you have the costs, on the other the proceeds. I am sorry to say that the proceeds just about balance the costs. On the first blush of it, that does not appear a very satisfactory state of things. The Board, however, had prevision enough last year, when we met, to point out that we must consider ourselves by no means "out of the wood." We had, for good or evil, launched ourselves on a new path; we had no beaten way to follow. Mr. Ferranti's system, as everyone knows, is different to the accepted system under which some other companies—most other companies—are at present working, and therefore it was in the nature of an experiment—a very costly experiment, if it should fail, a very lucrative one, probably, if it should succeed. This time last year, though we were lighting up, we were not lighting up with our permanent system, but, with temporary machinery, a system which had been originated and had grown from small beginnings at the Grosvenor; and we had before us the necessity of turning out of the Grosvenor during the year, and transferring the whole of our business, at the same time that we were going on constructing. I need hardly say that that is a very difficult thing to do. That turned out to be, perhaps, somewhat in the nature of a curse, because it was owing to that state of things that the fire occurred at the Grosvenor which put a sudden stop to our business. I said "a curse," but, like a good many of these things, it will probably turn out to be a blessing, because though we have lost a good many customers, and though, no doubt, during the time of that *interregnum* we shall have lost a great deal of money in the nature of revenue, it enabled us, by the total cessation of business for a considerable time, to complete the thing much more rapidly than we could have done had the business been running. You see what these expenditures are. It is a dangerous thing to prophesy, because, if it happens to turn out well, then it is well, as a matter of course; but if it should turn out not to be well, then blame is lavished pretty freely. Therefore "old birds" like myself are very cautious what we prophesy. At the same time you ought to know that we consider the costs represented by this account not to be at all normal in their character; and we have not had, up to this time, the advantages which we anticipate—which we are pretty positive we shall have—when the permanent thing goes by itself—that is to say, Deptford. During the greater part of the time we had the Grosvenor Station we had to keep up a large expenditure at Deptford, because this complicated and novel machine had to be learnt—in fact, all this business had to be learnt. We have had to find out as we have gone along, and our misfortunes have resulted from the very natural reason that you cannot find out everything at once. Still, we have found out one or two things. The main object of these particular observations which I am now making is to impress upon you that this large expenditure, which is about equal to the revenue, is not normal expenditure, but is quite abnormal. During a portion of the year we transmitted part of the supply from Deptford to the Grosvenor Station. The Grosvenor supplied a portion of the current, and Deptford the other. That was in order to test the possibility of doing what a good many people thought could not be done—that is to say, that this idea of transmitting electricity from so great a distance must fail; but it has not failed. We had to make a beginning, and we did so; and we found that the anticipations of Mr. Ferranti were entirely confirmed by the result. Then we have had a great number of mains laid on Mr. Ferranti's principle—concentric mains, the great trunk conduits which run from Deptford to London—to be distributed through the minor conduits, or smaller mains, to the consumers. They had to be tested, and testing them is an expensive business. Then, again, we had to clear out of the Grosvenor Station—to take out the engines, dynamos, the whole of the machinery, and to remove a great deal of it to Deptford. All that caused continual expense and continual interruptions to the business; and, in fact, I for one am surprised that the accounts have come out as well as they have, because, in addition to the difficulties and large expenditure incurred in working under the conditions of the moment, came the fire, when everything went out. The converters were all destroyed, and without the converters we cannot light. Well, we took advantage of the opportunity. We were a little staggered for the moment by the fire, but we made up our minds that that was the time to postpone for a sufficient length of time any attempt to light, trusting to the forbearance of our customers and their sympathy; and I must say, in passing, that we have received it without stint. We have now lighted up again. Lighting up, though, on the present modest scale has tested one or two important things. Our district of London, for the last two or three weeks, had been lighted from Deptford exclusively, because there are now no means of producing the light at the Grosvenor, and the mains have acted; and I am given to understand that recently, at all events, there have been no complaints about the light. For a day or two, when we first started, there were, of course, occasional hitches, but latterly it has been going without complaint. When the fire broke out we were lighting, probably, 36,000 lights—something like that—and now we have got back to 10,000; and we shall not be wanting in customers as our capacity to increase the supply grows from week to week and day to day. In the face of these difficulties you see what we took. We managed to get by the sale of the current per meter £16,283, and by the sale of current under contracts £9,701. If you have the accounts before you of last year you will see that they are very nearly identical in the totals, but quite different in division. Last year the great bulk of the lighting was done by contract, and very little of it by meter, and now much the largest part is done by meter and much the less by contract. That means that in the interval we have also found a reliable meter, and we, at all events—and I suppose most of our customers—prefer the supply to be paid for upon a reliable standard than upon the uncertain footing of contracts. I have no doubt that the contracts, particularly those of preceding years, were very bad for us. There was no experience in this business upon which to found lighting by contract. Rental, sales and repairs of apparatus, and transfer fees are the items which

Digitized by Google

follow; and the result of all that is that the income has just about covered the expenditure, and I confess that I am very much surprised that it was so, under all the circumstances. The fire occurred on November 15th, and from that date to the end of December we had no customers—no income and large expenditure. I hope that that explanation, and perhaps some further remarks which I may have to make when I get to Mr. Ferranti's report, will induce you to consider that, after all, the report is not so bad as it might have been—like so many other things in this world. The time is approaching when the capital part of the business is reaching completion. You cannot initiate a business of this kind and enter upon a large building operation like that at Deptford, putting thousands of pounds in lots of machinery, without an enormous amount of difficulty and trouble, and while that class of work is in progress it is both usual and reasonable that the bulk of the charges should fall upon the construction. The moment construction is finished, however, you are upon the footing of an ordinary commercial undertaking. The expenditure must then come upon the revenue, and what we have done this year, seeing that we were approaching so nearly the completion of the first stage in our business (the construction) is this—we have increased considerably the appropriation of revenue to the general charges. That item itself should account for about £1,500 – that is, the increased amount that we have charged revenue with as compared with the previous year. The amount carried to the management expenses in the preceding year was £2,500, while this year the amount, in round figures, is £3,900. I suppose when the thing runs purely and entirely as a going concern that the whole of these charges will come against revenue. We have made rather a larger reserve for bad and doubtful debts and other items. We had a good many accounts outstanding when the fire occurred, and people were very sore about it, but by explanation and persuasion and a little pleading they took a very reasonable view, and it is very gratifying to know that the great bulk of our accounts have been paid up in full. There were cases where we found it expedient to make some slight concessions, cases of peculiar hardship, and we thought it better, as all these points were not settled, to reserve more than in the previous year. Then we thought that as the fire was a calamity, we had better get rid of it by putting it against revenue. The mere loss by the fire was small—£1,183. The real loss we sustained was by the loss of our business; but that, we believe, we shall pick up by the opportunity which the fire gave us to proceed with our business more efficiently than we could have done if we had had to light and to construct at the same moment. The whole thing is in a nutshell when you come to the next account, where you see we carry forward a balance of £813, against last year £920. That is the result of all the patience, the responsibility, the blame, &c., of the past year. If it were at all a state of things which one had to accept as being the state of things under which one would have to live, it would be sufficiently discouraging, but I do not think it is. I think that there is every indication that during the present year things will assume a totally different aspect. The reserve fund account is a mere formal account. Then we come to the balance-sheet. I do not propose to go further into these accounts, except in the nature of answers to questions. I observe that there are some critics present, and I may be asked some questions, and to the best of my ability I will answer them. I am now going to reverse the order of things. Generally, we begin with the Directors' report, but the fact is that the Directors in this concern play a comparatively secondary *rôle*. At the present moment the important factor is the engineer, and we had to bring him to earth last year. We made him report last year to the shareholders. We adopted his report, of course, because we were satisfied as to its general accuracy. We thought this year that he had better report again, and we in the same way adopted his report again, believing in its general accuracy. I dare say every proprietor has taken the trouble to read Mr. Ferranti's report, and it is the whole story. I could tell it to you again in different words, but there it is; and, epitomising it, it comes to this—that during the past year the large expenditure which has been incurred seems to have been justified by the result. These concentric mains, which were an idea a year ago, are now a fact. A good many clever people thought they would not work, but they do work. A good many clever people thought they could not possibly work without great detriment to the Postmaster-General and the Telephone Company; but they do work without detriment to either. This system will be not only the most economic system when it is in full operation, but beyond question the safest system; and here I must say a word or two about the Board of Trade. They have already consented, as far as we are concerned, to suspend one of the stringent conditions of the original Order under which the different electric lighting companies were created. These companies were, under no circumstances whatever, to earth the current. The theory was that if we earthed the current the Postmaster-General, the Telephone Company, and the railway companies could not carry on their business; and there did appear, for a time, to be some fear that was so. However, the moment these concentric mains under the earth were made the channel of conveying the current, that difficulty vanished. Then we thought earthing can be done, and if earthing can be done it will make this the safest system; and after a great deal of difficulty, and only by bringing in the aid of some of the greatest scientific authorities—Mr. Ferranti, Sir William Thomson, and Dr. Fleming—we at length persuaded the Board of Trade to grant us this immense concession. We satisfied ourselves that earthing would not interfere with the Postmaster-General, and, with the entire concurrence of the Post-Office, that authority has been given, and we are now at earth. Being allowed to earth, all danger of fire is absolutely averted. I say "absolutely," but of course all things are relative. Still, those dangers which the timid apprehended have been enormously modified, at all events, if one may not say absolutely averted. I suppose under this system the electric lighting of houses will be infinitely safer than lighting by gas, and vastly safer than by either oil or candles. There is another remarkable thing which has to be mentioned. This 10,000 volts, which is to be the normal pressure of our work, was thought to be one of the impossibilities. There were two opinions about it. Some people thought it would not do at all, and others thought it could only be done at such enormous waste in transmission as to nullify altogether the economy in production. We have tested this, and that prognostication has been contradicted. The loss of current from the dynamo into the transformer at the transforming station is practically *nil*. Between the transformer, in our case, as in the case of all the other companies, there is an essential quantity of current wasted in getting into the houses of the customers; but as between Deptford and the transformer, which in our case answers to the dynamo of the low-tension people, there is no loss. It is at any rate quite insignificant. The idea of 10,000 volts made people's hair stand on end. Mr. Edison's hair stood on end when I told him about it, and he is not a man who is very lightly to be alarmed. He expressed some doubt first as to whether it could be done, and secondly, whether, if it were done, the waste would not be very great. Well, we have taught Mr. Edison that, anyhow. He has taught us a great deal, and it is a satisfaction to be able to help him. Now he will be able to turn Niagara to account, for if they are going to do that, they must have high tension. Low tension cannot do that business. In order to give you some idea of the capacity and the efficiency of these mains I may mention that they have really been tested up to 17,000 volts. I have now exhausted pretty nearly the first paragraph in Mr. Ferranti's report, which says, in other language, what I have just been telling you. There is, however, one little point in this paragraph which is pregnant with meaning, and which we all ought to study when, in the momentary annoyance caused by the light going out, we proceed to ejaculate about the evil deeds of the Company. Mr. Ferranti says: "The work of laying was of necessity performed by unskilled labourers, who had neither experience nor training in such work." Well, that is the whole story. It is not only the labourers who are unskilled in this matter; we are all unskilled. The skill has to be created, and people who take the trouble to consider this for a moment may find some sympathy in their minds or in their hearts for those who have to make everything, as we have to do, and find out things by stages. Paragraph 2 speaks of the Board of Trade allowing the earthing arrangement, which I have explained. In the next paragraph you are told that during the past year the whole of the machinery from the Grosvenor station has been removed to Deptford; and at the present moment it is the means by which we are lighting up. We have got a pair of dynamos working away up to a capacity of 30,000 lights. The dynamos of greater capacity are being finished. They are being readjusted, and when they are ready they will send up current to the extent of 60,000 volts. We have now before us, nearly completed, and paid for, a capacity of 90,000 lights. We should not think of using the full capacity, however, and, in fact, if the Board of Trade had not made any regulations on this subject we should have made them for ourselves. We should never work up to the full capacity, but should always have a reasonable reserve. No railway company I ever knew of ever turns out all its locomotives, and we shall not turn out all ours. All that is explained in the third paragraph of Mr. Ferranti's report. This brings me to the little bit of information interlined between the 3rd and 5th paragraphs: "With these two large machines supplying your circuits, the first important stage of your undertaking will be completed." That is to say, that up to 90,000 lights we have practically done all the work. There are some details yet to be completed, and Mr. Ferranti is always finding out something. He has found out that he can produce electricity on a great scale at Deptford with perfect ease and safety, and that he can transmit it to the transforming station in London with perfect ease and great economy, but I do not think he has found out quite enough about the little bit that is between the transforming station and the customer's house. I am quite sure that the mind, and the genius, I would almost say, which has overcome the difficulties which he has surmounted in the last two years can overcome the lesser difficulties in that matter. They are not very great. It is a question of adaptation of the transformer. There have been one or two fires in London, not exclusively connected with the lighting up of this Company, but we are all critics in a new business, and the experience of one new company is very much the experience of the others, and this experience has been used in reference to the installations, &c., of the consumers. It may as well go out from me to the world that the consumers themselves will be chiefly to blame if fire forms an element of serious consideration in electric lighting, because, with an installation conducted with care, and in accordance with plans which are now thoroughly well understood, and adopted by the insurance companies, fire is next to an impossibility; but of course, if the work is done in a scampy, slovenly, un-scientific manner, there will be fires. One hears of gas pipes being put in in a manner not altogether workmanlike. Then the gas escapes, and there is a blow up. One also knows that plumbers are not always trustworthy, and then something goes wrong with the water pipes. Every installer should take care that the work is put into proper hands, and properly supervised. However, that is the affair of the installer and not of the company. Now we come to the second stage. You see that our money is running out, and it is with companies just as it is with men. If you start young with a full purse you are never easy until you get to the bottom of it. You only begin to be prudent when the last gold pieces come out. That is our condition. We are now going to be mighty prudent, that is to say, before entering on the next stage of our operations, the stage which will complete and develop 200,000 more lights, we shall want some more money. I do not think we shall get it myself, or I do not think I shall have any hand in trying to get it, until we have established the first stage as a profitable commercial undertaking; because if you were to attempt to raise more money until that is tested, you could only raise it on disastrous terms. I think that when we have well secured 60,000 lights, which means something more, perhaps, than £60,000, we shall have no difficulty in going into the more heroic thing, and I hope that it will not be long before that experience is attained. I am much too old to be caught prophesying, but there are others who are

Digitized by Google

willing to do so. There is our secretary—he is very sanguine—he would say that he has no doubt we shall have 60,000 lights by next year. Well, if so, I think we may induct from what we know that our credit and our position will be so much improved that we shall have no difficulty in getting the money for our further progress. I want the shareholders to take what I am now about to say on the strength of Mr. Ferranti. I do not know any man who, during the last year, has had a more terrible responsibility upon his back than Mr. Ferranti. He pledged his reputation, his fortune, his labour —day and night—to achieve the result he promised to the Directors. He has achieved it greatly, and has done so much in redeeming what a year ago seemed a most difficult position and a most uncertain one, that he is justified in his present opinion, which is expressed in this paragraph :—" I desire to call attention to the fact that from the commencement of your operations to the present time, no engineering or electrical difficulties whatever have arisen which I have not been able to overcome, and at the present moment I know of no weak point in your system, and consider success to be now assured." Well, that is his frank opinion. He is a man with convictions of his own, and he has a very strong will, but he would not have said this if he were not absolutely convinced of its truth, nor should we have allowed it to appear in his report unless we had felt that we could believe it ourselves. In his next paragraph Mr. Ferranti deals with the fire, and states that that enabled us to do what I have already described to you. You know the bogey of fear about overhead wires, and, by the way, a Parliamentary Committee is sitting on that matter at the present moment. There is nothing in it, but everything is going to be closed by overhead wires. Therefore, when the companies in London got their constitutions, or Orders, they were put under the obligation to remove the wires within two years. Our time is up in August. The whole of our electricity was conducted, until very recently, from the Grosvenor Station over those wires. This fire that we had cut off all connection between those wires and the Grosvenor Station ; and as we had to get out by August, we have availed ourselves of the interregnum to put down our mains as rapidly as possible to supply the customers, and that process is going on from day to day. It is a long process, but we shall get it all done before August. The difficulty in connection with the switching has been greatly modified, and Mr. Ferranti has in that matter as in others made great improvements. We have secured sites for three additional distributing stations. I daresay anyone who lives in the neighbourhood of a steam engine will know the difference between a distributing station and a generating station. I am told that the latter are absolutely silent. Well, I am rather a night bird. Having a good deal of work to do in the day, I occasionally take a walk at night, and in the course of my perambulations I have found myself in the neighbourhood of some generating stations which have certainly not been altogether silent. In fact, if you take a walk up by that fine building known as Whitehall Court, where there is one of these stations, you will find considerable vibration; and I think anyone who lives in those chambers must have found that out. There are other evils attending these stations, and the speculative lawyer makes use of them. I was connected with a company before you were in existence, and we have now descended into the modest business of lamp making ; but we were an electric light company—the Edison and Swan—and we had several installations about London. We got out of them, however, as rapidly as possible, but with great loss, because the speculative lawyer got up damages for vibration, and so on, and we had to compound them. I hope that our rivals—no, I will not say our rivals, there is so much of this business that there is no room for rivalry—I hope that those who are working these stations will not find that they have to suffer from these disadvantages. We found them at the Grosvenor Station. Someone's shirt-fronts got dusty, and so did Savory and Moore's medicines, and we were required to make compensation. However, nothing of that kind can take place at a transforming station. The movement there is very silent. The electricity has to move in at one wire and get into another. That is done silently, and no one knows anything about it. We have got three of those stations, and some of them will be in operation almost immediately. One of them is called the Trafalgar, from its neighbourhood to the great monument, or, rather, the monument of the great hero, for I cannot think the monument itself great. There will be two separate sources of supply then. The current sent from Deptford to the Grosvenor, and sent at the same time from Deptford to the Trafalgar Station, will be at the service of both areas. If anything goes wrong at one, the other will have an ample source of supply. I think I have now said very nearly all that I need say, but I should like to finish up by this quotation from Mr. Ferranti. It is the last paragraph in his report, and he says :—" The great advantage of the high-pressure system is apparent in that the loss involved in transmission of current from Deptford to the distributing stations is inappreciable, while the facilities for procuring coal and water there, sufficiency of room for machinery and appliances, and freedom from the legal and financial consequences attending the erection of generating stations in crowded neighbourhoods, cannot fail to tell their own tale in the working expenses of the current year." That just shows what a young man he must be. He has said there something very encouraging to you ; but he has put himself at the same time under a serious obligation, which is to get down the expenses in current year. I should not have done that in my report, but I am glad he has done it, because he is now bound. I hope you have read Mr. Ferranti's report carefully. It deserves to be thoroughly read and studied. I have nothing further to say, because the peculiarity of our two last reports is that they have been mere echoes of Mr. Ferranti's. Having had him, as it were, to speak at first hand, you would probably not care to have it diluted by anything we could say. It really means all that I have told you. I think we have, well, " weathered the storm " is the familiar expression—that we have overcome great difficulties and see daylight. That is the opinion of all my colleagues, and certainly all the engineers. We have not only Mr. Ferranti, in whom we have deservedly great confidence, but we have also Dr. Fleming, an electrician of the greatest eminence. He has watched this thing very narrowly, and we believe now that we have really entered on the stage which will lead to prosperity. At all events we hope so. As to our customers, I will take this opportunity of expressing to them the deep thanks of the Board for the enormous amount of forbearance and consideration which they have shown us under circumstances which, of course, entailed upon them considerable annoyance and, probably, loss; but, on approaching and explaining the reasons, they have almost uniformly and unanimously met us by the greatest forbearance and consideration, and have paid their bills. With regard to the Board of Trade I must also say a few words. There seems now to be a desire to put us under a system—a grandmotherly system—which did not make England the place it is, and which has emasculated a great many places. We are going to be nursed by the State. There is a great disposition for the State to do everything, but how they are going to do it I don't know. With reference to the Board of Trade, a more efficient, honourable, disinterested, and courteous body does not exist in any country ; and if my experience had not satisfied me as to the abomination of State interference in commercial matters—of which I have seen a great deal abroad—I should be a little shaken by the manner in which we have been met by the Board of Trade ; because, so far from showing the least disposition to exact the letter of the law about the regulations, or to exercise any arbitrary authority, or to act like those busy-bodies who, " in another place," make themselves so cheaply popular in the interests of the working man or of someone else, they have always shown the greatest consideration and forbearance to us, and have assisted us in every possible way to overcome our difficulties. They are advised by an electrician—Major Cardew—to whom, I feel sure, the Board feel greatly indebted for the almost brotherly interest which he has taken in Mr. Ferranti. So far from there being any narrowness, or smallness, or desire to shirk responsibility, I am bound to say that the Board of Trade, from the highest official to the lowest, have done everything they could to afford the Company a chance of establishing its principle of electricity. I am sure that the shareholders will feel with us that the Board of Trade on that account deserve our best thanks. I feel that I should not have done my duty had I not said this. I now propose :

" *That the report and accounts be adopted.*"

LORD WANTAGE : I beg to second that.

Mr. ADAMS said that the Chairman had stated that 60,000 lights meant £60,000. He had himself endeavoured to find out from the Metropolitan Company what 60,000 lights meant, and the answer was nearly £30,000.

The CHAIRMAN : Our contracts were at £1 a light, and we thought it bad business. The difficulty in regard to this point, however, is that none of us have a common factor. We reduce ours to a common denominator of an eight candle-power lamp, whereas a great many of the lamps are of 16 candle-power. The experience in our own case is that £1 per light is not only not excessive, but is not enough. If we had 60,000 lights we should consider that £60,000 was the minimum amount that we ought to receive. We would not take a contract at £1 per light—that is, per annum.

The resolution was then carried unanimously.

On the motion of the CHAIRMAN, seconded by Lord WANTAGE, the retiring Directors—Mr. Francis Ince, Mr. Joseph Pyke, and Mr. Arthur F. Wade—were severally re-elected ; and Messrs. Kemp, Ford, and Co., the retiring auditors, were also re elected.

Mr. CROUCH then proposed a vote of thanks to the Chairman and Directors, and referred to the trying times through which they had passed last year.

Mr. ADAMS seconded the motion, which was carried unanimously.

The CHAIRMAN : I am sure, on behalf of myself and colleagues, that I thank you heartily for this vote expressing your confidence in us. The directors of a company in the position of this Company fulfil a duty which only strong convictions and strong personal interest and reputation make tolerable. I am not going to enlarge upon our anxieties during the last two years. They have been very great, but they have been cheerfully borne, because we felt, in the first place, that we had the confidence of the shareholders ; and, secondly, because if we had not had their confidence we should have felt it our duty to persevere to realise the principle on which this Company was started, and doing what we could in our small way to ensure its success. It is encouraging, particularly at moments which are not in themselves cheerful ones, to find the proprietors believing in those in whom they have been good enough to leave their interests.

Replying to an observation from a shareholder, the CHAIRMAN added : Mr. Edison, who has a face which immediately reveals what his tongue would say, told me himself that he had never seen anything like our Deptford Station, either in boldness of design or beauty of work. But then he was born in Canada, not America. If he had been born in America I am sure that he would not have said that (laughter).

The proceedings then terminated.

## The Direct Spanish Telegraph Company (Limited).

The thirty-fifth ordinary general meeting of this Company was held at Winchester House, Old Broad-street, on the 17th inst., under the presidency of Sir James Anderson.

The Manager (Mr. C. Gerhardi) having read the notice convening the meeting,

The CHAIRMAN said : Gentlemen, before moving the adoption of the report, I shall as usual make a few remarks upon such points as may interest you. You will see from the report that we have earned £1,612 more money in the half-year, and to do this we have carried 138,000 more words, at an increase of working expense of £221. You will be pleased to learn that the average length of our telegrams remains steadily at $10\frac{1}{4}$ to $10\frac{3}{4}$ words, and has so continued for two years. I hope this is evidence that the science of coding which has long baffled us has reached a point below which they

Digitized by Google

cannot usefully go, at least for some years to come. We have established the duplex upon our London-Bilbao circuit, and the average time occupied in transmission of telegrams to Bilbao is only three minutes, and to Madrid 30 minutes. Upon this we have been congratulated by the Director-General of Telegraphs in Madrid, and I venture to think it leaves little more to be desired, at least for the present. I will ask the Manager to read the letter we have received.

The MANAGER accordingly read the following translation of the letter, which was dated Madrid, March 5, 1891, and addressed by the Director-General of the Post Office and Telegraph Department of Spain to the Company's representative at Madrid, Senor Don Jose Aparicio :—"Dear Sir, I have with the greatest satisfaction taken good note of all you communicate to me in your official letter, No. 19, of the 14th February, concerning the duplex communication established since 15th January last between Bilbao and London, with automatic translation at Falmouth. I have much pleasure in addressing, through your intermedium, to the Direct Spanish Telegraph Company my hearty and warm congratulations for the solicitude shown by the Company, and the sacrifices they make in trying to render the line from Bilbao to London for rapidity and correct transmission equal to the best international communications of Europe. On my side, in communicating this improvement to the Inspector-General of the service, and to the Director-Chief of the Central Office of Madrid, I have again recommended strongly that the direct communication of Madrid with the station of the Direct Spanish Company at Bilbao shall be constantly kept up at any risk, and that for that purpose all efforts be made to maintain in good condition the wire by which this communication is effected. I reiterate my compliments to your Company and to yourself, with the assurance of my high consideration."

The CHAIRMAN, continuing, said that this was very satisfactory. I think that to be able to telegraph to Madrid in half an hour, and to Bilbao in three minutes, is about as much as we can expect to do at present. One does not know what the next generation will do, but we are going as fast ahead in regard to speed as modern science has taught. The report shows that our reserve fund now amounts to £23,051, nearly the whole of which is invested and bearing interest, which also goes to increase that reserve. Then we have expended upon duplexing our London-Bilbao circuit £886, and we have wiped off £431, the balance of the cost of fitting up our new London station in Gracechurch-street, and £43 for the removal of our Bilbao station, viz., £1,300, all out of revenue, and we carry to the contingencies account £566, after paying upon the ordinary shares 7 per cent. I confess this is a better result than I anticipated when I last addressed you, but we have yet to see the result of the half-penny per word reduction in our tariff, which commences upon the 1st July, and we shall have to count upon some decrease of traffic since the end of December, 1890, owing to the effect of frost upon the crops in Spain, the effect of strikes in our own country affecting the shipments of iron ore at Bilbao, and the recent unprecedented snow storms, interrupting all traffic beyond Exeter practically for a whole week. We are much indebted to the Post Office staff for their exertions to remove these serious obstructions. They did all they could to assist us and to put us through, but the storm was so blinding that it was a very arduous task, and we must be very thankful to them. I have been reading a letter this morning from the Eastern Telegraph Company's station at Lands End describing the storm, and the endeavours of the staff to get the traffic through from Porthcornow to Penzance, a distance of only seven miles. Two of the Eastern Company's men were nearly lost, but there were more volunteers immediately, and, in fact, everyone volunteered. I see that the superintendent fell off a hedge (I do not suppose that he knew that it was a hedge), and it was with difficulty that he was extricated from the snow. Altogether they have had a terrible time there, such as has never been experienced before, that I am aware of, in the South of England. Our people, as well as those of the Eastern Company, have zealously done their duty, and personally I feel indebted to them, for I am anxious that we should keep our traffic up. We went so far during that storm as to engage a tug boat at Plymouth to take the messages on to Falmouth, where our cables start from. That cost us only £20, and it enabled us to keep up so much traffic. In telegraphing we had to get round to the Land's End by New York and by Marseilles, Gibraltar, and Lisbon. We have managed to keep up the traffic all this time, losing very little indeed. Now that we have restored communications again, I doubt not that we shall get back all our traffic. At the same time I wish it to be known how much we endeavoured to do in order to keep up the communication. Happily, also, telegraphy is getting to be so arranged that there are many ways of reaching a given point, and it is almost impossible really to cut off communications from any place nowadays. There are so many lines to the continent, America, round by Marseilles, Trieste, and by India, that we can always get communication by a little trouble. I do not take any pessimistic view of our future revenue. We may not always be able to give you 7 per cent. We have therefore called 1 per cent. a bonus, which means that we do not yet consider this 1 per cent. part of an assured dividend which we can properly divide and promise to divide continually. We shall all hope, however, that it may really be continued. Then I express the hope that even if the traffic increases we shall not divide any more of our revenue than is represented by a dividend of seven per cent. I am extremely anxious that we should lay by every shilling we can after giving you this seven per cent. We have a large mortgage debt bearing six per cent., and we are only a single cable Company. It is true that we have a joint purse with the Eastern Telegraph Company, and that arrangement goes a long way to save us, but I do not consider any telegraph company a success until their system is duplicated. I hold that any enterprise of this kind—whether a telegraph or a railway—to be successful, should have a large margin of carrying capacity, and a large margin of security. Without that margin of security I do not think you can properly say that you are in a good position, and I look forward to the time when the increase of traffic and the increase of our revenue will justify us in duplicating our whole system. For that reason I should like to accumulate all the money we can. I think a dividend of seven per cent. is enough to pay until you have your property secured in the manner I have described. We look forward at this Board to be able to renew half our debentures in 1894 at four per cent. Now, gentlemen, I have heard from some friendly critics that the preference shareholders are feeling sore when they see the ordinary shareholders getting seven per cent. I propose to do what I can to explain what would have been the position of the proprietors had we not reduced our capital when this Board was reconstituted. You were not receiving any dividend, and it became evident that your principal cable was derelict, and beyond repair. The dividends upon the preference shares were three years in arrear, these shares were hardly saleable at £7. We had totally lost our main cable, and we had raised £62,000 in debentures to keep our Company's concession and property from being utterly lost. We had to go to court to get the question decided whether we could reduce our preference capital as well as our ordinary capital. I may remind you that we had our own doubts about this, and we had a desire to give the preference shareholders a larger proportion of shares than they have obtained, but the Court on appeal said decidedly no. But supposing we had not reduced our capital, we could not by law have paid any dividend whatever until our lost assets were restored. Even had our revenue shown the elasticity which it has recently done we could not have paid upon the preference shares any dividend for about 10 years. By the reduction of capital we were in a position to pay upon the preference shares the whole of the three years arrears at once, and a continuous dividend of 10 per cent. upon the reduced capital ever since. The shares are now at £10 in the market, before we reduced the capital they were hardly saleable at £7. I do think we acted altogether in your interest when we decided to know the worst, examine our cable, and decide upon facing the position. All your revenue would not have maintained the original cable. Now we have a reserve of £23,000 and a contingency fund of £3,000. We have a growing revenue and are justified in looking forward to the reduction of our debenture debt at a comparatively early period, and at a price which our improved credit will entitle us to ask either in the open market or from our shareholders. I do not think we can very well, looking back upon the whole thing, have possibly done anything better in any way. We have saved the concern from bankruptcy, and we have got a growing revenue, and a very fair result. I think that by calling up the £1 of the uncalled capital in 1894, and in one way and another we shall manage to get our debenture debt paid off, or such part of it as not to leave us in any position of anxiety. By-and-by, if the traffic grows, we may look forward to duplicating the cables. However, "sufficient for the day is the evil thereof." I have told you enough now in regard to our present position, and to me, at all events, it is satisfactory. If you have any questions to ask I shall do the best I can to answer them. Meantime, I will move—

*"That the report and accounts now presented be, and are hereby received and adopted."*

Mr. EDMUND ETLINGER: I beg to second the motion.

Mr. JACKSON said that the Chairman had dwelt upon the necessity of increasing the reserve fund, which was a matter of the greatest importance, especially in the case of a company having single cables; but no idea had been given to the shareholders of the amount which might be thought necessary. Of course it would affect the interests of the shareholders very largely while the fund was being accumulated, and he would like to know something as to the amount which would be regarded as sufficient to satisfy the Board.

The CHAIRMAN: I think you have got to consider, in regard to this question, that our tariffs are coming down on every occasion whenever any of these telegraph conventions are held, and I am very anxious in all the companies to which I belong to see our capital kept down and our carrying capacity increased, and I should like to have a large reserve so that we might be in a position to extend our carrying capacity to the best advantage, and to be able to go into the market and buy the cable for cash. I should be very sorry indeed to fix even in my own mind what reserve might be enough. I am not at all satisfied that we have got sufficient yet, or anything like sufficient. I think if you get 7 per cent. for your money you will not do badly.

A SHAREHOLDER inquired what the cost of a single cable would be.

The CHAIRMAN: I do not think you could buy that cable under £180 a knot. It would take about £100,000 to lay a cable to Bilbao, and about half as much from Marseilles to Barcelona. There is no doubt about this—that if your reserve is in 1894 as large as I hope it will be, you will get your Debenture in very easily at 4 per cent., for our credit will then be good. I think as long as we pay 7 per cent. we had better pause and realise our glory.

Mr. COCHRAN said he had not been aware that there were any critics of the Board now as regarded the policy which had been followed in reducing the preference capital at the time of the reconstruction of the Company. He had fought that matter with all his might, but the day had gone by now for questioning it, and he did not see any use in referring to it. He had, however, intended to speak about the very rapid increase of the reserve fund. He remembered that when the reconstruction scheme was proposed, and the attendant reduction of the capital, the Chairman said that he would not be connected with the Company unless the Board were permitted to put by £5,000 a year to reserve fund; but in the last eighteen months they had been putting by money at the rate of £7,000 a year. He was always in favour of a strong financial position for any company with which he was connected, and he was quite in favour of putting by £5,000 a year, but he did not know that his interest in posterity was so very strong that he must go on perpetually making sacrifices. He considered that if the Company went on constantly putting by £5,000 a year, it was not making a bad provision for the con-

Digitized by Google

tingencies that might overtake it. In their old and somewhat unsatisfactory position they were able to get the cable constructed on Debenture issue, although, no doubt, at an extravagant interest, and therefore he could not see any difficulty in providing for that eventuality, especially as they were building up a reserve fund, and that they would be able to deal with the Debentures when they fell in in 1894.

The CHAIRMAN: Half of them.

Mr. COCHRAN, continuing, repeated that he saw no reason why, in their present position, they should be making such a large sacrifice. He could not forget that on the faith that he was really getting a preferential security, he bought his preference shares, that half of that capital had been wiped off, and that he had thus only been receiving on half his capital the full dividend which had been promised him. Still, he thought that if the Chairman would give some indication of the amount of the reserve fund, with which the Board would be satisfied, the shareholders would probably be inclined to wait patiently for the development of the Directors' policy. It was to be remembered that, besides carrying forward £566, about £1,300 had been charged to revenue in the past half-year on account of exceptional expenditure; and, therefore, he did not think they ought to encourage the Board to consider that 7 per cent. even on the ordinary shares was the ultimate distribution which the holders of those shares should receive. He thought that if an available margin remained the Directors should give the shareholders a shade more.

The CHAIRMAN: As to this "shade more" (laughter) you know when we gave you 6 per cent. that was a shade more, and now we pay 7 per cent. I do not say that Mr. Cochran is wrong. It is the expression of a natural wish that you should get more, but I fall back upon this: It is not posterity that I am thinking about, but of making this a first-class property, and one that will make dividends, even if the tariff does go down, and it will go down. I want the margin of carrying capacity and that security for carrying capacity, which only money can give. I do beg the shareholders to be satisfied with it. You know when we went to the Court about this we showed only 2 per cent. on our ordinary shares. Now the traffic has improved, and the progress that has occurred since, has strengthened and improved our property. It is of no importance to me personally, but you will get along much more smoothly if you will agree to what is suggested. No company or telegraph company is in a right position unless it can have a large margin of carrying capacity and a large margin of security, and for that purpose you must have money. I do not think that at the price at which our ordinary shares are held anyone is to be pitied at getting 7 per cent.

The resolution was then put to the meeting and carried unanimously.

The CHAIRMAN then proposed,—

*"That the dividend at the rate of 10 per cent. per annum (less income-tax) on the preference shares, and a dividend at the rate of 6 per cent. per annum, together with a bonus of 1 per cent. (both free of income-tax) on the ordinary shares, all for the half-year ended December 31, 1890, be, and are hereby, declared."*

Mr. ETLINGER seconded the resolution, which was carried unanimously.

On the motion of Mr. ETLINGER, seconded by Mr. JOHN DENISON PENDER, Sir James Anderson was re-elected to his seat; as was also Mr. Etlinger, on the motion of the CHAIRMAN, seconded by Mr. PENDER.

Mr. COCHRAN then proposed and Mr. KENNETH ANDERSON seconded, the re-election of Mr. Herbert R. Duke as auditor, and the motion was agreed to.

Mr. COCHRAN next proposed a vote of thanks to the Chairman and Directors. They did not always see things in the same light, but the shareholders had no hesitation in believing that the intention of the Board was for the general good of the Company.

Mr. JACKSON seconded the motion, which was carried unanimously.

The CHAIRMAN: We are very much obliged to you. We can only have one object, of course, which is to make this property valuable. I like all the companies I am in to be very strong and firm, and to possess a good large reserve.

The meeting then separated.

## The South of England Telephone Company (Limited).

An extraordinary general meeting of the South of England Telephone Company (Limited) was held at Winchester House, Old Broad-street, London, on the 16th inst., under the presidency of Mr. D. Owen Bateson.

The SECRETARY (Mr. Fred. L. Robinson) having read the notice calling the meeting,

The CHAIRMAN said: Gentlemen, as Chairman of the South of England Telephone Company, it is my duty to preside on this very important occasion. You have all been informed by circular that the Board propose to sell the Company and all its assets to the National Telephone Company, and the terms of such sale. Personally, however, I have had little to do in this matter. When the National Company approached the South of England Company with reference to this business, it was decided to appoint a sub-committee, in whose hands the negotiations were placed, and after numerous conferences they resolved to recommend to the shareholders the acceptance of the terms embodied in the circular. I dare say you will wish to hear from the negotiators why you are asked to consent to this sale and upon these terms. I therefore now call upon Mr. Billett, my co-Director, who will doubtless satisfy you, as he has satisfied himself, that the proposal is a fair one and ought to be accepted by the shareholders. Mr. Billett, will you kindly explain the reasons for this sale?

Mr. BILLETT: Mr. Chairman and Gentlemen, I do not think, as we have stated in the circular which we have issued, that there could be much surprise, at any rate in the minds of most of the shareholders, that this matter has been entered upon. Amalgamation has been spoken of at most of our meetings, and it has been generally received, I think, among the shareholders as a thing that was very desirable indeed both on the part of this Company and the National. When the matter was brought more prominently before our Board, as our Chairman has just stated, two of the Directors were appointed to meet two from the National Company, and we formed a committee, and had the subject under our consideration; but previously we had consulted with several of the largest shareholders whether they considered that amalgamation was desirable or not. In every case we found that the opinion was that amalgamation was desirable, and we therefore entered upon the negotiations which have resulted in the terms now put before you. Of course our own idea of the terms was very different from what has been finally settled upon. We had to propose our terms, which were not received favourably by the National Company, and the National Company proposed terms to us which were equally not received by us, and which we did not feel justified in putting before the shareholders. We then had to discuss some modified proposal, which is now before you. There are several reasons why we have placed this proposal and these terms before you. We are perfectly well aware that there is no ground for exceeding enthusiasm about the terms, but we think, on the other hand, that the terms offered do represent an advantage to the shareholders of this Company. In the first place, with respect to the preference shareholders, I know there is a strong feeling that they are making a tremendous dip from 6 per cent. to 4½ per cent.; but they must take into consideration the very much better security which they will have in consequence of accepting 4½ per cent. In the first instance, you have got shares which, for some time past, with £3. 10s. paid upon them, have been bought in the market at £2. 10s. to £3 per share; and even after this amalgamation had been talked of and some of the terms had been known, we have passed transfers at the Board at from £3 to £3. 10s. for these shares. When you consider that the Four and a-Half per Cent. Debenture Stock now issued by the National Company is quoted at from 2 to 3 premium, or thereabouts, I think you will see, at any rate, that you secure a stock by means of which you are able at once, if you please, to get your money back again. You may say. "We do not want our money back again, we want our 6 per cent." It is true that if you can get 6 per cent. with the same security that you had with 4½ per cent. it would be so much more advantage to retain the higher interest; but if you are to accept better security you must face the fact that you must put up with a less dividend. There is no doubt about it that in the position of a company like this, with a comparatively small margin behind the dividend of 6 per cent., the connection with a company which is earning a 9 per cent. dividend behind its debenture stock affords a security which is certainly very much greater than you can possibly have in the South of England Company. You get your capital immediately back therefore, and we consider that this was certainly a favourable arrangement for the preference shareholders. There are some who want to get back their capital. They are placed in this extremely awkward position under the present circumstances, that they must go into the market and put up with a very large sacrifice, whereas now, if they want to secure their capital, they can secure it, and not only that, but with a small premium. Then, with respect to the ordinary shareholders, our own hope and thought was that we should have got one National Company share for 20 of our own, but the National Company, considering the dividend and the revenue which we show, and all the possibilities and risks that there are, and they are many, could not agree to this. You may say that there are risks in all companies, but there may be exceptional risks in our case which perhaps some of the shareholders do not see or know of. In the first place, we have got very near to the end of our capital. We may, however, borrow more, but then comes this fact—that when we borrow money and our revenues do not increase correspondingly, your shares must suffer. Then, again, there is one thing which ought to be done, and which must be done, if this Company goes on—that is, we must have a large reserve, or else a considerable amount of that which is paid away in dividends or that which is put to capital must come out of the revenue, and so decrease the dividend on the ordinary shares. In a telephone company there is a great deal of expended capital which cannot be recovered, and therefore a large reserve must be provided to make up for that capital which cannot be recovered. You run your lines especially in a district which is widespread, and with no large centres, and the cost of these lines ought somehow to be reserved. Then, again, the capital expenditure in a telephone company can never cease. You can never say there is so much capital, and now you must stop. If a telephone company is to go on you must go on and increase your capital, unless you have a reserve so large that you can draw upon it. We have comparatively a small concern, and we have got a district which, at any rate in our negotiations with the National Company, it has been said cannot be improved—that they do not see where they are to get any improvement. They said to us: "You have done the work so cheaply and so well that there is nothing for us by which we can get any improvement." However, notwithstanding that we have got a comparatively poor district, it has so far yielded us a fair revenue, but we cannot expect, without a large expenditure of capital, the dividends to go on increasing. Last year we were able to pay a dividend of ½ per cent., and the year before we paid 1 per cent. It is possible that we may pay a dividend of 1 per cent. again; but if we are to make the large reserve which we ought to make, it is a great question whether we can increase beyond that 1 per cent. Instead of continuing in this position, you get by this proposed arrangement with the National Company one share in that Company for 25 of your ordinary shares. You will say—it has been said—that the National Company's shares are at a discount Well, they earned 9 per cent. last year, and there is every prospect of their earning 9 per cent. this year. Although the terms were not so good as we had anticipated and hoped to get, at the same time they are terms which put us into a company much stronger, which gives us a marketable share, and which also affords the prospect of

Digitized by Google

a largely increased dividend. The National shares have already received a dividend of 6 per cent., and I believe that though they paid only a 5 per cent. interim dividend, there is no doubt that the dividend will be made up to 6 per cent. for the year. You would, therefore, get 6s. per share, whereas, supposing we could pay 1 per cent., you would receive only 5s. We also get the benefit of the very large reserve fund which they have in hand, and which will be increased continually. Then we get the prospect presently of a larger dividend. All these things have weighed with us before we put the matter before you, and before we submitted these terms to you; and we thought that, although we should have liked to get more, the terms offered to us were sufficiently favourable to justify us in putting them before you. We have therefore done so, and have submitted them to your approval, and in doing so I myself feel that we are doing right by you; and although the action of Directors in a peculiar case like this is always open to question, at the same time we think we have done our best, and that, taken altogether, they are favourable terms for the shareholders in the South of England Company. I am quite sure that the National Company will lose nothing, but the point is, do we lose anything? and I think we do not by exchanging our shares, either preference or ordinary, into shares and debenture stock of the National Company. I have therefore much pleasure in proposing this resolution:—

"*That the agreement submitted to this meeting, and expressed to be made between this Company and the National Telephone Company (Limited) for the amalgamation of the two Companies, by a transfer of the business and property of this Company (with certain exceptions) to the National Telephone Company (Limited) be, and the same is hereby, approved.*"

Mr. MacGREGOR: I rise to second the resolution proposed by Mr. Billett. He has so very clearly and ably pointed out to you the advantages of amalgamation and the difficulties and dangers which lie before us as an isolated company that I have very little to say. I thoroughly agree with and confirm all that he has said. The dangers ahead of us are very real, though, perhaps, not immediately apparent. Throughout these negotiations we have had but one object in view, namely, the interests of our shareholders, and of our shareholders only. We have endeavoured to make the best bargain we could, and I think that we have made a very fair one. I am myself the largest individual holder of the ordinary shares of the Company, I also hold a large number of preference shares, and I feel that I can confidently recommend this resolution for your adoption. I now therefore beg to second the resolution.

Mr. PAWLE moved the rejection of the proposal. They were, he said, asked to take 1s. 9d. each for their ordinary shares. At former meetings nothing had been said about the necessity of a reserve fund. Only ½ per cent. was paid last time, but they were led to believe that this was owing to snowstorms, &c., and that they would get better dividends in the future. They were asked to accept a price for their shares which had never existed, and which even in the worst times of the Company would not have been justified, and they were asked, moreover, to take shares in a company which were at a discount. One gentleman had said that they might pay 1 per cent. next time, and that would make the shares worth a great deal more than 2s. 6d., and yet they were asked to take 1s. 9d. each for them.

Mr. BILLETT: You are wrong in your figures. The price is 3s. 9d. anyhow. Get your figures right, and then let us have your particulars, and we may base some argument on it. What you are asked to take, even supposing you take the lowest figure quoted for the National Company's shares—which are now 4½ to 4¾—is 3s. 9d., not 1s. 9d.

Mr. H. H. THOMPSON seconded the amendment. It seemed to him that to sell their shares to the National Company at 3s. 9d. or 4s. was great folly, just when the Company was beginning to turn the corner, with the business beginning to increase, and with a good reasonable prospect of its steadily increasing. It seemed to him that the National Company were getting altogether the best of the bargain.

Mr. BREACH supported the amendment. He came from Brighton, and he knew that the Company was extending its business and growing in popular favour in the district.

Mr. FITZGERALD: I should like to say a few words upon this subject, because I think that among the body of shareholders there is a great deal of misapprehension. I am supposed to know a little about the telephone, and I think that one danger which the shareholders have overlooked is that of competition. Are the shareholders aware that there is such a thing as competition threatening them? Now, competition in the telephone business is a rather disastrous thing. I have had one or two telephone fights, and I know what it is to have your rates knocked down, and all your profits taken away. A small company like this Company, with its capital account running rather short, appears to me to be in rather a dangerous position. A few gentlemen could combine together, knowing very little about the business, and compete with us. (A Voice: "Are you a shareholder?") I have nearly £5,000 in preference shares and nearly 2,000 ordinary shares. I am not talking against my own interests. A few men, I say, could go into this business and compete with you and knock down your rates, and where would the South of England Company be then, with its capital nearly gone? Now, you are asked to join a big body, who have asked their shareholders for £300,000 and were offered £900,000. Is not that an argument for you to come into the big ship instead of remaining in the little one? Some one spoke about the price of the shares. But you cannot go into the market and sell 1,000 shares at 3s. 6d., whereas you are offered 3s. 9d. Again, some of the shareholders ignore the fact that they are to receive double the dividend which they received last year. I am very much pleased with the proposal. It is true I have to make a sacrifice as regards the amount of my preference dividend, but look at the security I get. The security of the debentures in the National Company is backed up by their large capital, on which they are earning, as Mr. Billett has said, 9 per cent. It is perfectly true it is not paid, but the fact makes that security an absolutely marketable security of very good value, and you are quite certain that you will receive your dividend. This sort of argument weighs with me a great deal more than the idea that because some one has paid too much for his shares in this Company, this is a bad bargain. If I give 7s. 6d. for a share for which I can only get back 3s. 6d., that is no reason why I should say that some one ought to give me 8s. for it. However, there is the big company offering to buy us up. You have to fix in your mind that you may have competition, thus reducing your subscriptions, and consequently your running the risk of earning no profit at all. Therefore, I for one say, and I think most of my clients too (and I have a very large number of them), that I shall support this resolution for the sale of the business. I should like to hear some of the gentlemen produce more argument against the resolution than simply the price of the shares. Personally, I think if the shareholders do not pass this resolution they will probably find themselves in a very bad way in about a year. That is my own private opinion. I may be wrong, but I think so.

Mr. TANNER: As a holder of 500 shares I beg to say that I shall support the sale.

Mr. SPICER said that there could be no two opinions that the amalgamation of this comparatively small Company with the National Company would be a very good thing for the South of England Company. It seemed to him that it was essential that the amalgamation should take place, but not necessarily on the basis proposed. That was the only matter for consideration. He was disappointed at the price that had been offered; but the meeting had heard what the seconder of the resolution and Mr. Fitzgerald had said in favour of the proposal. The remarks of these gentlemen should tend to convince them that the best bargain was being made; but at the same time he would like to be a little more certain on the point. If the National Company could not get into London without making an

arrangement with the South of England Company he thought they might stand out for better terms. Were they to receive an equal amount of the National Company's debenture stock for their preference shares?

The CHAIRMAN replied in the affirmative.

Mr. KAIN said that their Company were alone able to own or carry out any telephone matter in their own district, and therefore he would most strenuously stay any transfer to the National Company.

The CHAIRMAN: We are subject to competition. Anyone may run a telephone in our district.

Mr. TAYLOR thought that an amalgamation would be advantageous to both Companies. He, however, regretted that the National Company were not able to offer them 3,000 more shares.

The CHAIRMAN: I think a great many of us are of the same way of thinking as yourself. I will now put the amendment.

Mr. CRISP: There is no amendment; it is a rejection. You cannot put that.

The CHAIRMAN: Then I will put the resolution (read resolution again). Those in favour of that will kindly hold up their hands. On the contrary. There are 25 in favour of the motion and 14 against it, and, therefore, it is carried.

A SHAREHOLDER: May I ask what are the "certain exceptions" mentioned in the resolution?

Mr. CRISP: The principal exception is that we cannot sell the licence which we have from the Postmaster-General. The licence would be forfeited if we sold it.

Mr. BILLETT: I have now to move the second resolution:—

*"That with the view of giving effect to the above-mentioned agreement and in order to enable the Debenture stock and shares to be allotted thereunder, as part of the purchase consideration to be distributed among the members of this Company, this Company be wound up voluntarily under the Companies Act, and that Mr. Thomas Abercrombie Welton be, and is hereby, appointed liquidator for the purpose of winding up its affairs and distributing its property."*

Mr. MACGREGOR seconded the resolution, which was adopted.

On the motion of Mr. BILLETT, seconded by Mr. MACGREGOR, the following resolution was also passed:—

*"That pursuant to the 161st section of the Companies Act, 1862, the liquidator be, and is hereby, authorised to carry the said agreement into effect, and to receive the Debenture stock and shares agreed to be allotted, and the cash payable thereunder, and to distribute the same among the members of this Company."*

A SHAREHOLDER inquired what was intended to be done as regarded those who held shares which were not multiples of 25?

Mr. WELTON replied that he would probably issue fractional certificates, which could be combined together so as to command a whole share, which could be disposed of in the market. Those not brought in by a certain date would be represented by shares in his hands, the proceeds of which he would have to hand over to the holders of the fractional certificates.

A vote of thanks to the Chairman closed the proceedings.

## The Telephone Company of Egypt (Limited).

The following is the report of the Directors for the year ended December 31, 1890, to be presented at the eighth ordinary general meeting of the Company, to be held at the offices of the Company, 14, Austin Friars, E.C., on Tuesday, the 24th inst., at 1 p.m.

The revenue account, after providing £345 for interest on Debentures, shows an amount to credit of £3,670. 10s. 1d., adding to this the sum of £1,459. 1s. 4d. brought forward from December 31, 1889, there remains a balance for disposal of £5,129. 11s. 5d., out of which the Directors recommend the payment of a dividend of 6 per cent. on the preferred shares, free of income-tax, carrying forward £1,508. 5s. 5d.

Considerable expense has been incurred during the past year in the renewal of lines and instruments, all charges in connection therewith having been provided for out of revenue. The Directors have also deemed it advisable to eliminate from the accounts certain subscriptions, the collection of which appear doubtful.

A further issue of £1,500 Six per Cent. Debentures was made during the year in order to replace a portion of the revenue that has been expended on capital account.

The business at Alexandria and Cairo shows a less favourable tendency, due to local circumstances. The growth of the exchange at Port Said, on the other hand, has more than fulfilled the expectations of the Directors, and this exchange will in time add to the income of the Company. A small exchange was opened during the year at Assiout, and negotiations are now in progress for the establishment of an exchange at Suez, with a branch at Port Tewfick.

The gross revenue of the Company at December 31, 1890, was £10,852. 8s. 2d., and the total number of subscribers in Egypt, 994.

Under the Articles of Association Mr. Henry Grëwing retires from the Direction, but being eligible offers himself for re-election. Messrs. Price, Waterhouse, and Co., the Auditors of the Company, also retire, and offer themselves for re-election.

## NEW COMPANIES REGISTERED.

**JOHN PRIEST AND SON (LIMITED.)**—Registered with a capital of £30,000, in £10 shares. Object: To carry on generally the business of iron and steel founders, engineers, &c.

**THE LIVERPOOL AND DISTRICT PULSION TELEPHONE COMPANY (LIMITED).**—Registered by Thomas T. Hull, 22, Chancery-lane, with a capital of £5,100 in £1 shares. Object, to adopt an agreement made February 20th between the Primary Syndicate (Limited), of the one part, and Alfred Howard Cowie of the other part, and to carry on generally the business of a telephone, telegraph, and electric light, &c., company.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended March 13th amounted to £5,066.

**BRIGHTON AND HOVE ELECTRIC LIGHT COMPANY (LIMITED).**—The fifth annual report, to be presented at the meeting next week, recommends a dividend of 5 per cent., with £220 forward.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended March 14th amounted to £749.

**TAUNTON ELECTRIC LIGHTING COMPANY (LIMITED).**—The whole of the debentures in this Company have been taken up, and Colonel Milman has joined the directory.

**UNITED ASBESTOS COMPANY (LIMITED).**—At the annual meeting of the shareholders of this Company, held yesterday, a dividend of 10 per cent. was declared and paid upon the preference shares, and the balance of profit for the year, equal to a little over 5 per cent. on the ordinary shares, was carried forward.

**WEST COAST OF AMERICA TELEGRAPH COMPANY.**—The traffic receipts of this Company for the month ending February 28, 1891, amounted to £4,600.

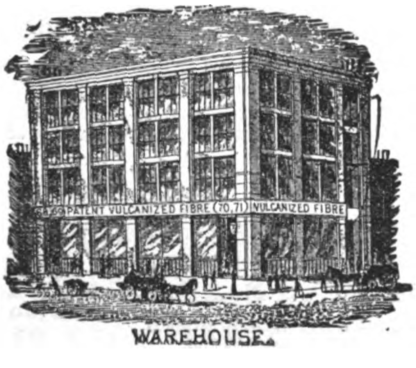
**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ending March 13, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,063.

**WEST INDIA AND PANAMA TELEGRAPH COMPANY.**—The receipts of this Company for the half-month ended March 15th, show a decrease of £368 as compared with the corresponding period.

**WHITE'S ASBESTOS COMPANY (LIMITED) v. HOARE.**—An appeal by the Company against a decision of Mr. Justice Day (*The Electrician*, December 26, 1890, page 249) came before the Appeal Court on Tuesday, when it was stated that the parties had arranged that an order should be taken by consent, dismissing the appeal, with costs.

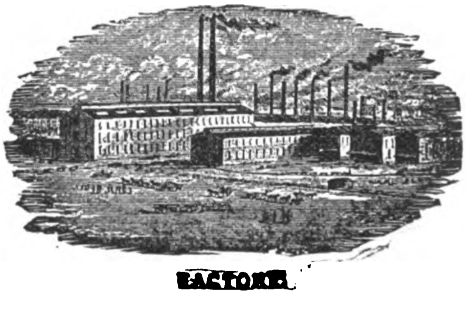
THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,
PATENTED.



WAREHOUSE.

This new material is supplied in two qualities, Flexible and Hard.
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.
It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.
The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.
Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.



FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

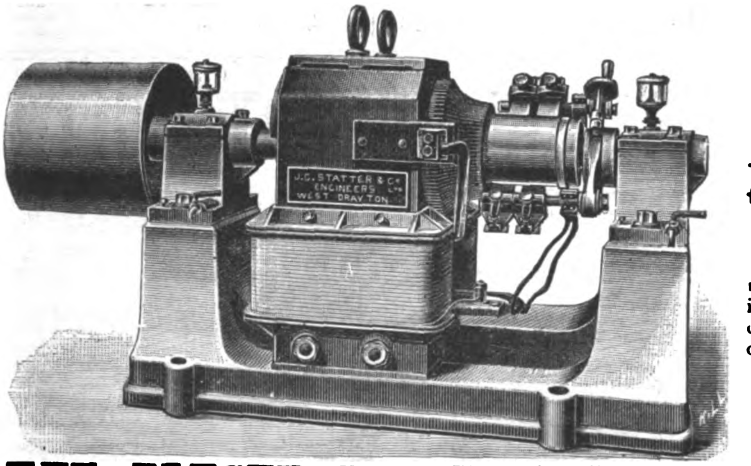
# IMPROVEMENTS IN DYNAMOS



## STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**
**MACHINES BUILT TO 500 KILOWATTS.**

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 671.—Vol. XXVI. FRIDAY, MARCH 27, 1891. Price Fourpence.

# NOTES.

It has been suggested by an ingenious evening contemporary that the Postmaster-General's course of action in regard to the Boy Messenger Company, is dictated solely by the desire to afford an "object lesson" writ very large, of the disadvantages of State interference. The Board of Trade is apparently doing likewise. The complicated tangle which that department has managed to make of such a simple matter as a clause for the protection of telephones, is a powerful argument against Governmental meddling in concerns which do not necessarily affect the public weal. The whole history of this unfortunate muddle is concisely set forth in the admirable report of the Sub-Committee of the Electrical Trades' Section, which will be found in another column. As a question of principle the Chamber of Commerce would do well to take the matter up.

The latest dispute which has arisen between the Municipal Council and the Paris electric lighting companies shows the danger of fixing charges on too scientific a basis. it has been asserted that the ideal method of charging for current supplied is by the light it produces. Now the Paris authorities, in fixing the price of the electric light, took the price of gas as the basis of their calculations. They assumed that a light of one carcel was produced for a consumption of some three cubic feet of gas per hour, and worked out the cost of the carcel hour at about 3d. Then they said to the electric light companies, you shall be allowed to charge some 50 per cent. more than this, namely, ·432d. per carcel hour. French lamp makers were equal to the occasion, and a lamp having a three-watt efficiency was soon on the market, at least so we must conclude, since the charge per 1,000 watt-hours was worked by the companies at 14·4d., which a little calculation will show can only be justified on that assumption. Taking the more ordinary efficiency of 4 watts per candle, the price per B.T. unit comes out at 10·8d.

In order that those of our readers who are interested in such matters may have an opportunity of comparing English with German practice, we publish in another column the full text of an Electric Lighting Bill at present before the German Parliament. The scope of the Bill is much wider than that of our own Act of 1882 (which relates solely to electric supply), including, as it does, private installations and electrical factories. For the cumbersome and costly procedure, which in this country is a necessary antecedent to the obtaining of electrical lighting powers, is substituted a month's notice to the Postal Telegraph Department, the Local Authority, and persons likely to be interfered with. If there is no opposition the Local Authority may give assent to the scheme subject to such conditions as it may think fit to impose. In case of refusal to grant permission an appeal within two weeks to the Central Land Court is open to the promoter. As an offset to this straighforward method there is frequent mention of special police regulations, so that it is possible that the evil day of petty harassing is in Germany only postponed until the electric light scheme is in operation, while with us Provisional Orders once obtained, comparative peace and quiet is assured.

The misrepresentation of the remarks of Mr. Newman Lawrence and Dr. Harries by our correspondent, last week, does not appear to us so serious as their letter in the present issue suggests; indeed, some of the qualifications which he omitted, accentuate rather than modify some of the views expressed. On the interesting subject of cataphoric medication, our correspondent gave several criticisms which we omitted. He complained that no counter-experiment was adduced, and that, in the absence of this, not even a qualitative experiment is of much value. The authors compare the effect of a drug applied by a pad under a metal electrode, a compress, in fact, with the mere painting of the solution on the skin. They have on former occasions brought forward interesting information on this subject, and we hope soon to hear more actual facts about it. Meanwhile, these gentlemen should remember that useful as their work is, they have hitherto met with but little criticism; less, probably, than they care for.

In the January number of the *Journal de Physique* will be found an account of some remarkable experimental work, by Mr. Otto Weiner, made with the object of determining the direction of the vibrations in a beam of polarised light. Hertz succeeded in getting stationary electro-magnetic waves by reflection at a metallic surface, and, as light waves only differ from these in mere magnitude, it occurred to Mr. Weiner to apply the method to a beam of polarised light reflected from the surface of a plane mirror. The method of test employed was very interesting, on account of its delicacy. If the light is reflected normally by the mirror the nodes and internodes occur in planes parallel with the reflecting surface, but by inclining a thin photographic film at a very small angle with the mirror, it was found possible, in spite of the minuteness of the wave length, to sufficiently separate the parts of the film where interference took place to obtain

Digitized by Google

photographic bands corresponding with them. The study of these bands, obtained under different circumstances, confirms FRESNEL'S theory in several ways. It is shown that in the act of reflection a reversal of phase occurs, and also that the chemically active vibrations are always perpendicular to the plane of polarisation. The latter point is important, and was established by studying the effect of reflecting polarised light at an angle of about 45deg. with the mirror. When the plane of polarisation coincided with the plane of incidence well defined bands were obtained, but when the planes were perpendicular to each other, none could be detected. The experiments form an interesting instance of the reaction, on optical theory, of recent researches on electrical oscillations; and, when taken in conjunction with the work of HERTZ and TROUTON, they prove for the first time that there is a distinct optical difference between the two kinds of vibration which occur in an electromagnetic wave. The magnetic vibrations have no influence on a photographic film, while the electric vibrations are chemically active.

THE conclusion that the electrical vibrations are those associated with chemical effect seems only natural when it is considered what close relations chemical and electrical phenomena exhibit. The electromotive force of a voltaic cell can be calculated from the chemical affinity of its different constituents, and the quantity of an electrolyte decomposed by the passage of a current is strictly proportional to the quantity of electricity which causes the decomposition. Many chemists have endeavoured to explain chemical action by supposing the atoms to be electrically charged, and it is possible that all known cases of electrification are to be accounted for by the presence of free atoms on the charged surfaces. Prof. J. J. THOMSON has very successfully applied the theory of atomic charges to explain the passage of electricity through gases; while in the current number of the *Philosophical Magazine* he endeavours to show that, even in the case of conductors, we may reasonably suppose that the passage of electricity through a body is essentially accompanied by chemical changes, and that, in fact, ordinary conduction is ultimately a form of electrolysis. That moceular actions take place is shown by the heating which occurs, and the change of structure ultimately caused by the passage of the current. On the other hand, very few instances are known in which magnetic phenomena exert any direct or indirect influence over chemical actions, so that it is not surprising to find that the magnetic vibrations in an electro-magnetic wave exert no chemical effect. To which set of vibrations is due the sensation of light experienced by the eye, Mr. WIENER'S experiments do not determine; and thus partisans of FRESNEL'S theory cannot claim that its truth is established by this research until they can show that the stimulation of the optic nerve is of the nature of a chemical action, and not of a magnetic one. It appears that the idea of determining the direction of the vibrations in a beam of polarised light by analysing the interference of two rays crossing at right angles is not new, having been suggested by Mr. ZENKER, of Berlin, in 1867. Mr. WIENER, however, was able to devise an indicator of sufficient delicacy to test the phenomena experimentally.

THE movement which has recently been made by Dr. FOERSTER, at the congress of makers of surveying instruments, at Bremen, in favour of the centesimal method of measuring angles elicited the fact that this system is gaining favour in Germany, and that its unpopularity is chiefly due to the unsatisfactory arrangement of the trigonometrical tables which have hitherto been published on the centesimal method. The circle, according to the German system, is divided into 400 degrees, instead of 360. The new graduation has been extensively employed at Baden, and since 1820 it has been used on the Government surveys. This change is, we think, rather too sweeping, abolishing, as it does, our convenient and well-known angles of 30°, 45°, and 60°; but we would gladly welcome a decimal subdivision of the degrees, retaining 90° to a quadrant.

THE transition from degrees to minutes always strikes us as barbarous. We arrive at a sine or tangent by simple decimal arithmetic, and turn to the tables to find the angle, for the purpose perhaps of finding its cosine or some other trigonometrical function. We find the nearest degree at once, and then we are forced into figures of another notation, interrupting the train of thought, and necessitating the careful use of proper signs to distinguish them from decimals, while confusing them with feet and inches. Where it is not necessary to use trigonometrical tables, we naturally fall into decimals, and at a recent meeting of the Physical Society, angles expressed in decimals of a degree, and in minutes, were given on the blackboard simultaneously. The complete change will no doubt come in the course of the next century, but it will probably follow the extension of the decimal system in other and more popular directions. The complete change after all only gives us 50° for 45°; and the well-known figures 33·33° instead of 30°. Meanwhile, the abolition of minutes and seconds would be a most useful preparation.

SURVEYORS, sailors, and astronomers are perhaps more concerned with angles than anyone else. The profession of the first is, or should be, a branch of engineering, and it is among engineers and scientific men that the decimal system has made its way. The second are rapidly becoming engineers, and, indeed, should be scientific engineers if they are to understand the modern warship and her intricate details. And lastly, astronomers are nothing if not scientific. No obstacle should be raised by them. Perhaps the most serious difficulty would be felt in connection with the Nautical Almanac. But electrical engineers have little to do with that important publication, and the decimal subdivision of angles would be peculiarly useful to them because minutes and seconds are the more troublesome since they have so rarely to use trigonometrical tables.

**St. Pancras Electrical Exhibition.**—It has been decided to keep this Exhibition open until April 1st.

**Personal.**—Mr. H. D. Wilkinson has been appointed electrical engineer to the Executive of the Royal Naval Exhibition.

**Telephone Extensions in Bavaria and Wurtemberg.**—The towns of Stuttgart and Ulm will shortly be placed in telephonic communication with Neu Ulm, Augsburg, and Münich.

Digitized by Google

**Hanover.**—The public supply of current was commenced on the 4th inst., and will be continued during the present month without any charge being made.

**Potsdam.**—The town of Potsdam is to be lighted by electricity. The central station is to be built by the German Continental Gas Company of Dessau.

**Telephonic Communication with Heligoland.**—A telephone now connects Heligoland with the bathing island of Sandy, and another connects it with Cuxhaven.

**Proposed Electrical Exhibition at the Crystal Palace.**—It has been decided by the Directors of the Crystal Palace to hold an Electrical Exhibition there in the autumn.

**Institution of Civil Engineers.**—On Friday, April 3rd, the students of this Institution will visit the mechanical laboratory of the Central Institution, Exhibition-road.

**"Cost of the Generation and Distribution of Electrical Energy."**—A Paper on this subject will be read by Mr. R. E. Crompton before the Institution of Civil Engineers on Tuesday, April 7.

**New Westinghouse Traction Motor.**—Following the example of the Thomson-Houston Company the Westinghouse Company have brought out a "single reduction gear" motor for tramway purposes.

**Indian Telegraphs.**—Something like 1,800 miles of wire were added to the Indian telegraphic network last year, and the profit on the operations of the year amounted to about 21 lakhs of rupees.

**Electric Lighting of the Hamburg Municipal Theatre.**—At a recent meeting of the Town Council of Hamburg, it was decided to vote the sum of £15,000 to the electric lighting of the Municipal Theatre.

**City and South London Railway.**—The Directors of the City and South London Railway Company are introducing on their trains a system of tablets which indicate to passengers the name of the next station.

**Telephonic Communication between London and Brussels.**—According to the Brussels correspondent of the *Times* the question of establishing telephonic communication between Brussels and London is under consideration.

**Technical Instruction Bill.**—This Bill having been read a third time in the House of Lords on Friday evening, was passed after amendment. The Lords' amendments to the Bill were considered and agreed to by the Commons the same evening.

**Electric Traction at Marseilles.**—The Compagnie Française des Tramways has adopted the overhead trolley system of electric traction for its new line at Marseilles. The work has been entrusted to MM. Sautter Harlé et Cie., and to the Oerlikon Works.

**Proposed Berlin-Vienna Telephone Trunk Wire.**—It is intended to lay a telephone line between Zittau and Reichenberg. This will establish connection between Berlin and Vienna, as lines already exist between Berlin and Zittau, and between Vienna and Reichenberg, through Pesth.

**Coast Telegraphic Communication.**—Telegraphic communication between the coastguard station at Ilfracombe and Morthoe, will, it is stated, shortly be established. The necessity of this has been long felt in the locality, and repeated efforts have been made to induce the authorities to carry out the proposal.

**Telegrams for Jelebu.**—Telegraphic communication has now been extended to Jelebu, in the Malay Peninsula, and telegraph offices have been opened in the towns of Jelebu and Kwala Kwalang. The rates are as follows for each word:—Eastern Company, 6s. 7d.; Indo-European Company, 6s. 7d.; *viâ* Turkey, 6s. 5d.

**Bristol.**—The Electric Light Committee of the Town Council have authorised Mr. Preece to proceed at once with the necessary steps for the initial electric light installation. The Temple Backs site will be at once cleared for building purposes. It has also been decided to appoint an engineer at a commencing salary of £300.

**Appointment Vacant.**—The Corporation of Bristol being about to establish an electric light installation, requires the services of a mechanical and electrical engineer, who has been trained in first-class workshops, and is thoroughly familiar with the theory and skilled in the practice of steam and of electrical science, machinery and appliances, and able to superintend and take charge of the same. Particulars will be found in our advertisement columns.

**Proposed Underground Electric Railway in Berlin.**—The Thomson-Houston International Electric Company have sent in a petition to the chief magistrate of Berlin, asking for permission to construct and work an underground electric railway in Berlin. The proposed railway to be built in iron tunnels similar to the City and South London Railway.

**The Albert Medal.**—The Council of the Society of Arts will consider early in May next the award of the Albert Medal, and invite members of the Society to forward to the secretary, on or before April 18th, the names of such men of high distinction as they may think worthy of the honour. The medal was struck to reward "distinguished merit for promoting arts, manufactures, or commerce."

**Postal Telegraph Appointments and Promotions.**—We notice that Mr. J. Little, formerly of West Strand Telegraph Office, has been promoted from the Postmastership of Staines to that of Chichester. Mr. G. F. Herring, telegraphist at Southport, has been appointed Postmaster of Beverley; and Mr. C. S. Covington, telegraphist at the Central Telegraph Office, Postmaster of Goole.

**The Italian Telegraph Service.**—The growth of the telegraphs in Italy is shown by a recent report of Mr. Dering, the Secretary of the British Embassy at Rome. It appears that at the end of 1861 there were 355 telegraph stations, exclusive of Venice and Rome, of which 40 were railway offices. At the close of 1871 the total amounted to 1,351, while in 1889 the number had risen to a total of 4,283, composed of 2,477 Government and 1,806 railway offices.

**Glasgow.**—Only four tenders for the lighting of the "compulsory area" scheduled by the Glasgow Electric Lighting Provisional Order have been received. The following firms tendered:—Messrs. Mavor and Coulson, R. E. Crompton and Co., the House-to-House Company, and the Thomson-Houston Company, of America. The Special Committee on Electric Lighting have seen the tenders, but have not done anything in regard to them. They have resolved to pay a visit to Bradford and Leeds to learn if they can collect any information.

**Electric Traction in Guernsey.**—In our issue of February 6th the Guernsey Railway Company invited tenders for the working of their line $2\frac{3}{4}$ miles long by some overhead system of electric traction. Tenders were received from Messrs. Siemens Bros. and Co., the Westinghouse Electric Company, the Brush Electrical Engineering Company, the Electrical Engineering Corporation, the Electrical Construction Corporation, Messrs. Crompton and Co., and the Thomson-Houston International Electric Company. The tender of Messrs. Siemens Bros. and Co. has been accepted.

**The Electric Light in the Suez Canal.**—Last year of a total of 3,389 vessels as many as 2,836 are reported to have employed the electric light. The following table shows the progress that has been made in diminishing the average time of transit:—

| —— | 1887. | | 1888. | | 1889. | | 1890. | |
|---|---|---|---|---|---|---|---|---|
| | h. | m. | h. | m. | h. | m. | h. | m. |
| Average time of transit ........... | 33 | 58 | 31 | 15 | 25 | 50 | 24 | 06 |
| " with electric light... | ... | | 21 | 26 | 22 | 30 | 22 | 09 |
| Shortest time........................ | 14 | 65 | 14 | 55 | 14 | 45 | 14 | 15 |

**The Telegraph Line between Calcutta and Bombay.**—It was a great event in the annals of Indian telegraphy, says the *Indian Engineer*, when one day last week the new copper wire just completed between Calcutta and Bombay, along the line of the Bengal-Nagpore Railway, was worked direct for the first time. Messages at once poured in as fast as the operators could receive and signal them, showing how the line is likely to be appreciated by the public. The total length of the circuit is nearly 1,300 miles, and the Indian Department can now boast that it works the longest aerial circuit in the world.

Digitized by Google

**Aberdeen.**—Some time ago the Gas Committee of the Town Council issued circulars to gas consumers whose annual bills amount to £5 and upwards, within the area scheduled by the Board of Trade, asking whether they would be likely to adopt the electric light. It was carefully explained in the circular that the quantity of electricity sufficient to give the same amount of light compared with gas was estimated to cost about four times the price of gas. It is not surprising, therefore, that the replies show that gas consumers whose accounts represent annually a total in all of £4000, do not wish the light; consumers representing £900 have not made up their minds, and consumers representing £100 are favourable. The Corporation now propose to allow a Company to come in.

**Gas and Electric Light Mains in Paris.**—At a recent meeting of the Paris Municipal Council the Director of Works reporting on an accident in connection with the Popp Company's mains which has lately taken place in the Rue Royale, stated that, in his opinion, gas and electric light mains should be kept as widely apart as possible, and he proposed to submit sundry regulations on this point to the Council at an early date. The Council, after the reading of this report, passed a resolution calling for a complete list of the accidents attributable either to gas or electricity, to be submitted to the Council, together with the new regulations, at the earliest possible date. The Council at the same meeting voted £240 for the expense of analysing the smoke emitted by municipal works.

**The Lighting of the City.**—"The Commissioners of Sewers," says the *Journal of Gas-Lighting,* "ever since the days of Jablochkoff, have neglected the possibility of improvement in gas lighting, presumably in view of the prospect of the City streets being delivered over, some time or another, to the electricians. Then, at the last, they take a plunge from old-fashioned gloom into meretricious glitter; paying for superfluous brilliancy far more than either it is worth or than they ought to afford for such a purpose." On the other hand, in the *Saturday Globe* of New York, we read that "London has for many centuries bent the knee and veiled the eyes before the presence of her November fogs; now, however, the grim visitor must yield before the radiant usurper of her wintery throne."

**The Accident at the Walbrook Installation.**—The accounts of the accident at this installation which have appeared in the daily papers were much exaggerated. One of the injured men was back at his work within an hour, and the other the next day (Friday). Mr. Williams is also getting along very well. What took place was somewhat as follows:—Fluctuations having been noticed in the light, Mr. Williams went down to the engine-room and found the two men in charge on the floor insensible. Mr. Williams, in trying to restore them, was himself overcome, and, shortly afterwards, Mr. Frank King found all three on the ground, and became himself in turn affected. An alarm was given, however, and all the sufferers were removed. The mishap was due to the inhalation of coal gas escaping from the engines into the heated atmosphere.

**Science at South Kensington.**—In the House of Commons on Thursday evening last week, Sir H. Roscoe asked the Chancellor of the Exchequer whether an unknown donor had offered £80,000 to build an art gallery on a site at South Kensington, the erection of which would interfere with the purposes for which land was recently bought by Government for housing the science collections, and for the necessary erection of suitable chemical and physical laboratories in connection with the Royal School of Science. In reply, the Chancellor of the Exchequer stated that it was true that a public-spirited gentleman had offered £80,000 to build an art gallery on a site at South Kensington; but the offer only affected about one-tenth of the land recently bought by Government, and the remainder would still be left available, if required, for science collections. The interests of the Royal School of Science, and of the science collections, were being carefully kept in view.

**The Overhead Wire Question in New York.**—In December, 1889, it will be remembered that the New York municipal authorities made a sudden raid upon the overhead electric light circuits, and poles were chopped down in all directions. One result of these energetic measures was an action for damages by the Brush Electric Illuminating Company and the United States Electric Illuminating Company against the city authorities. The first-named Company places its damages at $525,000, while the latter presents a claim for $550,000, making a total of $1,075,000, or £215,000, which the city of New York are called upon to pay. The claims include the temporary loss of business caused by the destruction of the poles and wires. The defence is that the city has the right to regulate structures in the public thoroughfares which affect the life and health of the public, and that the plaintiffs had wrongfully neglected and refused to remove the poles.

**The London-Paris Telephone Line.**—The capacity per mile of the land line in this country is slightly higher than in France, since the Post Office earths each pole. The 83 miles to Dover have a capacity of ·015 microfarad per mile, the 204 miles in France have ·012 microfarad per mile. The cable, which is 24 miles long, has a capacity of ·23 microfarads per mile. The whole line is perfectly balanced, and the introduction of $\frac{1}{10}$ microfarad into either wire is enough to seriously interrupt communication. The four wires are maintained apart at the uniform distance of 14in. The line was recently put through to the Treasury, and it was found that speaking was quite impossible until the magnet of an indicator was cut out, when communication was found to be excellent. Those who consider that self-induction assists telephony should see to this. The call is made by twelve 6-block agglomerate Leclanché cells. Only two of these are used for speaking.

**Cambridge.**—An inquiry on behalf of the Local Government Board was recently held at Cambridge respecting the application made by the Corporation for authority to borrow £35,000 for the carrying out of the electric lighting scheme. The Town Clerk stated that tenders involving an expenditure amounting to £25,000 had been received, and there was an estimate for a further outlay of £10,000. It was further stated that the authorities of Trinity College alone had intimated that they would require 2,000 lights installed, 1,500 of them to be in simultaneous use. If all the colleges had a similar supply, the first scheme would be quite inadequate. The Inspector then remarked that it was very possible the Local Government Board would say that £35,000 was a very large sum of money to spend on electric lighting when the town was still undrained. Dr. J. A. Fleming then gave evidence in favour of the scheme, and Alderman Balls, Chairman of the Gas Company, argued that the Gas Company had done their duty alike to the town and to the shareholders, and he protested against the Corporation fighting a battle with the money of the ratepayers. The inquiry then closed.

**The Edison Telephone Patents in France.**—In the letter which appeared on p. 586 of our issue of the 13th March, our Paris correspondent referred to a decision which had been recently given in favour of the Edison telephone patents. These patents are owned by the Société Génerale des Téléphones and have between eighteen months and two years to run, being dated December 19, 1877 (English patent No. 2909, 1877), and January 15, 1878. The following is a *précis* of the judgment delivered in the French Court of Appeal. ——The combination of an induction coil and a telephone is novel application of known parts giving a commercial result. The experts' report makes it clear that the advantages of this combination are considerable, and that it is indispensable in the transmission of articulate speech to a distance. If Elisha Gray and Graham Bell employed this combination before Edison, they only did so in connection with the transmission of musical sounds. The conclusion must, therefore, be, that Edison or his assigns have an exclusive property in the combination of the induction coil and a speaking telephone. The instruments seized are, therefore, infringements, and may be confiscated, and it is necessary to grant damages to the Telephone Company; but the Court cannot, owing to absence of precise information, at present, fix the amount. The demand for further reports and experiments is rejected. The Berliner patent only takes date from January 15, 1878, and not from October 16, 1887.

## ELECTROMAGNETIC THEORY.—VII.

BY OLIVER HEAVISIDE.

*(Continued from page 567.)*

§ 39. The vectors representing impressed electric and magnetic force demand consideration as to the different forms they may assume. Their line-integrals are impressed voltage and gaussage. Their activities or powers are **eJ** and **hG** respectively per unit volume, and in this statement we have a sort of definition of what is to be understood by impressed force. For, **J** being the electric current anywhere, if there be an impressed force **e** acting, the amount **eJ** of energy per unit volume is communicated to, or taken in by, the electromagnetic system per second; and this should be understood to take place at the spot in question. It must then be either stored on the spot, or wasted on the spot, or be somehow transmitted away to other places, to be there stored or wasted, according to a law which will appear later on. Similarly as regards **h** and **G**.

But this concerns only the reckoning of impressed force, and is independent of its physical origin, which may be of several kinds. Thus under **e** we include,—

(1.) Voltaic force.
(2.) Thermo-electric force.
(3.) The force of intrinsic electrisation.
(4.) Motional electric force.
(5.) Perhaps due to various secondary causes, especially in connection with strains.

And under **h** we include :—

(1.) The force of intrinsic magnetisation.
(2.) Motional magnetic force.
(3.) Perhaps due to secondary causes.

§ 40. Voltaic force has its origin in chemical affinity. This is still a very obscure matter. For a rational theory of Chemistry, one of the oldest of the sciences, we may have to wait long, in spite of the activity of chemical research and of the development of the suggestive periodic law. Yet Chemistry and Electricity are so intimately connected that we cannot understand either without some explanation of the other. Electricity is, in its essentials, a far simpler matter than Chemistry, and it is possible that great light may be cast upon chemical problems (and molecular physics generally) by previous discoveries and speculations in Electricity. The very abstract nature of Electricity is, in some respects, in its favour. For there is considerable truth in the remark (which, if it has not been made before, is now originated) that the more abstract a theory is, the more likely it is to be true. For example, it may be that Maxwell's theory of displacement and induction in the ether is far more than a working theory, and is something very near the truth, though we know not what displacement and induction are. But if we try to materialise the theory by inventing a special mechanism we are almost certain to go wrong, however useful the materialisation may be for certain purposes. No one knows what matter is, any more than ether. But we do know that the properties of matter are remarkably complex. It is, therefore, a real advantage to get away from matter when possible, and think of something far more simple and uniform in its properties. We should rather explain matter in terms of ether, than go the other way to work.

However this be, we have the fact that definite chemical changes involve definite voltages, and herein lies one of the most important sources of electric current. Furthermore, there is the remarkable connection between the quantity of matter and the time-integral of the current (or quantity of electricity) produced, involved in the law of electro-chemical equivalents, which is one of the most suggestive facts in physics, and must be a necessary part of the theory of the atom which is to come. That the energy of chemical affinity may itself be partly electromagnetic is likely enough. That even conduction may be an electrolytic process is possible, in spite of the sweet simplicity of Ohm's law and that of Joule. For these laws are most probably merely laws of averages. The well-known failure of Ohm's law (apparent at any rate) when the periodicity of electromagnetic waves in a conductor amounts to billions per second may perhaps arise from the period being too short to allow of the averages concerned in Ohm's law to be established. If so, this may give a clue to the required modification.

§ 41. Thermo-electric force has its origin in the heat of bodies, manifesting itself at the contact of different substances or between parts of the same substance differing in temperature. Now heat is generally supposed to consist in the energy of agitation of the molecules of bodies, and this is constantly being transferred to the ether in the form of radiant energy, *i.e.*, electromagnetic vibrations of very great frequency, but in a thoroughly irregular manner. It is this irregularity that is a general characteristic of radiation. Now the result of subjecting conductors to electric force is to dissipate energy and to heat them. This is, however, an irreversible process. But when contiguous parts of a body are at different temperatures, a differential action on the ether results, whereby a continued effect of a regular type is produced, reversible with the current, and therefore formularisable as due to an intrinsic electric force, the thermo-electric force. At the junction of different materials at the same temperature it is still the heat that is the source of energy.

The theory of thermo-electric force due to Sir W. Thomson, based upon the application of the Second Law of Thermodynamics (the First is a matter of course) to the reversible heat effects has been verified for conductive metallic circuits by the experiments of its author, and those of Prof. Tait and others. With some success the same principle has also been applied by von Helmholtz to voltaic cells, which are thermo-electric as well as voltaic cells. There are wheels within wheels, and Ohm's law is merely the crust of the pie.

§ 42. Intrinsic electrisation is a phenomenon shown by most solid dielectrics under the continued action of electric force. It is the manifestation of a departure from perfect electric elasticity, and is probably due to a molecular rearrangement, resulting in a partial fixation of the electric displacement, whereby it is rendered independent of the "external" electrising force. Thus the displacement initially produced by a given voltage slowly increases, and upon the removal of the impressed voltage only the initial displacement will subside, if permitted, immediately. The remainder has become intrinsic, for the time, and may be considered due to an intrinsic electric force **e**. If $\mathbf{I}_1$ be the intensity of intrinsic electrisation, and $c$ the permittivity, then

$$\mathbf{I}_1 = c\mathbf{e} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$\mathbf{I}_1$ is the full displacement the force **e** can produce elastically, all external reaction being removed by short circuiting. It is not necessarily the actual displacement. The phenomenon of "residual charge," "soakage," &c., are accounted for by this **e** and its slow variations.

Maxwell attempted to give a physical explanation of this phenomenon by supposing the dielectric to be heterogeneously conductive. This is perhaps not the most lucidly successful of Maxwell's speculations. How far electrolysis is concerned in the matter is not thoroughly clear.

§ 43. Intrinsic magnetisation is, in some respects, a similar phenomenon, due to a passage from the elastic to the intrinsic form of induction externally induced in solid materials. Calling the intensity of intrinsic magnetisation $\mathbf{I}_2$, we have

$$\mathbf{I}_2 = \mu\mathbf{h}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where **h** is the equivalent intrinsic magnetic force, and $\mu$ the inductivity (elastically reckoned).

In one important respect intrinsic induction is a less general phenomenon than intrinsic displacement. There is no magnetic conductivity to produce similar results as regards the magnetic current as there is electric conductivity as regards the electric current. But if there were, then we could have a magnetic "condenser," with a magnetically conductive external circuit, and get our residual results to show themselves in it, quite similarly in kind to, though varying in magnitude and permanence from, what we find with an electric condenser.

Digitized by Google

The analogue of Maxwell's explanation of "absorption" would be heterogeneous magnetic conductivity. This is infinitely more speculative than the other, which is sufficiently doubtful.

Ewing's recent improvement of Weber's theory of magnetism seems important. But as in static explanations of dynamical phenomena the very vigorous molecular agitations are ignored, it is clear that we have not got to the root of the matter. We want another Newton, the Newton of molecular physics. Facts there are in plenty to work upon, and perhaps another heaven born genius may come to make their meaning plain. Properties of matter are all very well, but what is matter, and why these properties? This is not a metaphysical inquiry, but concerns the construction of a physical theory.

§ **44.** The motional electric and magnetic forces are the forces induced by the motion of the medium supporting the fluxes. To express them symbolically, it will save much and repeated circumlocution if we first define the vector-product of a pair of vectors.

Let **a** and **b** be any vectors, and **c** their vector-product. This is denoted by

$$\mathbf{c} = \mathrm{V}\mathbf{ab}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

the prefix V meaning "vector," or, more particularly here, "vector-product." The vector **c** is perpendicular to the plane of the vectors **a** and **b**, and its tensor (or magnitude) equals the product of the tensor of **a** into the tensor of **b** into the sine of the angle between **a** and **b**. Thus

$$c = ab \sin \theta, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

if the italic letters denote the tensors, and $\theta$ be the included angle of the vectors. As regards the positive sense of the vector **c**, this is reckoned in the same way as before explained with regard to circuitation. Thus, when the tensor $c$ is positive, a positive rotation about **c** in the plane of **a** and **b** will carry **a** to **b**. If the time by a watch is three o'clock, and the big hand be **a** and the little hand **b**, then the vector **c** is directed through the watch from its face to its back. These vector-products are of such frequent occurrence, and their Cartesian representation is so complex, that the above concise way of representing them should be clearly understood.

On this understanding then, we can conveniently say that the motional electric force is the vector-product of the velocity and the induction, and that the motional magnetic force is the vector-product of the displacement and the velocity. Or, in symbols, according to (3),

$$\mathbf{e} = \mathrm{V}\mathbf{qB}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$$\mathbf{h} = \mathrm{V}\mathbf{Dq}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where **q** is the vector velocity.

§ **45.** It should be remembered that we regard the displacement and the induction as actual states of the medium, and therefore if the medium be moving, it carries its states with it. Besides this, it usually happens that these states are themselves being transferred through the medium (independently of its translational motion), so that the resultant effect on propagation, considered with respect to fixed space, is a combination of the natural propagation through a medium at rest, and what we may call the convective propagation. Of course we could not expect the two laws of circuitation for a medium at rest to remain true when there is convective propagation.

The matter is placed in a very clear light by considering the very simple case of an infinite plane lamina of **E** and **H** travelling at the speed of light $v$ perpendicularly to itself through a homogeneous dielectric. This is possible, as will appear later, when **E** and **H** are perpendicular, and their tensors are thus related:—

$$\mathrm{E} = \mu v \mathrm{H} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Or, vectorising $v$ to **v**,

$$\mathbf{E} = \mu \mathrm{V}\mathbf{Hv} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

according to the definition of a vector-product, gives the directional relations as well as the numerical.

Now, suppose we set the whole medium moving the other way at the speed of light. The travelling plane electromagnetic sheet will be brought to rest *in space*, whilst the medium pours past it. Being at rest and steady, the electric displacement and magnetic induction can only be kept up by coincident *impressed* forces, viz. :—

$$\mathbf{e} = \mathbf{E} \qquad \mathbf{h} = \mathbf{H}.$$

Now compare (8) with (5) and (6); consider the directions carefully, and remember that the velocity **q** is the negative of the velocity **v**, and we shall obtain the formulæ (5), (6), which are thus proved for the case of plane wave motion, by starting with a simple solution belonging to a medium at rest.

The method is, however, principally useful in showing the necessity of, and the inner meaning of the motional electric and magnetic forces. To show the general application of (5) and (6) requires a more general consideration of the motional question, to which we now proceed.

*(To be continued.)*

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

*(Continued from page 599.)*

§ **43.** Suppose No. 2 closed transformer is run by an alternator giving a zig-zag E.M.F. wave (Fig. 11). Of course no such alternator exists, every practicable machine having the angles of the zig-zags rounded off to some extent, but the plain zig-zag can be looked on as a limiting curve more or less closely approached by some actual generators. In dealing with zig-zag functions, such old friends as

$$\text{effective E} = \frac{\text{maximum E}}{\sqrt{2}}$$

and mean power $= \dfrac{\text{max. E} \times \text{max. C}}{2} \cos$ (angle of lag) must be abandoned. If A′ is the maximum value of a zig-zag function, and T the period, the equation to the "curve" from

$$t = 0 \text{ to } t = \frac{1}{4}\,\mathrm{T}$$

is

$$y = \frac{4\,\mathrm{A}'}{\mathrm{T}}\,t$$

and the mean square of $y$ is

$$y^2_m = \frac{4}{\mathrm{T}} \int_0^{\frac{\mathrm{T}}{4}} \frac{16\,\mathrm{A}^2}{\mathrm{T}^2}\,t^2\,dt = \frac{\mathrm{A}'^2}{3}$$

so that the *effective* value of $y$ is $\dfrac{\mathrm{A}'}{\sqrt{3}}$

The *mean* value of $y$ is, of course, $\dfrac{\mathrm{A}'}{2}$, so that mean value = effective value $\times \dfrac{\sqrt{3}}{2} = \cdot 87 \times$ effective value. To find the expression for the mean power in a circuit in which a zig-zag current differs in phase from a zig-zag electromotive force, involves a somewhat tedious integration of several terms, for discontinous functions are here being dealt with, and those of us who are not Oliver Heavisides find it requires very wary walking to avoid a fatal slip into infinity. As the expression when found is of no practical importance, the working out will not be given, but the result may be set down as a curiosity.

Mean power for zig-zag E and C having a time lag $= \theta$

$$\mathrm{W} = \frac{\mathrm{E}'\,\mathrm{C}'}{6}\left(2 - 48\frac{\theta^2}{\mathrm{T}^2} + 64\frac{\theta^3}{\mathrm{T}^3}\right)$$

E′ and C′ are the maxima of E and C; T is the periodic time and $\theta$ is the lag in *time* of C behind E. Note that when $\theta = 0$, $\mathrm{W} = \dfrac{\mathrm{E}'\,\mathrm{C}'}{3}$, as it ought to be; when $\theta = \dfrac{1}{4}\,\mathrm{T}$, the factor in

Digitized by Google

brackets vanishes, and $W = 0$; and, lastly, when $\theta = \frac{1}{2}$ T, and the current therefore cophasal with E, but of opposite sign, the bracketed expression becomes $-2$, and $W = -\frac{E'C'}{3}$, that is to say, the part of the circuit considered is the seat of the electromotive force. With these rough and ready tools we proceed to discuss the working of transformers by a zig-zag E.M.F. wave.

§ 44. The value of a zig-zag E., reckoning time from the epoch when E has its maximum value E′, is

$$E_t = E' - at \qquad = 0 \text{ when } t = \frac{E'}{a},$$

but $E = 0$ when $t = \frac{T}{4}$, so that $a = \frac{4\,E'}{T}$; now since E is the counter E.M.F. in the primary coil, it is due to $\frac{d\,B}{d\,t}$, and is equal to $N\,A\frac{d\,B}{d\,t}$, (A being the area of the core), and we have

$$E_t = N\,A\frac{d\,B}{d\,t} = E'\left(1 - \frac{4}{T}t\right)$$

and therefore $B_t = \frac{E'}{N\,A}\int\left(1 - \frac{4}{T}t\right)dt = \frac{E'}{N\,A}\left(t - \frac{2\,t^2}{T}\right)$ the equation for $\frac{d\,B}{d\,t}$ shows us that B is a maximum when $t = \frac{T}{4}$ as we should expect, and this value being inserted in the equation for $B_t$ we have for the maximum value of B

$$B' = \frac{E'\,T}{8\,N\,A} = \frac{\sqrt{3}E\,T}{8\,N\,A}.$$

Recalling the corresponding expression in the case of a sine function, namely :—

$$B' = \frac{9}{10}\frac{E\,T}{4\,N\,A} = \frac{3\sqrt{3}}{5}\cdot\frac{\sqrt{3}E\,T}{8\,N\,A},$$

we notice that if E is to be 2,000 volts, we must put $E_z = E_s$, or B′ N A F (for zig-zag) $= \frac{5}{3\sqrt{3}}$ B′ N A F (for sine), so that one of the four factors, B′ N A F, must be reduced in the ratio $\frac{5}{3\sqrt{3}}$, or by about 4 per cent., in order that the values of E for the sine function and zig-zag may be equal. The simplest change to make to keep the effective E.M.F. right is to reduce the frequency so that the transformer will require no alteration of windings or core, and the induction cycle will be the same as before, namely 5,000 gausses, so that the the B H curve given in Fig. 9 can be used in drawing the new diagram. The frequency then will be reduced from 70 to 66·4 periods per second, and a slight diminution in the hysteresis loss follows as a necessary consequence. The time scale should remain as before, but quarter periods corresponding to the lower frequency (*greater* periodic time) must be marked before the E.M.F. zig-zag is drawn. E′ is evidently $2{,}000 \times \sqrt{3} = 3{,}470$ volts, and this value is plotted alternately positive and negative at intervals equal to $\frac{T}{2}$, and these points when connected by a zig-zag series of lines, complete the E wave.

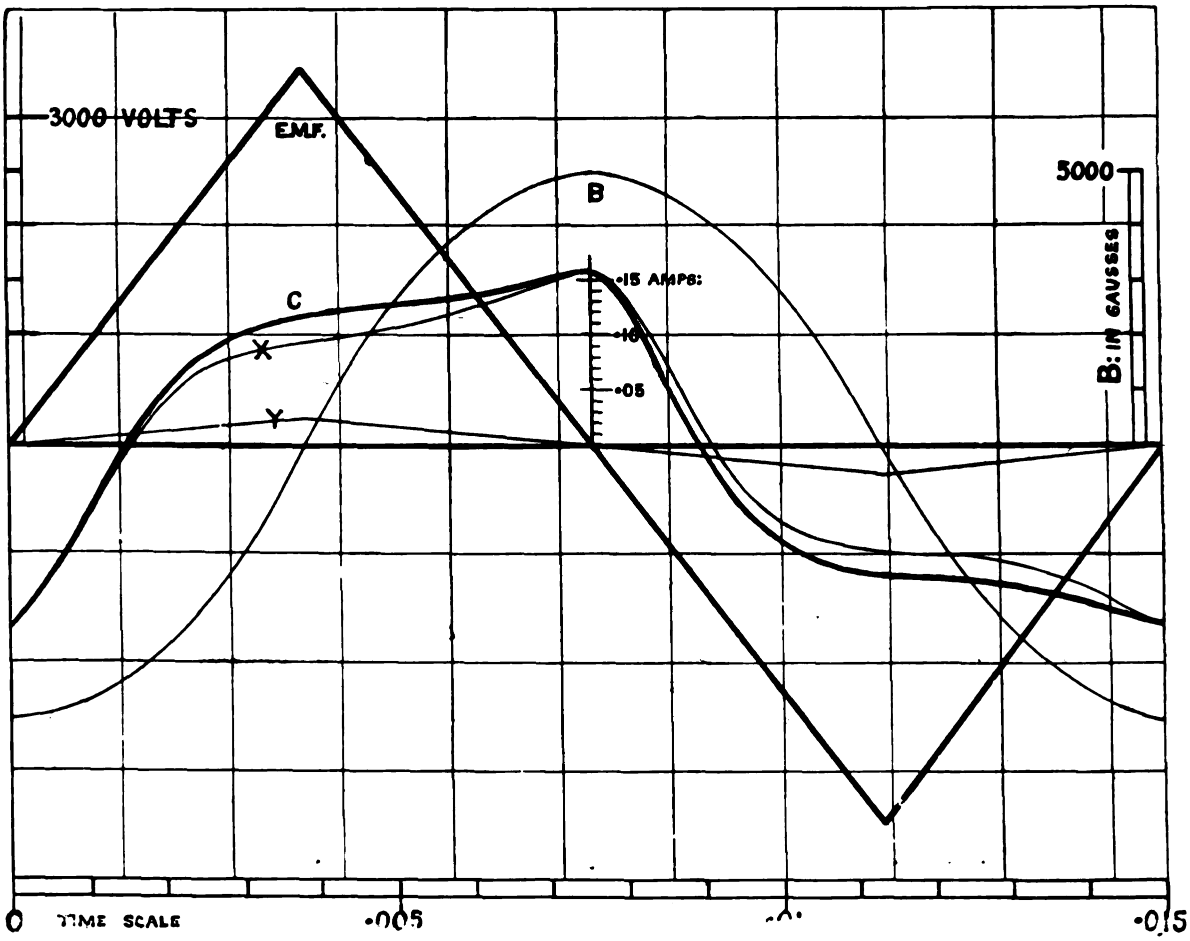

Fig. 11.—No. 2 Closed Transformer excited by zig-zag E.M.F. Output = 0.

§ 45. The induction curve is easily plotted from the equation

$$B_t = \frac{E'}{N\,A}\left(t - \frac{2\,t^2}{T}\right),$$

remembering that T is now $\frac{1}{66\cdot3} = \cdot0151$ second. It is perhaps simpler to eliminate $\frac{E'}{N\,A}$ by inserting the value found for the maximum induction, viz. :—

$$8\,B' = \frac{E'\,T}{N\,A},$$

so that $\qquad B_t = 8\,B'\,F\,t\,(T - 2\,t).$

The geometrical student will see a conic section in these equations for **B**; and in fact the positive and negative waves of induction are a series of parabolas having parallel axes normal to the time axis, spaced at intervals equal to $\frac{1}{2}$T. Where the induction changes sign one parabola ends and the next begins, at which point there is an abrupt change in the *direction* of curvature of the otherwise continuous line. In fact, the value of $\frac{d\mathbf{B}}{dt}$, while having the same numerical value for the curves on each side of zero, suddenly changes its sign; this is, of course, only a roundabout way of saying that E at this epoch suddenly changes the sign of its slope. It is interesting to note how very little the parabolic induction wave differs in form from the sine wave in Fig. 10, *Electrician*, March 20, p. 598; yet how great a change has been brought about in the counter E wave. Note also that the slightest departure from a true parabolic form when carrying the induction wave through zero (so as to make the two parabolas melt into each other with abrupt change) leads to a rounding of the angles in the E zig-zag resulting in a curve closely resembling those given by some actual alternators. No calculations are needed before drawing the X component of the exciting current, for a sufficient number of values of X have already been worked out from the **B H** curve when making Fig. 10. To draw the Y (eddy current) component of the exciting current we require its maximum value, and the investigation made in the case of the sine function diagram shows that this depends only on the maximum value attained by the **H** due to eddy currents, and this again on the maximum of $\frac{d\mathbf{B}}{dt}$ or $\dot{\mathbf{B}}$; now clearly

$$\frac{\dot{\mathbf{B}} \text{ for zig-zag}}{\dot{\mathbf{B}} \text{ for sine}} = \frac{E'_z}{E'_s} = \frac{3470}{2830}$$

so that the required maximum for Y is

$$Y' = \cdot0225 \times \frac{3470}{2830} = \cdot027 \text{ ampere.}$$

Y can now be plotted, being a zig-zag curve cophasal with E.

§ 46. The last diagram we shall draw for this transformer (No. 2 closed) is one in which E is assumed to alternate between − 2,000 and + 2,000 volts (Fig. 12), the change from + to − being instantaneous. The induction wave will now be a zig-zag, for $N A \frac{d\mathbf{B}}{dt} = E =$ constant. In the present case effective E = mean E = maximum E, and E = 4 **B**′ A N F. Now for a sine wave we had E = 4·4 **B**′ A N F, so that we must *increase* one of the factors **B**′ A N F, in order to make E = 2000 volts. As before we will alter the frequency, making it $F = \frac{4 \cdot 4}{4}$ (F for a sine) = 77·6 periods per second. It must be noticed here that if the frequency is worked out from the equation E = 4 **B**′ A N F, by inserting the known values of E **B**′, A and N, the result is F = 76·4 instead of 77·6. The discrepancy is due to our original sin in neglecting the fact pointed out in the first article, that **B**′ is only 4,900 gausses, and not 5,000 as assumed in the whole of the calculations. We must therefore take the value F = 76·4 if we make **B**′ = 5,000. After plotting E and **B**, X may be put in, and we note that it is now precisely the same shape as the **B H** curve from which it is obtained; in fact it is put on the diagram (Fig. 12) just as though the cyclic loop had been placed with its **B** axis along the time axis of the diagram, and the loop then cut at one of its turning points, and the negative portion folded forward along the time axis. Of course the values of **H** are replaced by the corresponding values of C before carrying out the operation. The Y component is of the same form as the E wave, and its value (which is constant) is found by precisely the same method as we have described in connection with Figs. 10 and 11.

$$C' = Y = \cdot0156 \text{ ampere.}$$

(*To be continued.*)

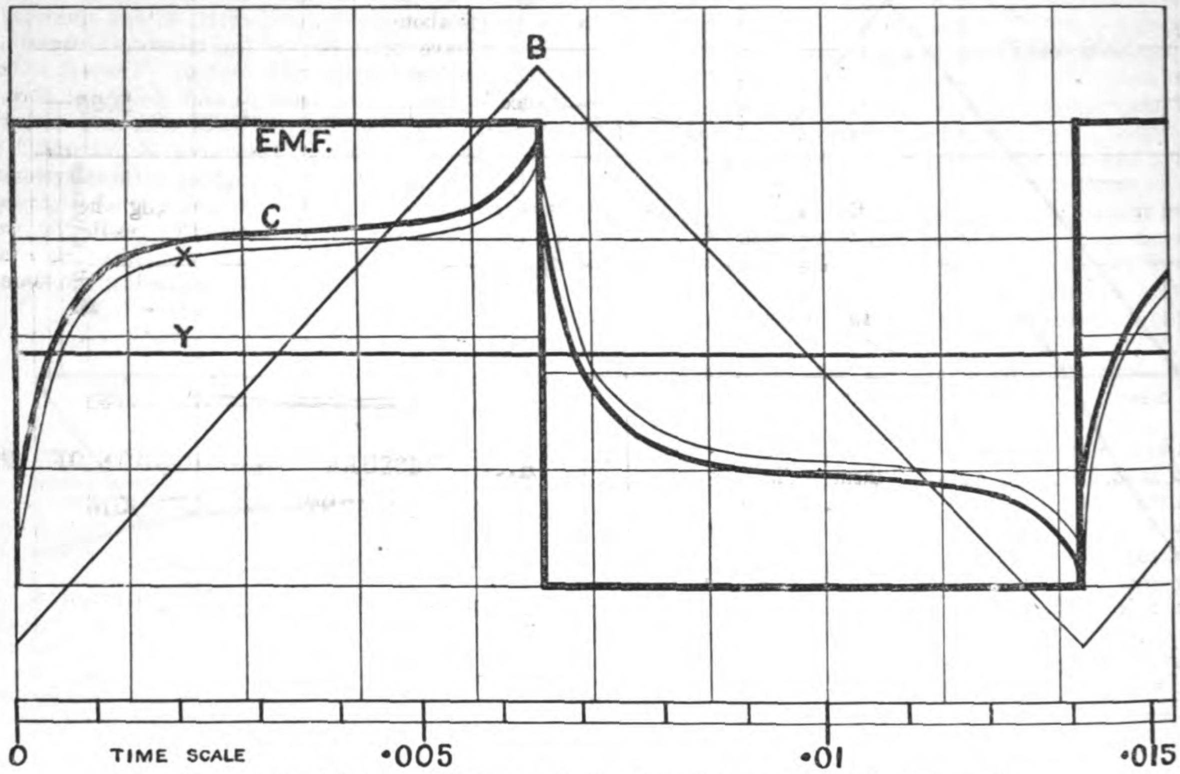

FIG. 12.—No. 2 Closed Transformer excited by alternating constant E.M.F. Output = 0

## ELECTROMOTIVE FORCE.

The side issues of discussions on electrolysis are of more general interest than the fundamental theories. Two papers on this subject were read at the Physical Society on Friday last, and in the latter of these, formulæ were introduced dealing with a number of different electromotive forces which may be assumed to be present in a cell. These, it was said, were "entirely a question of definition." The author suggested that perhaps there was, after all, no "seat of electromotive force" in a cell, in the same way that there is no difference of potential, according to the

Digitized by Google

ordinary use of the term, in a unipolar dynamo. Where is the seat of motive force" in a steam boiler?

If electro-chemists would only consent to drop electromotive forces and differences of potential, and try to account for the observed facts in the first place by simple current, resistance, and energy, there would be some chance that others might follow them, and that the teaching of elementary electricity might be modified. Let current be treated as the important thing, and resistance as that which impedes it. Then consider the volts as a loss or drop due to the resistanee; an effect, not a cause; a consequence, not a principle. Then you can call it "difference of potential," if you like such an academical expression, but "electromotive force" will have ceased to have any remnant of sense. The current and the resistance, according to all authorities, are *in* the conductor, so it is better to deal with them than with energy which (*pace* Mr. Sprague) is elsewhere.

Chemists do not hesitate to say that a chemical combination gives rise to heat, or generates or liberates heat. More broadly, it liberates energy. Why, then, should not a cell be said to liberate energy? Electrical energy is made up of two components, pressure and quantity. Or it may be said to generate power. Power is made up of pressure and current. Why take one of these only, and speak of setting up an electromotive force? It would be just as logical to say that a current is set up. To be exact, one must take both components into consideration, and speak of the energy. But it is difficult to deal with the energy of a circuit. Most students accept the conclusions of Prof. Poynting and the deductions of Dr. Oliver Lodge, while Mr. Sprague is quite justified in opposing them, because he cannot believe them, and he attempts to find another explanation. In the meantime, the student may leave open the difficult question of energy; and if he is to deal with one component, let current be that component. When a cell is on open circuit, it tries to generate a current and cannot. It only succeeds in giving an electrostatic charge to its terminals. Measure that electrostatically if you will, and estimate it in volts by all means. What do we want with electromotive force?

Again, you have a pair of terminals on an electric supply system. You have 100 volts between them. The current is ready to rush through the lamp when it is connected. Why need you say that, in the first place, there are 100 volts waiting for the lamp, and as soon as it is switched on these volts urge a current through the filament? Why not say that the magnetic field in which the armature of the dynamo rotates urges a current through the wire? You measure the amount of urging by noticing the relation between the current that will pass, with this urging, through a resistance. But if the current being constant, the resistance were reduced to a minimum, the urging would vanish also, but the current would still be there. Let the current, then, be the main thing, and of the first importance. Then consider the resistance, and leave the volts to take care of themselves. To teach electrical science thus, the text-books would have to be re-written. No matter, they need it.

Electro-dynamics would get on very well if current were put first and difference of potential followed as a result. Oersted's experiment of the deflection of a magnetic needle by a current can be clearly explained, and is generally taught without any allusion whatever to electromotive force. Such a needle was used by Wheatstone for driving clocks by suitably-timed impulses. A magnetic needle in a simple galvanometer coil may then be considered as the simplest form of electric motor. It is reversible; the motion of the needle in the coil will generate a current. But to account for the *reversed* action a totally different explanation is generally offered, and the cutting of lines of force by closed conductors is said to give rise to electromotive force, and, except under certain circumstances, to a difference of potential. Let it be granted that a dynamo and a motor are not designed on exactly the same lines, and that therefore a dynamo is not strictly reversible. But the want of complete reversibility is so slight that it has often been ignored; it consists of certain secondary effects. The general principle is reversible, why, then, should not the explanation be reversible? It is less difficult to imagine how magnetic induction sets up a current than to understand how "cutting" or "linking" lines of force can set up an "electromotive force." Every student is expected to accept this "explanation." The electro-chemists, too, stop the way with their "seat of electromotive force." Take the old paradox of a hundred cells, each giving one volt, and each of one ohm resistance; join them all in series in one "*couronne de tasses.*" One ampere will then flow through one hundred ohms. According to Ohm's law, there should be one hundred volts. Take a voltmeter, you who are so fond of electromotive force, and show us where and between which two points you will find these hundred volts. Take an electrometer, a proof plane, what you will; show us this difference of potential. If you take a proof plane and carry it round, you are cutting lines of force and are doing work. Carry it ten times round, and you will get a thousand volts. If you try and talk about cyclic potential you will drift into metaphysics.

This is not a question of what is the ultimate truth and the real accurate description, but one of ordinary every-day use of scientific terms, especially in relation to teaching. The idea of pressure or voltage must often present itself, but it is too often treated as the thing generated, and thus confusion arises, especially when it is necessary to locate it. It is easy to get into a tangle about cause and effect, we can generally observe effects and have to guess at the number of causes present. Let some teacher change this system. Current is there and resistance is there; work, energy, and power are there. It is no explanation to say that in some awkward cases there is electromotive force, but no difference of potential. Exactly the same thing happens when a magnet is thrust symmetrically through a ring. Dr. Oliver Lodge's cog-wheel analogy will readily give an idea how the magnetism pulls the current in the ring. You get the current and you have the resistance, but as the pressure is generated and used at the same place, you cannot point to the difference of potential. If electromotive force wants a seat, let it take a back seat.

## THE HIGH-PRESSURE TRANSMISSION OF POWER EXPERIMENTS AT OERLIKON.*

BY DR. OSCAR MAY.

As is already known, the Maschinenfabrik Oerlikon, in conjunction with the Allgemeine Elektricitäts Gesellschaft of Berlin, propose to transmit 300 horse-power derived from a waterfall at Lauffen, near Heilbronn on the Neckar, to Frankfort-on-Main, in connection with the Electrical Exhibition. This transmission is, of course, to be effected by electricity, and the power obtained is to be used both to run motors and lighting installations. The distance between the two places is not less than 112 miles, and the conductor will have to pass through portions of Württemberg, Bavaria, and Prussia. The allowable fall in potential being taken at 10 per cent., and the section of the copper at ·06 sq. in. (38 sq. mm.), we find that the current strength must be about eight amperes and the initial pressure about 27,600 volts. A pressure as high as this has not hitherto been applied for transmitting power. The nearest approach to it is the pressure of 10,000 volts in the Deptford mains, which, however, have not yet (February 5, 1891) started work permanently. It was consequently decided, having regard to the enormous length of conductor required and to the fact that pressures of 20,000 volts and upwards are no more dangerous than those of 1,000 volts (inasmuch as either may prove fatal if proper precautions are not taken), to carry on preliminary experiments to prove that currents at pressures hitherto unapproached may be made to satisfy all demands as to reliability in working, insulation and immunity from danger. The utilisation on the spot of natural sources of energy such as waterfalls and coal beds, and the construction of huge plants for the distribution of the power in a rational manner to various localities are advantages which must cause all objections to the high pressures to be overcome. The state of affairs is similar to that which obtained before the introduction of steam boilers, gas lighting, railways, &c., with this important difference that whereas these, in spite of rules and regulations, annually give rise to thousands of fatalities, the use of electricity of a "fatally high" pressure, although it has been employed for many years in several countries,

* From the *Elektrotechnischer Anzeiger.*

notably in Germany, has hitherto caused very few fatal accidents. The objection that the danger of a high pressure current increases with the length of the conductor is hardly likely to be brought forward now when conductors of such lengths as to prohibit their being continually watched throughout have frequently been erected without any dangerous results following. The installation carried out in 1882 by Marcel Deprez between Miesbach and the Münich Exhibition may be cited. In this case the Bavarian Government acted most liberally, as they erected the line under the direction of their telegraph engineer, Herr Behringer. Its length was 35½ miles, which was quite long enough to make it impossible to keep

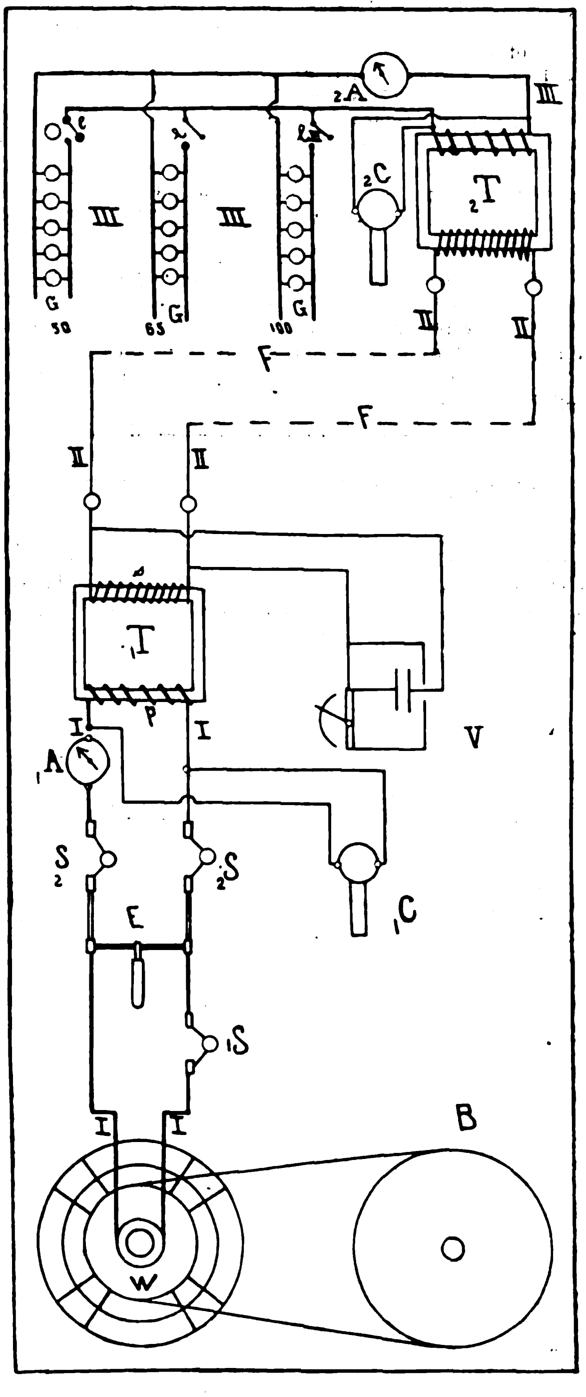

FIG. 1.—Diagram of the Oerlikon arrangements for Transmitting Power at High Pressure.

B source of power, W alternator, S safety fuse, $A_1$ and $A_2$ ampere meters, $T_1$ and $T_2$ transformers, $C_1$ and $C_2$ Cardew voltmeters, V Thomson electrostatic voltmeter, $G_{50}$, $G_{65}$, $G_{100}$ banks of glow lamps for 50, 65, and 100 volts respectively; F main conductor, I. primary, II. secondary, and III. tertiary, E and e switches

the whole of the line under constant supervision. It was worked at a pressure of from 1,000 to 1,300 volts, quite high enough to be considered "fatal," but no accidents happened.

For carrying out the Lauffen-Frankfort scheme, as in that between Miesbach and Münich, the consent and assistance of the local authorities, and in particular the postal and telegraph authorities was necessary. In order to obtain an impartial opinion on the practicability of the scheme, the committee of the Frankfort Exhibition invited these authorities to inspect the model plant erected by the Maschinenfabrik Oerlikon. This inspection took place on January 24th.

The arrangement of the test plant was as shown in the accompanying sketch (Fig. 1). The source of power was one of the electromotors in the factory, from which the pulley of the alternator was driven, the voltage given out by it being capable of regulation between 40 and 100 volts by altering the speed. In the Lauffen installation it is intended to use machines giving 4,000 amperes at 50 volts. In this respect the Oerlikon system differs from most of those employing alternators and transformers. This arrangement is regarded as decidedly cheaper, besides ensuring greater safety in working. From the alternator the low-tension current is led by the primary conductor to the tranformer $T_1$. The primary conductor is provided with a sensitive cut-out $S_1$, with a two-pole switch E and a two-pole Cockburn cut-out $S_2$. The working of these cut-outs was entirely satisfactory. The transformer $T_1$ was on Mr. C. E. L. Brown's system, and consisted of a core built up of sheet iron, on which are wound the primary and secondary windings in coils of circular section. The magnetic circuit is closed by two ⊔-shaped irons as shown in Fig. 2. Experiments have proved that for such high tensions vulcanite is an adequate insulator so long as it remains undamaged, but that as soon as a crack appears in it sparking takes place through the air which fills the crack. Some varieties of oils

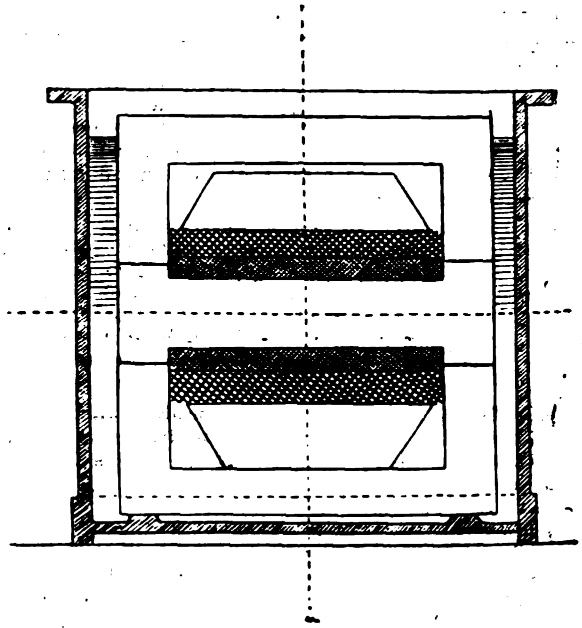

FIG. 2.—Section of the Oerlikon Oil Transformer.

have been proved to be as efficacious as vulcanite in the way of insulation; in order, therefore, to prevent a spark passing, the transformer as shown in the figure is enclosed in a chamber filled with oil, so that the oil fills the whole of the otherwise unoccupied space, and expels the air which might endanger the insulation. According to Mr. Brown, transformers constructed on this principle are perfectly safe up to pressures of 50,000 volts. The transformer multiplied the pressure 300 times. The currents supplied by the alternator in the present tests were at pressures of 40, 50, 65, 100, and 110 volts, so that in the secondary conductor pressures of 12,000, 15,000, 20,000, 30,000, and 33,000 volts were obtained. The conductor consisted of about ½ mile (1 km.) of bare copper wire of ·16in. (4mm.) in diameter, which was laid in four parallel lines on the same posts. The line was insulated from earth by Johnson and Phillips' oil insulators. The insulation was tested by allowing a hydrant to play upon the insulators. A 100-volt Cardew voltmeter was connected between the high-pressure secondary conductor and earth and showed no deflection. No leakage was observed during the recent snowstorms. In the experiments the number of insulators used was altogether 120. In the actual line, copper wire of ·16in. (4mm.) diameter will be used in spans of from 260 to 330ft., so that the test installation represented from 6¼ to 7½ miles of the actual line, so far as regards the insulation resistance of the insulators. The secondary conductor is led to a second transformer, $T_2$, which reduces the pressure 300 times, so that the current in the tertiary circuit is at the same pressure as that in the primary, which is fed direct by the alternator.

The tests of special interest were those relating to the action of the safety fuses, to the distance through which a discharge could take place through air, and to the working of a telephone circuit arranged parallel to the main wires on the same poles. In order to test the safety fuses, both a direct short circuit and the discharge current were employed. As may be seen from Fig. 1, the fuses were placed in the primary circuit. This was done, as it was impracticable to put them in the secondary, since the current strength in the latter is so small that it would have been necessary to use inconveniently thin wires. When the secondary conductor was short circuited by dropping across the two portions of it a short copper wire, the safety fuse was instantaneously melted. As is well known, the production of a momentary short circuit and the consequent melting of a fuse, both produce slight noises: in this case it was not possible for the ear to distinguish even the slightest difference in time between them. The extreme rapidity of the action is further shown by the fact that neither the secondary mains nor the short-circuiting wire showed signs of burning, although the arrangements adopted in the numerous tests made necessitated the contact being made at exactly the same spots both of the short-circuiting wire and the conductors. For producing an arc between the two conductors two wires were attached to them, so that their extremities were 22 mm. apart. When the pressure in the mains reached 18,000 volts. a momentary arc was started, which was immediately extinguished by the melting of the safety fuse.

To ascertain the influence of the secondary current on a telephone circuit, the latter was arranged on the same posts at equal distances from the two wires. It is to be noted that the secondary conductors were not arranged as shown in Fig. 1, but in four parallel lines, in order to get as great a length of wire as was possible in the limited space. The working of the telephone was quite satisfactory, although a slight noise, due to the proximity of the secondary conductors, could be clearly distinguished. The tests were only of a qualitative nature, but they clearly established that the working of the telephone between Heilbronn and Frankfort can be perfectly well carried on.

The action of the fuses proves that a short circuit such as may occur through the breaking of a pole or any other accident, will instantly cut off the current. The insulation under the most unfavourable circumstances that could be brought to bear (drenching insulators and posts with water) was practically perfect. It is impossible that any accident could happen through the breaking of a wire, and the installation can therefore be carried out with perfect security.

The experiments just described were made with an ordinary alternating current, but in the Lauffen installation it is intended to employ a totally new system depending upon what has been termed a "rotating" or "multiple phase," instead of an "alternating" current. This system is the invention of Herr von Dobrowolsky, head engineer of the Allgemeine Elektricitäts Gesellschaft. The current he uses is practically a combination of alternating currents, in which the phases are displaced with regard to each other; as a general rule three alternating currents are employed, though in special cases the number is increased. The currents are produced by a specially constructed alternator excited by a continuous current, the number of contact rings on the alternator corresponding to the number of currents used. When three currents are employed the angular displacement between each set of phases is 120°. The current impulses are made to follow one another in a fixed order, *e g.*, either 1, 2, 3; 1, 2, 3; 1, 2, 3, or 3, 2, 1; 3, 2, 1; 3, 2, 1, and they consequently produce a rotating magnetic field. A "rotating" current can therefore, unlike an "alternating" current be considered to possess a direction of flow. The difference between the three classes of current, "continuous," "alternating," and "rotating," can be clearly brought out by the action of a compass needle when surrounded by the conducting circuit. When the current is continuous, the needle takes up a position determined by the resultant of the earth's field, and that due to the circuit, and remains then at rest. If the current is alternating, the needle oscillates about the position it would take under the influence of the earth's field alone. When the current is rotating, the needle commences to rotate on its pivot. If the compass needle is replaced by an iron cylinder, a "rotating-current" motor is obtained, which has neither winding, collector, nor contact ring in its moving part, and the armature of which (if it may be so called) is not included in the circuit. Motors made on this principle, like continuous current motors, will start with a load, whereas alternating motors will only start from certain positions, even when without load. The "rotating-current" motors, moreover, are not larger than those for continuous currents for the same capacities, and they run perfectly quietly. In these respects they are distinctly superior to alternating current motors. They are extremely simple in construction, and work with perfect reliability; they are of course not synchronous, and can be regulated to run at very nearly constant speeds between light and full loads. As I am informed by Herr Dobrowolsky, the efficiency for a two-horse "rotating-current" motor was found to be 82 per cent. between outputs of $1\frac{1}{2}$ and $2\frac{1}{2}$ horse-power.

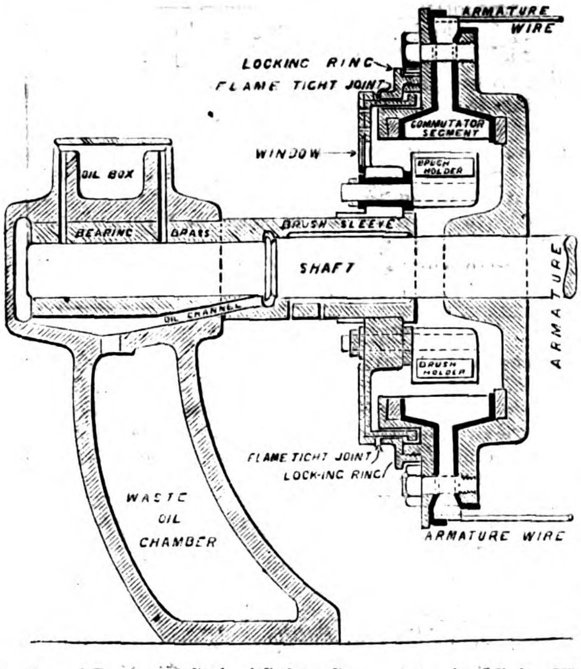
The "rotating current" transformer transforms all three currents together. It consists of three cores connected together at one end, the other extremity of each being attached to an iron ring. The apparatus, therefore, resembles an iron wheel with three spokes. On each core there is a primary and secondary coil. The whole arrangement is immersed in oil as above described. In driving motors each of the three conductors has to be connected to the coils of the motor fields. Arc lamps and incandescents are connected in equal numbers across each pair of the three conductors.

An installation on this system is in process of erection for transmitting water-power at Bülach to the Oerlikon factory. The available power is 400 to 500 horse-power, and drives four turbines, one of which serves as reserve. Each of these is coupled directly to a "rotating current" dynamo; the latter together supply 4,000 amperes at 50 volts. This current is transformed to one of 8 amperes at 25,000 volts, which is conveyed to Oerlikon, a distance of $13\frac{1}{2}$ miles (22 km.) by means of four conductors of bare copper ·16in. (4 mm.) in diameter, supported on Johnson and Phillips oil insulators. The loss in the wires is $1\frac{1}{4}$ per cent., one-eighth of that allowed for in the Lauffen-Frankfort installation. The Municipal Electric Works at Heilbronn, $12\frac{1}{2}$ miles from Lauffen, are also to be carried on on the same principle, and, in fact, the identical machines used in this case will be employed for the longer transmission to the Frankfort Exhibition.

From the above remarks, it will be seen that the employment of the means adopted will enable the project to be carried out with perfect security, and that its satisfactory working can be safely relied upon.

## DAVIS AND STOKES' SAFETY COMMUTATOR.

When motors are used in coal mines it is necessary, as a rule, to enclose the commutator in an air-tight casing. It is important from one point of view that the cubic contents of such a casing should be kept small, so that if an explosion takes place the surrounding metal will cool down the gases and thus prevent ignition of the surrounding gas. On the other hand, it must be remembered that a cubic inch of gas leaking into a closed chamber full of air will form an explosive mixture sooner if the contents of the chamber are small than if they are large.



Section of Davis and Stokes' Safety Commutator for Mining Work.

The accompanying illustration from the *Engineer* explains itself. A locking ring prevents the bolts which hold the commutator segments from turning, and the machine cannot be run until this is in place. If provision can be made for taking up the wear, for reducing the size of joint, and for preventing the accumulation of copper dust on the working surface of the commutator, this ought to prove a very useful arrangement.

# The Electrician.

**Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny**
**Editorial, Publishing, and Printing Offices:**
**SALISBURY COURT, FLEET ST., LONDON, E.C.**
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher, "THE ELECTRICIAN," Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "THE ELECTRICIAN" Printing and Publishing Company, Limited, and be crossed "Coutts and Co." All other letters to be addressed to the Editor.*

*All letters intended for insertion in "THE ELECTRICIAN," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

*"THE ELECTRICIAN" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

*"THE ELECTRICIAN" is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of "THE ELECTRICIAN" commence in May and November.*

## SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months. s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

*"THE ELECTRICIAN" offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS.

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## STEEL-PLATE PORTRAITS

*Of W. H. Preece, F.R.S.; Michael Faraday; Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S., and Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers), have been issued as Supplements to* "THE ELECTRICIAN." *A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar of Brown Ornamental Frames, price, post free, 4s. 6d.*

## THE UNITED STATES AND THE TELEGRAPHS.

The portly volume which represents the Annual Report of the United States POSTMASTER-GENERAL is this year of unusual dimensions, and, what is equally rare, contains much that will be interesting to English readers. Apart from the discussion of reduced rates to foreign countries, the vexed question of what constitutes a book packet, the abuses of the sample post, and so forth, the project of introducing a postal savings bank system is seriously entertained, on the lines followed by almost every civilised country outside the American States. The fact is instructive for those who labour under the impression that the United States is ahead of the world in everything that is popular and useful, and the further circumstance that a great part of the POSTMASTER-GENERAL'S Report is devoted to the still more instructive subject of postal telegraphy, which has not yet taken root in the States, affords another piece of evidence for the same class of people. Not only is the American Continent behind European countries in respect to the telegraph service, it seems to be powerless to raise itself to their level. Making every allowance for the exaggeration of partisanship—and there is a good deal of it in the pages now before us—it would seem to be the fact that the telegraphs in the States are not so cheap as they ought to be, and not as expeditous as in Europe. A scheme is now on foot, strongly backed by the post office authorities, for, at all events, cheapening the service; but so far from hastening it, the aim is confessedly to introduce what is neither more nor less than a "deferred service," to meet the real or supposed needs of the industrial classes. We may be sure

Digitized by Google

that such a limited reform as this would not satisfy the official mind, much less inspire it with enthusiasm, if anything more drastic or comprehensive were easily attainable. Indeed we are led to the conclusion that the telegraph companies are supposed to be in a position from which the United States Government has neither the courage nor the power to oust them, although supported by all the strength of the Knights of Labour, the Farmers' Alliance, Boards of Trade, Chambers of Commerce, and monster petitions signed by millions of enlightened citizens who, on paper, never want for anything long without getting it.

It is a curious and somewhat painful spectacle, rendered not less so by the lame, and, as we think, futile attempt at legislation to satisfy this great outcry. The authors of the "Bill to establish a limited post and telegraph service," describe it as a modest and harmless experiment, and we are not disposed to quarrel with it on that score. The remarkable thing about it is that so much fervid eloquence and acrimony have been brought to bear upon it. "To carry the postal system from pony-riders to stage-coach, and on to a railroad service, and to stop all further progress because 8,000 owners of telegraph stock oppose, is," we are told, "not in accord with the genius of our people or the spirit of the times." Again, it is grandiloquently asserted that "the measureless body of producers, in order not to be robbed by the speculators, need to be nearer the consumers; and the measureless body of consumers, in order not to be manipulated and robbed by the same speculators, need to be nearer the producers." This being granted, and we may readily grant it without endorsing the strong language, one naturally turns to the proposed remedy which is to do away with all this intermediate robbery by bringing the consumers and producers nearer together. Briefly stated, it amounts to this: Every post office where any telegraph business is likely to be done may be converted into a receiving-house for telegrams. If the telegraph companies extend their wires to these offices and pay the postal *employés* a commission for their services as telegraphists, then the telegrams handed in will go by wire; but if not they will be sent by post to the nearest telegraph office and thence to the telegraph office nearest to the place of destination, which, if it happens not to be a telegraph station, will again be served by post. For this service the State will charge two cents for postage, and a rate for the telegraph varying from 15 cents to 25 cents, according to distance—the present charges of the Western Union Telegraph Company averaging apparently 31 cents. The scheme, therefore, goes no further, at present, than to constitute the Post Office collectors for the telegraph companies, and to a certain extent their messengers. In return for this the Company will be required to take the post-office telegrams at lower rates.

We say that the project contemplates no more than this at present; but we can hardly suppose that its promoters intend to stop at that. Probably there is a covert intention of bringing down the rates of the Telegraph Company—for virtually there is only one—so that at length its acquisition by the State may be within measurable distance. Be this as it may, except for ulterior designs, the Company will probably not object to a multiplication of its agencies in the manner suggested, seeing that their establishment will dispense the Company from all further obligation to extend its wires to unremunerative districts, the criterion as to which will be accurately furnished by the number of telegrams collected at the postal receiving houses. It is just such a scheme as might have taken shape in this country twenty-one years ago, if Mr. Scudamore, instead of taking over the telegraph companies, had proposed to save them the trouble and risk of extending their wires, by opening in every rural district a post office for the receipt of *quasi* telegrams, to be despatched partly by post and partly by wire. That proposition, happily, was never before us; and we spent twelve or thirteen millions sterling in buying up the telegraph system bodily and doing what we liked with it instead. Had such a very "limited" extension of telegraphic facilities been offered us as is now being favoured by the American Postmaster-General, we might possibly have accepted it for lack of something better; but we should have found it hard to go into raptures over it as a heaven-inspired scheme for bringing the measureless body of producers nearer to the ditto of consumers, and robbing the plundering speculators of their prey.

We suspect that the real cause of all this vehement advocacy of a very tame proposal is, that it costs the State nothing but the trouble of proposing it, and the popularity which it may be capable of evoking in a country so sparingly provided with telegraphic facilities as are many parts of the United States. In this respect we can make no comparison with other countries that would not be perhaps unfair to the States. Its enormous area, the unequal distribution of its vast populations, and the varied character of their industrial pursuits, all combine to make it next to impossible for any private corporation to extend the advantages of telegraphy everywhere and to all alike. But all the greater reason for the State to step in, as it has done in Europe, and supply what is needed at the State's expense. That this is not an unprecedented proposition, even in America, is evidenced by the Postmaster-General's Report, on which we are commenting. In eloquent and convincing paragraphs, time after time, he dwells upon the social and economic advantages of having extended the beneficent arm of the Post Office to the remotest regions, and into every far off nook and corner, notwithstanding the fact that the service is conducted at a loss, and that the cost is defrayed by the more accessible, more populous, and wealthier areas. If it be true that the telegraph is of like importance to the welfare and well-being of the people—and the so-called Post Office Telegraph scheme is propounded on this assumption—surely it follows that the duty of providing it on the same terms is not less pressing and not less beneficial in its probable results. Whatever comes of the "modest" experiment now under discussion, a more ambitious and bolder one will have to be essayed by the United States Government sooner or later—and the sooner the better, we should imagine.

## REVIEWS.

**The Metal Workers' Handy Book of Receipts and Processes.** W. T. Brant. (London: Sampson, Low and Co.)

This book, published originally in America, appears at first sight to be an excellently arranged work upon a wide subject which has never been systemetically dealt with. It opens with chapters on the chemistry of metals, the properties of their more important compounds, and qualitative tests of alloys, &c. But, on reaching the fourth chapter, which describes numerous alloys and amalgams, the author begins to drift into discontinuous paragraphs, and the subsequent chapters on annealing and tempering, bronzing, casting, polishing, enamelling, plating, lacquering, soldering, &c., are merely collected from various sources and printed in the style of Spon's Workshop Receipts with even less attempt at classification than is to be found in those useful but unequal volumes.

Metal-working is an art which ramifies into numerous departments, and no one worker can ever have a thorough knowledge of them all. Where an art has not become a

science, there is nothing but skill and knowledge. The skill can only be acquired by practice; and the knowledge, until such books as this were compiled, was handed on traditionally from craftsman to apprentice. All that has been done has been to collect innumerable "receipts," to sort them out into a score of headings, and to make a book of so many chapters. Some systematic work has been done by Mr. Roberts-Austen, especially with reference to alloys, and the heavier subject of metallurgy has been raised to a science by Dr. Percy. Little is known about the changes which take place in tempering, and why soapy water is sometimes useful and sometimes disadvantageous; or if "blazing off" a spring depends on "letting down" by the heat of the flame, or on the chemical effect of the carbon in the mixture. Those who are practically engaged in working with metals rarely have time to inquire into reasons, and those who could usefully investigate the subject seldom have any workshop experience.

**Traite des Piles Electriques.** By DONATO TOMMASI. (Paris: Georges Carré.)

The literature of the primary cell must by this time have attained appalling dimensions, and a work giving within the compass of a single volume a reliable *résumé* of the history, theory and practice of the subject would be a welcome substitute for the numerous incomplete treatises which exist at present. Some such compilation could evidently have been brought out by M. Tommasi. He has, however, preferred to omit history and theory and devote himself mainly to a bald enumeration of the primary cells, single and double fluid, dry and wet, which have been devised by ingenious minds from the time of Sulzer to that of De Meritens. A mere enumeration, however, provided it be of manageable size, would have its uses, and the author, by the exercise of little more method and the excision of useless tables and extraneous matter, might have reduced the 600 pages of his book to half that number without in any way diminishing its value for reference purposes. To sanguine spirits, who fondly believe they have succeeded in inventing something new in primary cells, M. Tommasi's compilation may be safely recommended. If nothing similar is unearthed from among the three hundred and odd combinations mentioned by him, it may be reasonably concluded that the invention is novel.

**The Electroplater's Handbook.** By G. E. BONNEY. (London: Whittaker and Co., 1891).

This little book is one of the series which is headed by Sir David Salomons' well-known work. It is addressed to "amateurs and young workmen." The author is apparently unconscious of the fact that the ignorance among electroplaters, of dynamos, and indeed of electrical matters generally, is very remarkable. The machines which are made for the purpose, by manufacturers who turn out no other kind of dynamo, frequently show a complete want of knowledge of the principles of design, and they only find a market by the care which the salesman takes to find out what his customer wants; for the latter cannot, as a rule, make himself intelligible to the ordinary electrical engineer. About a dozen obsolete or unheard of dynamos are described, and two or three good ones. The prices of many of the tools and appliances are given. Only six pages are devoted to copper deposition, but the book contains a good deal of useful information and numerous receipes for plating solutions.

**Practical Inorganic Chemistry.** By EBENEZER J. COX, F.C.S. (London: Percival and Co.)

So long as our present examination system endures, books will be brought out which are "intended for the use of students preparing for the examinations." This little book dishes up in a palatable, *aide-memoire* style just those tests and analyses required to be assimilated for the time being by students preparing for the Science and Art Department examinations in elementary practical inorganic chemistry. The typography and general arrangement are excellent, and examinees desirous of passing by the path of least resistance will do well to study this manual.

## TRANSFORMER DISTRIBUTION.

BY G. L. ADDENBROOKE.

(*Concluded from page 601.*)

In the first portion of this article, which appeared last week, the great theoretical gain was pointed out which might be anticipated from the employment of transformers placed in sub-stations, a small transformer being used for supplying current to the system of secondary mains during the day and large ones being only switched on in the evening when the amount of current needed for lighting is largest.

There are, of course, a great many different ways varying in detail in which such a system can be carried out in practice, and the exact method which would be employed in any given case would largely depend on local conditions. Still, as all these variations would only be in points of detail, by taking one general case of an average character, as was done in the former portion of this article, and working that out carefully, we shall arrive at conclusions which, varied in a slight degree to meet particular cases, will be accurate within a small percentage of error, and quite sufficiently so for the purposes of the argument.

In the first place let us consider the transformer sub-stations themselves, and how they would be best situated. In this connection of course a good deal will depend on the distance apart at which it is decided that these transformer stations should be located, and also on the quantity of lighting which will have to be done in the area which they will supply. In any case they will not be very large.

I shall take it that such stations are designed for the supply of 100 kilowatts, as this is a convenient size, and if the transformer sub-station is constructed for this output, transformers could of course be placed in it for a smaller output if such alone is required. For such a station as this it would be necessary to keep always in circuit with the mains, after twelve o'clock at night, and during the day, a transformer of about 10 unit capacity, and a second transformer of the same capacity would need to be installed for use in case of an accident happening to the first. For the evening work an additional transformer capacity of 90 units would be necessary, and this might be conveniently arranged by having three transformers each of 30 units capacity. In addition to these it would also be advisable to install two further transformers of 30 units capacity each as a reserve.

The total transformer capacity therefore of such a substation would be two transformers each of 10 units, and five transformers each of 30 units.

Now a 10 unit transformer can easily be set in a space of eight cubic feet capacity, and a 30 unit transformer will not occupy more than about 15 cubic feet. The transformers in the sub-station, therefore, would altogether not occupy more than a space of 91 cubic feet, or, making some allowance for supports and intervals between them, say 100 cubic feet.

Now 100 cubic feet is contained in a space 5ft. long by 5ft. high by 4ft. deep. For the sake of accessibility it would be advisable to arrange the transformers partly on one side of the chamber and partly on the other, with a passage between; the switching and measuring instruments being situated on one end of the walls, say that opposite the entrance.

Now supposing that the transformers occupied a space of 2 feet deep at each side of the chamber, and that the passage down the centre was 3 feet broad, we should have a total cubical capacity necessary for the transformer sub-station of 175 cubic feet. But as a height of only 5 feet would be inconvenient, let us increase this height to 7 feet to allow proper head-room. Then the dimensions of the sub-station will be 7 feet broad by 7 feet high by 5 feet deep, and the total cubical capacity will be 245, or say, for convenience, 250 cubic feet, and as we have seen above, a sub-station of such a size would permit of the installation, with ample reserves, of transformers of sufficient capacity to supply current for 3,000 eight candle-power lamps burning at one time, each taking 33 watts.

Digitized by Google

This would permit of at least the equivalent of 6,000 such lamps being connected to the secondary circuits of the transformers.

Now in closely populated residential districts, such a substation would be about the size for the supply of all the houses situated within an area, measuring 300 yards each way. I shall therefore assume that the transformer sub-stations are situated about 300 yards apart in each direction, the secondary mains extending from them therefore will, on an average, of course, be considerably less than 300 yards in length, but in some cases may extend to as much as 400 or 450 yards where they have to be carried along one street and then down another at right angles to the first.

On this plan, supposing the transformer sub-stations were distributed evenly, we should get an average number of 35 such sub-stations to the square mile, and, according to the metropolitan returns, a square mile contains on an average a population of about 33,000 persons. The number of lights therefore provided in this scheme for each person is 3 eight candle-power lamps burning, or six installed, which would be a fair average for moderately wealthy residential districts, containing also a due proportion of shops and public buildings.

In poorer or in suburban districts, where the number of lights required from a given length of main would be less, the transformer sub-stations could, of course, be situated at greater distances apart, but as the secondary mains leading from them would be required to supply less current per unit length, they could be proportionately reduced in size, so that within moderate limits the arguments here used in dealing with more densely populated portions of ordinary towns will still apply with some slight modifications, or until, in fact, the houses were so far apart that it would be better to install a separate transformer in each. Of course, in practice, the two systems of placing transformers in houses and in sub-stations would be employed together, the transformers at first being situated in the houses until the number of houses lighted in any area became sufficiently numerous to warrant the adoption of the sub-transformer system.

In densely populated districts, however, such as the central portions of large towns, it would be probably cheaper to introduce the sub-transformer system in all the principal streets from the beginning, in order to avoid the expense of twice taking up roads paved with asphalte or wood blocks.

Coming to the economics of this sub-transformer station system, it will now be advisable to endeavour roughly to ascertain how the cost of such a system compares with the present methods of placing transformers in each house, or with the supply of current at low pressure from central stations working on the direct current system.

It goes almost without saying that the character of the secondary mains emanating from the sub-transformer stations will be almost precisely similar to those which are used with a low tension direct current system of supply, the only difference being that, as the transformer sub-stations are situated fairly close together, it would never be necessary to employ copper conductors of very large section, especially as the secondary mains from the various sub-stations, would be connected together at various points so as to equalise the pressure on the mains all over the system as far as possible. This is leaving out of the question the propriety of having more than one primary connection to each transformer sub-station, but this is an engineering matter which would have to be dealt with in accordance with the local circumstances of each particular case.

The first point to consider with respect to this low tension system of secondary distribution is whether it should be on the two wire or three wire plan. For districts where the population is dense, and there are a considerable number of houses supplied from the mains, no doubt the three wire system is much the most advantageous; and in the case which it is proposed now to present it will be assumed that the three wire system is used, and that secondary mains are connected to two transformer sub-stations situated 300 yards apart.

Now, as we have already seen, the maximum current which will ever be supplied from any sub-station at any time will not exceed the equivalent of 3,000 eight candle-power lamps taking 33 watts each. That is, supposing for argument's sake, that the lamps installed need a pressure of 100 volts, the maximum current sent out from the sub-station will be roughly 1,000 amperes. I shall also assume that the voltage is not to vary more than one volt on either side of the standard pressure anywhere on the secondary system. The maximum loss therefore between the sub-station and the most distant lamp must not be greater than two volts during the hours of maximum lighting. At a pressure of 1,000 amperes per square inch section of conductor on the two wire system the loss of pressure is about one volt for every 20 yards the mains extend. In the present case I shall not consider the mains as extending more than 200 yards on an average, because they would, at about that average distance from one substation, be joined to mains coming from another station, so that, except for purposes of regulation, current would very seldom have to flow over distances of more than 200 yards on the secondary mains.

On the two wire system, therefore, and according to the basis given above, the loss in the secondary mains would be in 200 yards, 10 volts, supposing that the mains were reduced in size as they extended further from the sub-stations, so as always to keep the current density at 1,000 amperes per square inch, but on the three wire system this loss would be reduced to about one-third, or let us say to 4 volts in the 200 yards, the same amount of copper being used. But it is not quite practical to put the question in this form, because it would be very inconvenient to constantly reduce the size of the mains as they extended from the sub-station, and in practice it would probably be found easiest to run them of the same section or nearly the same section direct from substation to sub-station, or at any rate to arrange so that the section of copper in the portions of the districts furthest from the sub-station should be so large that the current passing through such portions of the main would not equal more than 500 amperes to the square inch during the hours of maximum lighting.

At any rate, a little consideration of the above figures will show that if a densely populated area 300 yards each way were lighted from transformer sub-stations situated about 300 yards apart and with a secondary system of distribution on the three wire principle with the secondary mains connected together at various points, the secondary mains branching from any one sub-station would not in the aggregate equal much more than one square inch of copper in section, or $2\frac{1}{2}$ square inches for the three conductors, and the loss over the whole system would not be greater than 2 per cent., or 1 per cent. on each side of the standard.

As probably at least four sets of mains would branch from each sub-station going in different directions, and as, moreover, branches would again be taken from these mains down side streets, it will readily be apparent that the copper sections of all this system will be of very small areas, that they will not take up much room under the street, and will at the same time be easily laid.

Such systems of mains can of course be laid, using any of the methods which have found approval with engineers so far, but it is doubtful if anything much better and cheaper than the system of drawing cables into cast iron pipes can be devised. It must be borne in mind that the amount of insulation which will be required on these cables will be very much less than what is now necessary for high tension cables; so that the secondary cables themselves would be very much cheaper section for section and length for length. With a transformer sub-station system the length of the primary mains would be greatly reduced, and also, consequently, their cost. Even at present it is always necessary to lay down, for facility in working, considerably larger pipes or culverts than are actually necessary in order to carry the primary wires. In fact, when the expense of taking up the streets and opening up the ground is considered, the making of some sort of culvert, and the covering of it up again and making good the roadway, the difference in cost of one section of pipe or culvert over another, within moderate limits, is a matter of very secondary consideration, so that I think

Digitized by Google

that it might be reasonably taken that the cost of laying secondary mains from transformer sub-stations throughout a district would not be more than would have to be spent on laying primary mains throughout that district for the supply of the houses therein by converters installed in each house separately.

In this comparison I have said nothing about the reduction in transformer capacity obtained by using sub-stations, and, again, the greatly decreased cost per unit of large transformers over small ones; and, further, the immense saving in carrying secondary wires direct into a house without any special safety appliances beyond the ordinary switch and cut-out, over the introduction into each house of primary wires with all the elaborate precautions necessary to protect them, besides high tension switches and cut-outs, the cost of which is out of all proportion to those needed for currents at a pressure of only 100 volts.

It will thus be seen that the transformer sub-stations system compares directly and most favourably with the supply of direct currents at low tension from central stations, while it has the advantage that the central station or stations themselves may be situated at any distance which is most convenient from the centres of supply, and can be located where the smoke made will be no nuisance, where the delivery of coals will be cheapest, and where, in most cases, water can easily be secured for condensing engines. Although, therefore, at present it may seem in many ways that the advocates of low-tension have scored largely against their alternating-current opponents, and that much reconstruction work must be done in order to bring the economy of the alternating and transformer system into comparison with that obtained with low-tension direct-current stations, yet, in the end, if such a system as that I have indicated above is adopted, both in actual first cost, in convenience of working, and in safety, the alternating system will not only compare favourably with, but will surpass its rivals.

## PHYSIOLOGICAL EFFECTS OF ALTERNATING CURRENTS OF HIGH FREQUENCY.

BY ELIHU THOMSON.

The following is an abstract of a Paper of which an advance proof was kindly sent us by Prof. Elihu Thomson:—

In connection with an experimental investigation of the properties of alternating currents of high frequency, and the phenomena which they present, it had occurred to me that it would be desirable to obtain data concerning the physiological effects of these currents as compared with the effects of currents of ordinary frequency. I had constructed a machine on the type of my new alternating dynamo, accounts of which were published some time last year. In this machine an iron mass only is revolved, the central portion of which carries projections which pass near to the coils in which the currents are induced, which may be termed the armature coils, carried on the inner face of a laminated structure, in turn supported by the outer frame work of the machine. The machine, with 100 armature coils and a speed of 5,000 revolutions per minute, gives a little over 8,000 alternations per second. The publication of brief notices of some of the results obtained in the operation of this machine led Dr. Edward Tatum, of Yonkers, N.Y., to correspond with me with the view of finding out whether I had intended to conduct any physiological experiments with the currents, and indicating his desire to experiment in this direction if the machinery for obtaining the currents could be placed at his disposal for a short time. Accordingly the machine was sent to Dr. Tatum some time last fall, and was used by him in making a series of experiments, the results of which cannot fail to be of the highest interest to electricians and physiologists.

"The most definite and perhaps the most striking, as well as physiologically instructive result has been in regard to the fatal efficiency of such rapidly alternating currents. When the circuit is formed through the head and body (of dogs) death occurs in the same manner as with other sources of current (which are made strong enough to kill by a closure lasting not more than two or three seconds)—that is, by primary arrest and paralysis of the heart; but, taking the fatal efficiencies of different sorts of currents as inversely proportional to the current strengths required to kill under otherwise similar conditions, a rate of 4,500 per second is not only far less efficient than rates of a few hundred, but it is distinctly less efficient than a continuous battery current. It is remarkable that rates of 300 and of 120 alternations per second are fatally efficient at very nearly the inverse ratio of the numbers; but, still more remarkable, that the very highest rates should also present a strikingly near approach to a similar ratio. It must be noted, however, that no such ratio can hold throughout the whole range, for 36 alternations per second (from the same machine as furnished 120 and the 300 rates) are again distinctly less efficient than 120—something like two-thirds as efficient."

Dr. Tatum goes on to point out that a potential of 450 volts was survived at the high rate of alternations, and the fatal current reached only at 495 volts, while 45 volts at 120 alternations similarly applied to the dog suffices to pass a fatal current. Dr. Tatum also determined the ratio of pressure or potential to current in the dog just after the cessation of respiration, using in rotation, twice repeated, first, a continuous pressure or potential; secondly, an alternating one at a rate of 120; and, thirdly, an alternating potential at a rate of 4,500 per second, at about 100 volts, and states:—"This ratio was so uniform (the extremes observed differing by less than 3 per cent.) as to dispose of any suspicion that the high-period currents distributed themselves essentially different from others in the animal's body.

". . . In regard to the physiological as distinguished from the fatal characteristics of the high-period machine, I am only able to state the results in terms of pressure instead of terms of current, as I should prefer. The limits of voluntary toleration for alternating pressures (applied with sponge electrodes) seems to depend very little on the frequency of alternation. For all the frequencies I have mentioned the limit has been found between 10 and 15 volts for applications about the face and head, and between 40 and 50 volts between the hands, without any decided preference in either case for one rate more than another.

"The cause of the pain which limits voluntary toleration seems to be in all cases chiefly in the muscular contraction produced. At 4,500 this muscular contraction is usually free from the thrill experienced even at 300; resembling, on the temples, nothing I can think of so much as firm pressure with the knuckles.

"The cutaneous nerves are distinctly less painfully affected at the high rate. The visual mechanism cannot be excited at the high rate, even by a pressure of 15 volts, so as to cause a sensation of flashes of light, although two or three volts similarly applied at 120 alternations causes such flashes very energetically. Sensations of taste are also absent."

In presenting these results I take occasion to express my sincere regret that his ill-health has prevented the continuance of the work in the direction laid out by the Doctor himself, and to express, also, the hope that he may be able to take up the further investigations at some other future time.

## THE FRANKFORT INTERNATIONAL ELECTRICAL EXHIBITION.

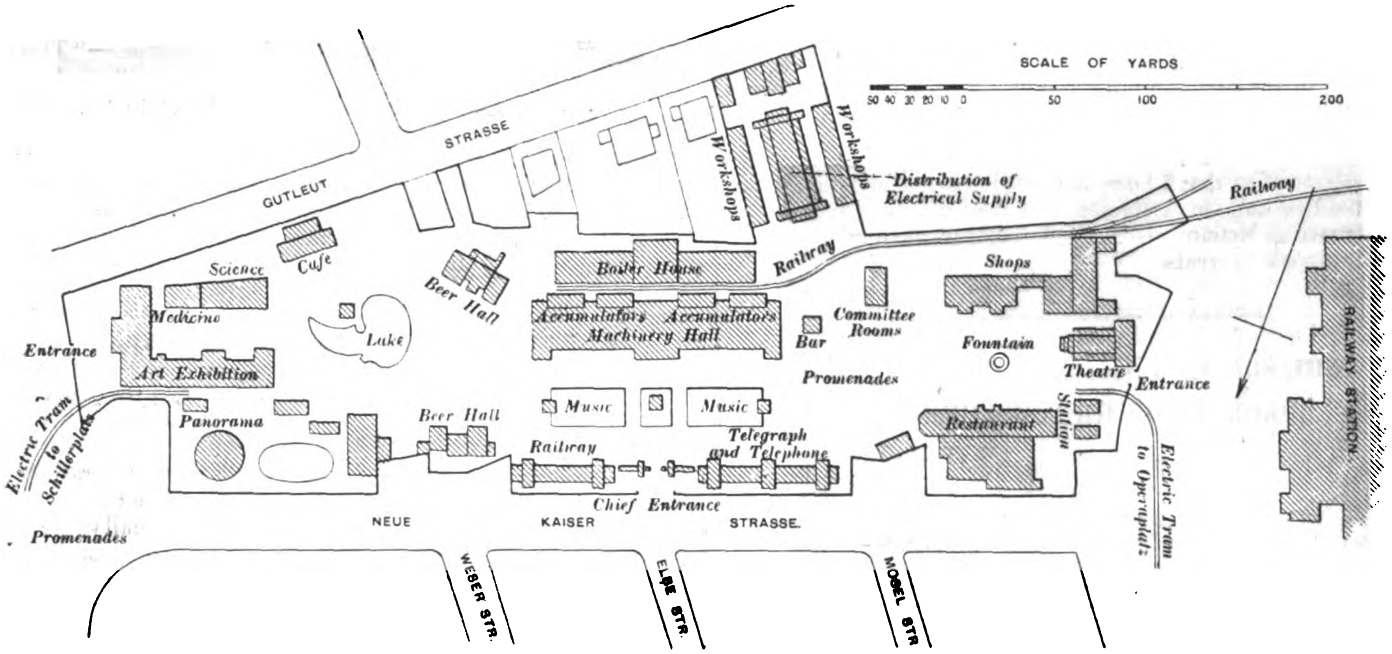
The great attraction afforded by the department of the Paris Exhibition dealing with electricity and its industrial applications seems to have suggested the idea of holding an International Electrical Exhibition in Germany, and the scheme found all the more favour here from the fact that at Paris the German electrical industry was not adequately represented. A proposal to undertake the Exhibition last year fell to the ground, as the notice given was too short, and it was accordingly determined to defer it to 1891. Considerable anxiety was naturally felt lest

Digitized by Google

the great firms and the capital itself would look with jealousy on an Exhibition of this magnitude held away from Berlin. Such fears have proved groundless, and the decision of Frankfort to undertake and promote the Exhibition has been received on all sides enthusiastically.

The easy access to this town and its air of wealth and convenience have always made it the resort of numerous visitors in the summer, and English people staying at Homburg greatly add to the number by their almost daily visits. It is certain that the first sight a visitor to Frankfort this year will have will be the Exhibition, for it lies exactly opposite the railway station. The site chosen for the buildings is very advantageous. The railway station, one of the finest and most imposing on the Continent, is separated from the chief part of the town by a large open piece of ground over which the lines used to run to the old railway station, which was further in the town. This space happened, luckily, this year to be still unoccupied, and the owners have liberally placed the south side at the disposal of the promoters of the Exhibition. Here the buildings are rapidly rising, and some 300 workmen busily engaged. The exhibits will, as far as possible, be classified not so much according to firms, but according to the technical head under which they fall. Thus, there is a great machinery hall, forming the central power available from this source will be 400 H.P. A building on the right of the machinery hall, but lying further back, will be devoted to the display of the various methods by which the electric current is supplied in the streets of a town. Other buildings on the right of the machinery hall are devoted to materials and appliances for electric lighting. There will be seven shops electrically lighted, and a theatre, where the visitor will have the opportunity of hearing operas telephoned from Wiesbaden and Munich, and of course from the opera here.

There will be four different kinds of electric railways connecting the Exhibition with the Opera House, the Schiller Platz, which is in the centre of the town, and the Main. A tower will be erected by the river, on which large reflectors and powerful electric lights will be provided. Excursions on the river by electric launches will add to the numerous entertainments provided for the visitors. A large grotto, lighted with glow lamps, is also being built. A captive dirigible balloon is announced, which from its novelty is sure to awaken considerable interest. It is to ascend to a height of 600 metres, and experiments are being made for preparing the necessary hydrogen by electrical means. The electrical transmission of power will be strikingly illustrated by the application of water-power developed at Lauffen, on the Neckar, for driving machines,



Ground Plan of the Frankfort Electrical Exhibition.

part of the Exhibition, behind which the boilers will be found in a separate house. Telegraphy and telephony, model electric light installations, electro-chemistry, and all possible branches of electro-technology will have their separate departments and in many cases separate buildings. The structures are entirely of wood, and those that are completed or nearly so, strike one as particularly graceful, and well adapted for their purposes.

The machinery hall is very nearly ready, and preparations are already being made and foundations laid for the reception of the machines. In the boiler-house behind four boilers are now being laid down, three from Paucksel, of Landsberg, and one from Berningshaus, of Dursburg, the last working at a pressure of 12 atmospheres. There will be in all 20 of different kinds, with 2,400 square metres heating surface. The total power developed by the motors in the machinery hall will reach over 4,000 H.P., the separate motors varying from ½ H.P. to 600 H.P. The number and variety of dynamos shown at the Exhibition promises to be very large. Altogether, in the machinery hall and boiler-house, 60 firms will be represented, of whom 22 will exhibit dynamos. The direct-current machines will require 600 H.P., while the alternators will require 400 H.P. Accumulators will be found at the back of the machinery hall. Six firms are exhibiting, and the or giving electric light at the Exhibition. The distance is about 100 miles, and the water-power at Lauffen 300 H.P. Of this only 2 per cent. is to be lost in the transmission. A pressure of 20,000 volts will be used. The cable will be made by Siemens Bros., of London. The interest which is taken in this particular project in the highest quarters has just been shown by a gift of 10,000 marks from the Emperor himself, and a similar one from the Frankfort Chamber of Commerce. In addition, power will be electrically transmitted from Offenbach—about five miles—and from a steam engine in the Palm Gardens, at the north side of the town. Twenty-two workshops of different trades are being set up in the Exhibition, having their lathes and other machines driven by electric motors, varying from $\frac{1}{20}$ H.P. to 6 H.P., thus showing the possibility of supplying small power cheaply and conveniently to the mechanic and others to whom a steam or gas engine would be inconvenient, or out of the question.

The list of names forming the organising body numbers more than 150. The honorary presidents are Finance Minister Dr. Miguel and Herr Heldberg, the Postmaster-General of Frankfort. Then come as honorary members Dr. Werner von Siemens, Professor A. von Waltenhofen, Professor Silvanus P. Thompson, Marcel Deprez, and Thomas A. Edison. The chairman of the

Digitized by Google

committee is Herr Leopold Sonneman, and the honorary secretary Herr Carl Stiebel.

The Exhibition is to be opened on May 16th, it is hoped by the Emperor, and will close towards the middle of October.

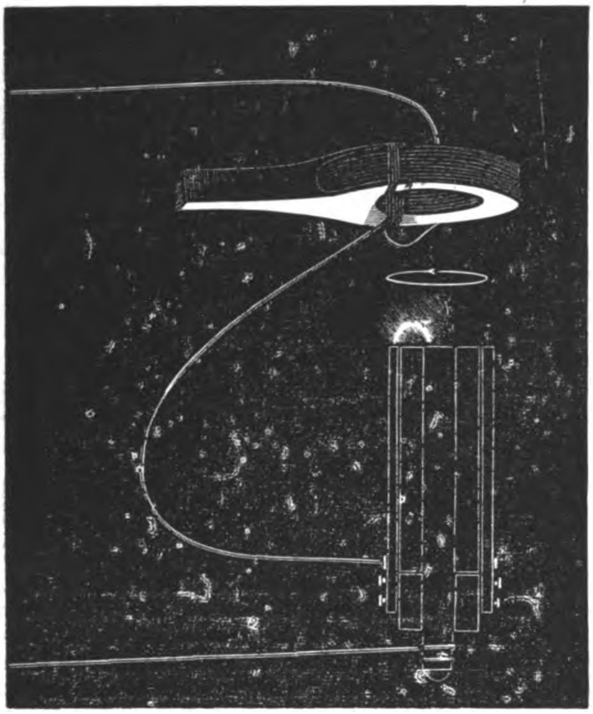
The accompanying plan will give some idea of the size and relative positions of the buildings. It has been impossible, of course, in this preliminary article to more than mention some of the more important features of the Exhibition; but we hope, later on, to deal with those separately and at greater length.

## AN EXPERIMENT WITH THE ELECTRIC ARC.*

BY WM. STANLEY, JR.

Prof. Thomson's Paper on arc lights calls to my mind an experiment in the laboratory some time ago with an alternate current arc, which presented a very beautiful illustration of the deflecting power of a strong magnetic field. Inside a hollow carbon tube about 2in. in diameter was placed an ordinary seven-eighths inch carbon, separated from the tube by about one-quarter of an inch air space all around except where it was held in place by an insulating ring, as shown in Fig. 1. A coil of wire connected in series with the carbons, and with a constant current transformer by a flexible cord, was mounted to a handle for convenient handling.

If an arc was started between the inner carbon and the concentric tube, and if the coil was approached parallel to the face of the carbons, the arc revolved around the centre carbon after the manner of a pin-wheel. Reversing the face of the coil—that is, the direction of the field threading the arc—caused an instantaneous reversal in the direction of rotation of the arc.



F.G. 1.—Rotation of the Electric Arc.

When the coil was placed around the concentric carbons and near the arc, the latter became distorted, as shown in Fig. 2, while it continued to revolve about the axis of the coil.

Many modifications will suggest themselves to any one attempting the experiments. One point observed by Prof. Thomson was very clearly evidenced, which was that, when the arc was whirling (and it might be made to whirl so rapidly as to appear continuous about the centre carbon), the potential required to maintain a constant current rose enormously, so high, in fact, that the transformer was often unable to supply the demand for increased potential necessary to maintain the arc, although it was constructed to deliver a constant current from short circuit to 800 volts; as a consequence, the whirling arc would repeatedly blow itself out with a loud report if the deflecting coil was approached very near the seat of the arc. Of course, the arc revolves and becomes distorted, because of the reactions between the field produced by the coil and the weaker field about the arc, and an apparent continuous effort exists between the two fields to coincide or join together. Many beautiful lecture and

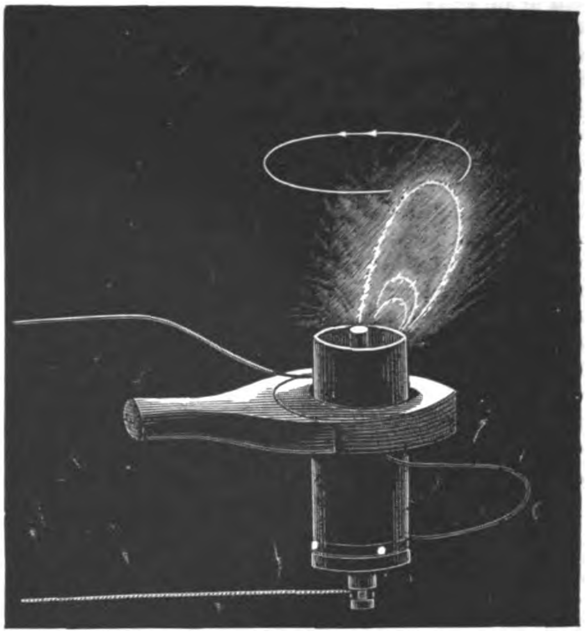


FIG. 2.—Simultaneous Repulsion and Rotation of the Arc.

demonstration experiments for classes may be obtained from this same simple apparatus, which, of course, may be operated with equal success by either alternate or direct currents.

* From *The Electrical World* of New York.

## NOTE ON THE DESIGN OF DYNAMOS.*

BY FELIX MELOTTE.

The method of calculation which I propose to describe does not lay claim to any novelty in principle. It is only the result of my endeavours to arrive at the result in the simplest way from a given set of initial conditions. I shall not concern myself with the choice of the proper type of machine, but suppose this already decided upon from economical, or other reasons.

There is no denying that the design of a dynamo presents considerable difficulties. The constructor should produce an economical machine; but we may understand by economy either high efficiency or cheapness. These qualities are each highly desirable, but it is difficult to unite them in the same dynamo.

When it is determined to design a dynamo of a given horse-power, certain initial conditions are usually imposed, such as the efficiency, the number of turns, and the voltage or the output in amperes. From these data we can deduce successively all the dimensions of the machine if, at the proper time and place, we make use of certain coefficients, and other results of experience. The result may not be altogether satisfactory at first, but is so after a few trials.

The number of revolutions determines the diameter of the armature if the peripheral speed is fixed. This speed should be as great as possible, as the useful power increases with the speed; but it is necessary to keep within the limits determined by the relation of the centrifugal force to the strength of the revolving material. Generally 12 to 15 metres per second may be taken as the proper peripheral speed for drum or ring armatures. For flat rings and discs the speed may be as great as 25 metres per second, but for ordinary armatures 15 metres per second is a good limit. Taking this number we have, if N is the number of revolutions per minute, and D is the diameter in metres of the armature,

$$D=\frac{15\times 60}{\pi N} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1).$$

The next question is to determine the size of the wire and the number of convolutions on the armature. In choosing these data we may be guided by the following considerations. The fewer the

* Abstracted from a Paper read before the Montefiore Institute, Old Students' Association, in January, 1891.

Digitized by Google

number of turns the less the reactive influence of the armature, and the less the loss in wasteful heating, so that the section of the wire which can be used is relatively small. On the other hand, the diminution of the number of turns necessitates a corresponding increase in the flux of magnetic lines, and in consequence an increase of section at every part of the magnetic circuit. This involves an increase in weight of the castings, of the iron, and of the copper required for exciting purposes.

It is well to adopt a current density of about four amperes per square millimetre. This rule is not rigorous, and admits of wide variation, but we shall adopt it as a first approximation, and shall assume that the wire is round in section and has a diameter $d$. If then D is the external diameter of the iron, we have for $n$, the number of convolutions,

$$n = \frac{\pi (D + d)}{d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

For machines of small output it is possible to wind several layers of conductor on the armature core, especially if the voltage is high. On the contrary, for powerful machines only one layer of conductors is used.

The number of turns being fixed, the next thing is to calculate the data of the magnetic field. If $\phi$ is the magnetic flux proceeding from one pole, a single armature conductor in the course of a revolution cuts 2 $\phi$ lines. The flux in each half of the ring is $\frac{1}{2}\phi$, and this is sometimes positive and sometimes negative, the total change being $2\phi$. The electromotive force per conductor is, therefore,

$$E = \frac{2\ N\ \phi}{60} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

or, if we reduce E to volts, and multiply by $n$ (the number of turns in series between the two brushes) to get the total electromotive force, we have, on the assumption of a uniform field,

$$E = \frac{2\,N\,n\,\phi}{60}\,10,^{-8} \text{ or } \phi = \frac{E.60.10^8}{2\,N\,n} \quad . \quad . \quad . \quad (4).$$

The same expression is true of drum armatures, only $n$ refers no longer to turns, but to conductors counted separately round the periphery of the armature. For multipolar machines the equation is still true if we substitute for the factor 2 the number of poles in the machine in question.

As regards the proper induction density to adopt, it is well to choose values lying between 12,000 and 18,000 lines of force per square centimetre. These values refer naturally to the space actually occupied by the iron. Thus for iron wire cores, as in the classical Gramme ring, it is necessary to remember that the space filled by the metal is only about $\frac{3}{4}$ of that which it occupies, while for sheet iron discs from 10 to 15 per cent. of the space is occupied by the insulating medium, and this must be taken into account.

The axial length of the armature varies according to the type of machine. In drum armatures it is greater than the diameter (twice or even more), while in ring armatures the two dimensions are about equal.

It is desirable to avoid too great an induction density in the air space, for an abnormal amount of excitation will otherwise be needed. According to M. Amoux it is best to design the polar surfaces so that the induction density in the air space is from 2,500 to 4,000 lines per square centimetre.

The radial thickness of the armature core should not be too small, or else the length of armature conductor for a given section of iron will be too large, and the wasteful heating will be increased. These losses, increased by Foucault currents and hysteresis, cause a heating of the armature, the harmful effect of which on the insulation can only be prevented by providing a radiating surface sufficiently great to dissipate the heat by radiation and convection.

Mr. Esson, in his Paper on "Some Points in Dynamo and Motor Design,"* gives an empirical formula connecting the elevation of temperature C° which an armature exhibits when constantly absorbing W watts. This formula is

$$C^0 = \frac{225\ W}{S} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where C° is in degrees centigrade, and S is the cooling surface in square centimetres. The coefficient 225 relates to ring armatures whose peripheral speed is about 15 metres per second.

These different considerations must influence the choice of the length of armature conductor. Let $\lambda$ be the length of an armature convolution, $n$ the number of convolutions in series between the brushes, $s$ the section of the wire, C the coefficient of conductivity, and $r$ the resistance of the armature. Then

$$r = \frac{n\,\lambda}{2\,C s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6).$$

The voltage lost in the armature is A times this, where A is the current in amperes. In the engine-room, where the temperature is often as high as 30deg., it is not at all unusual for the armatures to attain a temperature of 65deg. At this temperature the coefficient of resistance is nearly two, and the coefficient of conductivity is ·5. The specific resistance of copper at 0deg. is 1·62 microhms per cubic centimetre. By substitution, and by expressing $n \times \lambda$ in metres (denoted by M) we have for E the loss in volts,

$$E = \frac{M\ A}{50\,s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7).$$

This gives the loss in the armature, and if it does not differ too much from what is assumed to take place, we can adopt it provisionally and proceed with the calculations.

The next thing to do is to determine the conditions relating to the production of the magnetic field. Here we shall follow the Hopkinson method. The leakage coefficients must be determined from experiments on analogous machines, and the relative section of the different portions of the magnetic circuit can then be calculated. The lengths of these different portions are partially determined by the type of machine chosen, but there are certain limits between which variations are possible. Theoretically the shortest possible circuit is the best, but it is necessary that the magnet limbs should be more than a certain length in order that their cooling surface should be sufficient. From 10 to 12 square centimetres of cooling surface are required per watt, and it is necessary that the current density should not exceed two amperes per square centimetre. Mr. Esson has given the formula

$$C^0 = \frac{355\ W}{S} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

expressing the heating in degrees centigrade in terms of the number of watts divided by the dissipating surface in square centimetres. The constant 355 is supposed to apply to bobbins of medium thickness, and my experience goes to show that the formula is practically correct.

Having determined the dimensions of the different parts of the magnetic circuit, the Hopkinson method must be applied to determine the number of ampere turns needed to produce the required magnetic flux. The Hopkinson equation, applied to a single magnetic circuit, is equivalent to

$$n\,a = \frac{1}{1{\cdot}256}\,\Sigma\,\frac{\phi\,l}{\mu\,s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where $n$ is the number of turns, $a$ the current in amperes, $\phi$ the magnetic flux, $\mu$ the permeability, $l$ the length, and $s$ the section of the part of the magnetic circuit considered.

This application of the equation gives the number of ampere turns, and from this we can get the section of the wire by use of the formula

$$E = \frac{M\ A}{50\,s}, \text{ or } s = \frac{M\ A}{50\,E} \quad . \quad . \quad . \quad . \quad . \quad (10)$$

The product M A is known, for it is the product of the total number of ampere turns, multiplied by the length in metres of an average convolution round the magnet limbs. We also know E, the electromotive force at the terminals of the dynamo. It is thus easy to calculate the section of wire to use.

It is seen that this section only depends on the number of metre-amperes required, and on the disposable electromotive force. The number of ampere turns does not vary. If the number of convolutions is increased, the resistance augments and the current diminishes in the same ratio. As the temperature of the magnets is generally a little lower than that of the armature, the number 50 in the denominator of the expression for E should be increased to 52 or 53.

In what precedes we have not taken account of the reaction of the armature currents on the field. In order to counterbalance this reactive influence it is necessary to supplement the exciting current by 25 to 35 per cent. in ring armatures, and from 10 to 15 per cent. in drum armatures. Some of the preceding calculations will be modified owing to the neglect of this reactive influence of the armature. Thus we must take a number of metre-amperes 30 per cent. greater than that previously found, and by substitution for M A in the formula $s = \frac{M\ A}{50\,E}$ we can find the proper section of the wire.

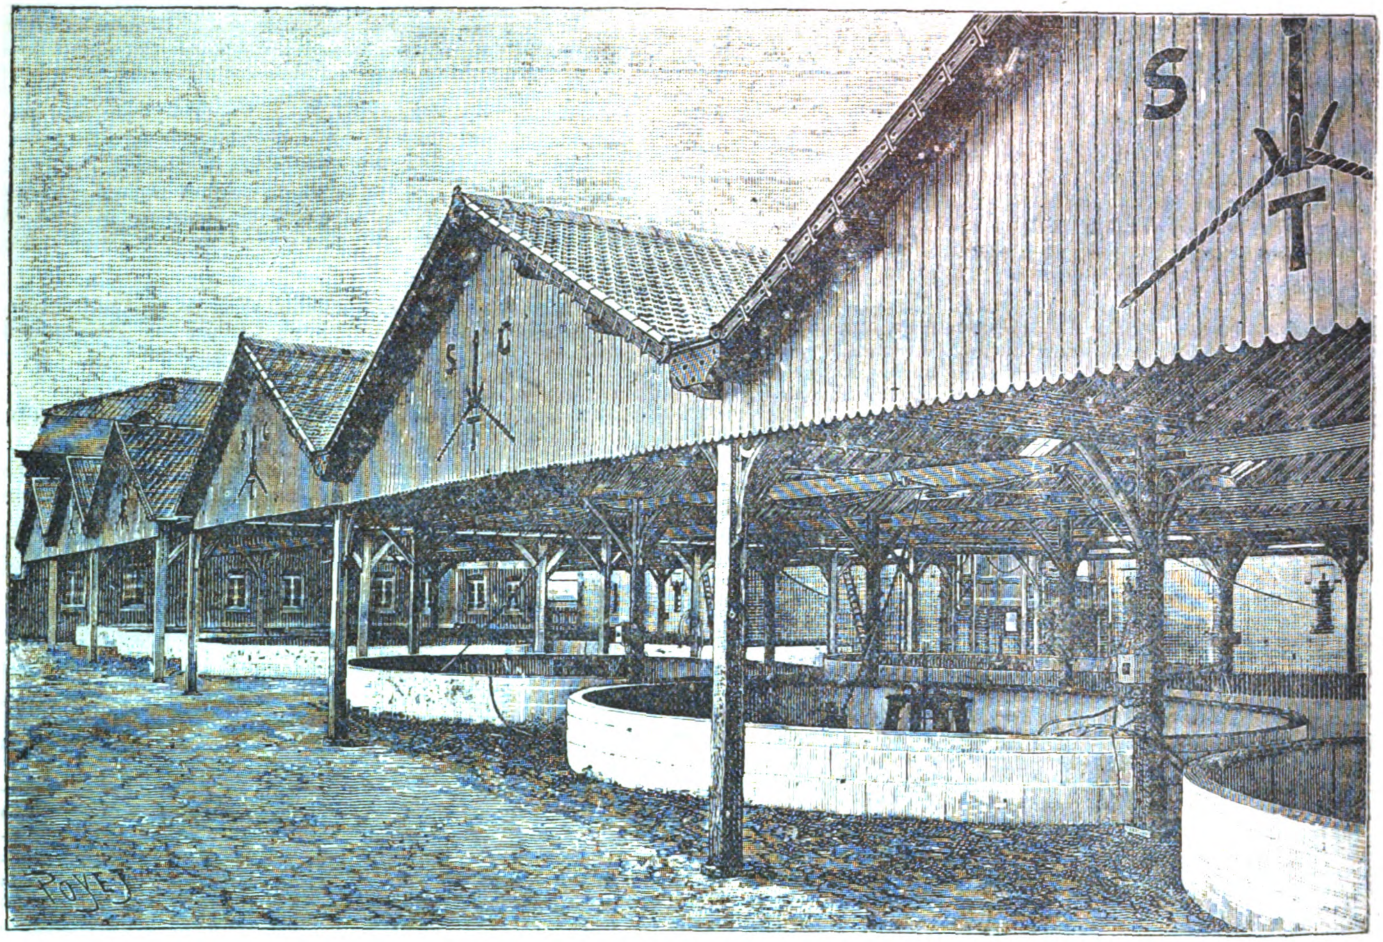
## THE MANUFACTURE OF SUBMARINE CABLES IN FRANCE.*

BY MAX DE NANSOUTY.

The Société Générale des Téléphones deprived in 1889 of the telephone system which it had introduced into France, turned its attention to the manufacture of submarine cables, an industry previously unknown in France. The moment was opportune and even propitious. The auspicious extension of our colonial dominions rendered it necessary that France should not remain at the mercy of a Power, friendly, it is true, but which might require its laying and repairing ships to be at the Antipodes. Moreover, in England, in contrast to the spirit which prevails with us, it is held that the State should neither manufacture nor own submarine lines. We had therefore only to deal with private firms. Now, the few who remember the incidents immediately preceding the commencement of hostilities in 1870 will recollect what a price our Department of Posts and Telegraphs had to pay for a cable laid down the Seine, between Paris and Rouen, and what mishaps might have been avoided, and what services rendered, if this cable had been leisurely and coolly laid.



Submarine Cable Works of the Société Génerale des Téléphones.—Tanks for storing the finished Cable.

The Société Générale des Téléphones, encouraged we may at least suppose by the State, decided, therefore, to enter the lists against the one Italian and the three or four big English works. In Italy the firm of Pirelli, brought forth, supported and subsidised directly and indirectly by the State, enjoys at the expense of the Budget, a somewhat artificial prosperity at Spezzia, and, owing to the intelligent activity of its founder, it cuts a very creditable figure.

For some time past the Société des Téléphones had made the cores of coast cables at Bézons, which were armoured in the small Government shops at Seyne. The Société des Téléphones eagerly took advantage of the first propitious opportunity for heavier work, namely, the 100-knot cable from Martinique to Guadaloupe. This cable, which was a great success, and a useful piece of experience for the Bézons works, was laid in 1890. The cable had to be taken to Havre on barges, where it was placed on a German steamer (no English vessel being anxious to undertake the job) and carried to Halifax, where it was deposited on the quay and was subsequently placed on board the French cable ship Pouyer-Quertier. So little was cared in France about the success of this enterprise that, contrary to what was done in Italy and even in England at the time of their first cables, no representative of the State was present during the operation. Possibly no one was aware that it was taking place.

This first success settled the question. The Bézons-sur-Seine site was, however, speedily seen to be unsuitable for the new industry; what with the rise and fall of the river, droughts in summer, and ice in winter. After much study Calais was fixed on. The new harbour, so easy of access, the Carnot basin, with its depth of 26½ feet, the price of land, the facilities for obtaining English, French, or Belgian coal, the abundance of labour in the north, were all arguments in favour of Calais. At Calais, therefore, the works were erected, and they are, from every point of view, at least as well situated as the English ones, which have the disadvantage of being situated on a tidal river instead of alongside a dock. A site was purchased in August, 1890, and the construction of the works was commenced. Boilers were ordered from MM. Weyher et Richemond, and three 90 H.P. engines and the necessary shafting from V. Brasseur, of Lille. The machines for sheathing the cables were ordered in England. So carefully were the specifications, &c., drawn up, that the Société des Téléphones, at the moment when it bought the Calais site, boldly accepted a £3,200,000 order for the Cayenne-Brazil, Martinique-Cayenne network, to be delivered partly in March and partly in June, 1891. By December the works were in full swing, and at the present moment the first order is completed and the cable will be shortly shipped.

The cores are manufactured and tested at Bézons, where the plant is equal to a monthly output of more that 600 knots, and they are then sent by rail to Calais, wound in three-knot lengths on specially constructed drums. As soon as the core arrives at Calais it is stored in tanks capable of taking 800 knots. After having been served with jute and armoured, the cables are coiled in the immense concrete tanks, 33ft. in diameter, shown in the accompanying figure. The works of the Société des Téléphones are very roomy and are methodically arranged, the main workshop consisting of 14 bays 46ft. high and 231ft. long. The monthly output of the works is estimated at 500 knots. What this means may be realised by quoting the figures connected with the 1,000 knots of cable now coiled in the tanks at Calais :—

| | Tons. |
|---|---|
| Core (copper and guttapercha) | 130 |
| Jute serving | 400 |
| Sheathing | 1,000 |
| Bituminous and other compositions | 400 |
| Total | 1,930 |

* From *Le Génie Civil.*

Digitized by Google

Some 300 men and 50 women are employed at the works. In order to facilitate the shipment of cables, the Société des Téléphones have run a tunnel from the factory to the Carnot dock, some 165 yards distant.

The above slight sketch only gives a feeble idea of the Calais works, but unfortunately, as in England, the public is rigidly excluded. The few competent persons who have visited both the English and the Calais factories assert unhesitatingly that neither from the point of view of economy nor from the point of view of output, can the rival works compare with our own. We are thus at last freed from the tax levied on us by England. During the past 30 years we must have paid her from £1,600,000 to £2,000,000 for submarine cables. We must not forget, however, that if we have been successful from the start, we owe it to the intelligence, the perseverence, and the money spent long ago by our English rivals and competitors. The credit of this factory is due to M. E. Vlasto, who has acquitted himself most meritoriously in the carrying out of this patriotic and useful undertaking; the technical organisation and the special machinery, the details of which are kept secret by the English, all had to be thought out by him.

## ELECTRIC LIGHTING LEGISLATION IN GERMANY.

The following are the regulations regarding electrical installations contained in a Bill which is at present before the German Parliament:—

### PREAMBLE.

The application of electricity for lighting and other technical objects has latterly assumed so much importance that it has become necessary in order to remove the dangers connected with electric installations to issue regulations concerning the erection, arrangement and working of such installations. Under this head are to be included current supply stations, conductors, installations and electrical factories. The dangers connected with these installations consist in the possibilities of accident in consequence of the human body coming into contact with the electric apparatus and conductors, in the danger of fire, in the possible interference with the working of the public telegraph and telephone by the conductors erected for other purposes, and in the chance of a thick tightly strained wire carried over streets and houses becoming broken.

In order to guard against these dangers precautions must be taken that all electric installations are provided with such arrangements as are capable of entirely averting danger to human life and of fire, and that all conductors are so disposed as to cause no interference, and that the breaking of a wire is so far as possible prevented, or in any case rendered harmless.

The proposal to insist upon the adoption in the specifications for all electric installations of § 16 of the police industrial regulations was set aside, as it was considered that this course would carry with it difficulties and hardships out of proportion to the danger connected with the industry, and the public interests brought into question, whilst at the same time it would operate to hinder the development of the electrical trades. In every case, therefore, special regulations will have to be observed, which will vary according to the danger involved in the scheme, &c. General police regulations will be issued with reference to the various classes of electric installations, which will be equally binding on all. The following out of these regulations will be enforced by the infliction of fines in cases of contravention thereof. An exception from this rule will be made in the case of installations in the arrangement of which public commerce, &c., are taken into consideration, or which are specially dangerous. In the one case the carrying out of the project will depend upon the granting of the police permission; in the other the work may be commenced when it is officially ascertained that the project is in conformity with the general police regulations.

§ 1. The erection and working of installations for producing, distributing, and applying electric currents for lighting, transmission of energy, and other purposes (electric installations) are subject to the general police regulations sanctioned by Parliament.

§ 2. Electric conductors, which are carried on, under, or over public land, must be so laid as not to interfere with the working of existing electric installations, nor to render impossible the utilisation of public land for the further erection for public use of electric telegraphs, telephones, or signalling installations.

3. For the erection of electric installations for which public land is to be used, the previous permission of the administrative authorities is necessary. Electric installations which have been erected before the publication of this Act and are brought to the notice of the administrative authorities within six months, by a description of their present state with the necessary explanatory particulars, do not require this permission.

§ 4. Three copies of the application for the permission, together with the necessary explanatory information and descriptions, have to be submitted. A copy of the application with drawings has also to be laid before the Imperial or State telegraph authorities. In the application it is to be stated that copies thereof, together with sketches, have been laid before the authorities of other telegraph, telephone, or signalling installations serving public purposes, as well as before the owners of electric installations already sanctioned, or notice of the erection of which has been duly served as required by § 3. Such authorities and owners of installations may, within four weeks of the filing of such application or notice, oppose the carrying out of such installation on the grounds set forth in § 2.

§ 5. If within the above term no opposition is made, the administrative authorities have power, subject to the regulations of § 2 and the decision of Parliament with regard to § 1, as well as to the existing street-railway, fire-alarm and police regulations, to examine the project, and on the result of this examination, either to grant the permission or to impose such conditions as may appear to them to be necessary. Their decision must be given in writing and must contain the conditions imposed. It must give the reasons if the permission is refused or only granted subject to conditions. If doubts arise as to the advisability of granting an unconditional permission, opportunity of verbal discussion is to be allowed the applicants before the decision is arrived at.

§ 6. If the application is opposed, the objection is to be discussed verbally by the administrative authorities with the applicants. In case the objection is answered by the applicants, the opinion of an expert on the project is to be obtained. In this case the experts' opinion is to be allowed to be examined by the applicants before a final decision is arrived at. At the conclusion of the discussion the project is to be examined and decided upon, as enacted in § 5. Notice of the decision is to be given to both the applicant and the opposer.

§ 7. Appeal to the Central Land Court against this decision is permitted. To be valid the appeal must be made within two weeks of the decision. The decision on the appeal must be delivered to the parties in writing, and the reason for such decision must be therein stated. If the telegraph authorities are concerned in the decision, they have the right of appeal against the Central Land Court to Parliament within two weeks. The Parliament will arrive at their decision after hearing the Central Land Court.

§ 8. The increased costs due to groundless objections are to be borne by the opposer, all the remaining costs entailed by the procedure falling upon the applicant. In an application for permission for a new installation, the question as to the division of the costs will be at the same time decided upon.

§ 9. The permission for projects included in § 3 remains in force so long as no alteration thereof takes place, and no new application is necessary if the project is handed over to a fresh applicant. Every alteration to any project requires a previous permission, as set forth in §§ 3 to 8. The preceding regulations also hold good in the case of installations falling under the head of § 3.

§ 10. The use of additional land in one of the projects referred to in § 3 is not to be considered as an alteration for the purposes of § 9, and does not require the permission if the additional land immediately adjoin such public land as is to be utilised for the installation. At least a week's notice has to be given to the local police authorities of the intention to use such additional land. The same holds good with regard to the fixing of lamps on the exteriors of buildings and their conductors.

§ 11. The regulations contained in §§ 3 to 10 do not apply (1) to electric installations to be erected on ground belonging to railway companies, provided no other public land is to be utilised for the same, and (2) to electric installations belonging to the Imperial and State Telegraph Department. The authorities and owners of installations referred to in § 4, section 2, are authorised to bring before the administrative authorities objections against the projects put forward by the Imperial and State Telegraph Department within four weeks after they have received notice thereof. In the event of such objection being made, the administrative authorities are to decide, in case they do not reject the objection as being groundless, whether the project is to be abandoned or modifications are to be made therein. §§ 6, 7, and 8 then apply as to the procedure.

§ 12. Installations of the kind referred to in § 1 for rooms intended for holding public exhibitions, festivals, or meetings as well as for rooms in which explosive materials are manipulated, stored, manufactured, or can collect, must only be put into operation after it has been ascertained and certified by the local police authorities that they have been erected in accordance with the terms of the regulations.

§ 13. A fine not exceeding 300 marks (£15) will be imposed on any person who (1) contravenes the regulations issued under § 1, (2) erects or carries on an installation requiring the permission referred to in § 3 without having obtained such permission, or who does not adhere to the conditions subject to which the permission was granted, or who effects alterations in such installation without the above-mentioned permission, or (3) contravenes the regulations contained in § 12. The police authorities may in cases (1) and (2) order the project to be abandoned or to be modified so as to comply with the rules and requirements, or in case (3) may require the cessation of working.

§ 14. Any person who has omitted to supply the notice required in § 10 is liable to a fine not exceeding 150 marks (£7. 10s.)

§ 15. It is to be determined by the Central Land Court what authorities are to be considered as "administrative authorities" for the purposes of this Act.

## LONDON CHAMBER OF COMMERCE.

### MEETING OF THE ELECTRICAL TRADES SECTION COMMITTEE.

A meeting of the Committee of the Electrical Trades Section of the London Chamber of Commerce was held on the 20th inst., at the offices of the Chamber, Botolph House, Eastcheap, Mr. Emil Garcke being voted to the chair.

The SECRETARY (Mr. Kenric B. Murray) having read the minutes,

The CHAIRMAN stated that Mr. Crompton had asked him to express his regret at his inability to attend the meeting, owing to his being ill in bed. Continuing, the Chairman stated that, to meet the convenience of some of the members present, it was proposed to vary the order of proceedings as set out on the agenda paper. They would remember what occurred at the last meeting, and the minutes which Mr. Murray had read recapitulated the circumstances. There had, moreover, been a very full report of the proceedings in *The Electrician*, and a memorandum had been printed by the Chairman of the Committee by which, he thought, anyone could inform himself in regard to the matter. He, therefore, thought it would be best to at once read the report of the sub-Committee, who had met several times:

The SECRETARY read the following report.

Your Committee have to report that in pursuance of the resolution of the Electrical Section of January 26, 1891, they have met and considered the matters referred to them. Your Committee find that the history of the telephone clauses in connection with the Electric Lighting Acts is as follows :—

In the Session of 1889 the first large batch of Provisional Orders were applied for consequent upon the passing of the Amendment Act of 1888. The question of the protection to be given by the Orders to the telephone companies was naturally raised, and in order to settle the matter a meeting was held at the Board of Trade, when there were present, on behalf of the Board of Trade, Mr. Courtenay Boyle (the Assistant-Secretary), Sir Thomas Blomefield, Major Cardew, as the Electrical Adviser of the Board of Trade, and Major Marindin, who had held the local inquiry in London and upon whose report the Board of Trade have throughout acted. The Telephone Companies were represented by Mr. Winterbotham, of Messrs. Waterhouse and Co. ; and the Electric Light Companies by Mr. Medcalf, agent for the London Electric Supply Corporation, and by Mr. Bonner-Maurice, agent for the Metropolitan Electric Supply Company. At this meeting the clause inserted by the Board of Trade in all Electric Lighting Orders of 1889 was settled after discussion. This clause was the result of a compromise, but was considered by the parties present, including the Board of Trade, to be the best that could be adopted in the conflicting interests of the parties. It may not be improper, however, to state here that your Committee understand that *it was not deemed wholly* satisfactory by either the telephone companies or by the electric lighting companies, but it was inserted in all the 1889 Provisional Orders, all but three of which related to the metropolis. This clause of 1889 was subsequently adopted by the Board of Trade in the Model Order issued by them in 1890.

During the Session of 1890, a very large number of Provisional Orders were granted by the Board of Trade. In the great majority of these the 1889 clause was inserted by the Board of Trade, and no objection was taken to that clause by any of the parties promoting the Orders, or by the Telephone Company. Certain of the local authorities, however, tried to amend the clause in their own favour, and the Board of Trade (which authority, it may be stated, has made it part of its policy to pay the greatest deference to the wishes of the local authority), without expressing any opinion on the merits of the difference, decided not to take the responsibility of determining the difference, but to refer the matter to Parliament. The machinery by which this was done was by altering the clause and leaving the Telephone Company to petition, but the Board of Trade distinctly disclaimed having settled the clause in the altered form, and explained this to the Chairman of the Committee. The question thus raised came up first before the Committee on the Electric Lighting Provisional Orders Confirmation (No. 6) (Birkenhead Electric Lighting Order) Bill, on July 3, 1890. The night before that Bill came into Committee, the Board of Trade wrote to the various agents representing the promoters of Provisional Orders, stating that the question was coming before the Committee on the Birkenhead Order (without saying when), and that the clause settled by the Committee would be inserted by them in all Provisional Orders of the Session. Your Committee understand that this notice was received by some agents so late that they could not get to the Committee Room in time even to be present at the discussion, or until after the question had been decided. Moreover, it is clear that the question was merely one between the promoters of the Birkenhead Order and the other promoters who had objected to the clause as agreed in 1889 (all of whom were represented by the same agents) and their opponents, and that neither the representatives of the London Companies nor the promoters of other Orders had any locus to be heard by the Committee. This Committee, however, settled a clause which is *admittedly more favourable* to the Telephone Companies than the clause of 1889, and the Board of Trade, in pursuance of the determination, of which notice was so tardily given by them to the other promoters, took steps to insert this clause in all pending Provisional Orders.

Your Committee desires that the Section should clearly understand that when a Provisional Order Confirmation Bill comes to Parliament, the promoters of a Provisional Order have to promote *it in the form in which it has been granted by the Board of Trade*, that they have no power to ask the Committee to alter the form of the Order in any manner, and that no question can be raised by any one upon the Order except with the consent of the Board of Trade, or upon petition presented by parties having a locus *against* the Order. Your Committee are informed that it so happened that a great many Orders affecting London and other places had been granted by the Board of Trade, with the telephone protection clause of 1889 inserted, and that the confirming Bills had been introduced into Parliament prior to the date when the Committee considered the Birkenhead Order. Many of these Bills, however, were not opposed, and none of them by the Telephone Company (who had throughout expressed their readiness to abide by the settlement made in 1889), and came therefore before Mr. Leonard Courtney, the Chairman of Committees, as unopposed Bills. The Board of Trade gave notice of their intention to request the Chairman to inserted the Birkenhead Committee clause in lieu of the clause inserted in the Order as granted. When the question came before Mr. Leonard Courtney, he decided that, in the face of opposition by the promoters of the Order, he could not make any substantial alteration, even at the instance of the Board of Trade ; and in those cases, therefore, where the Order had been granted previous to the decision of the Birkenhead Committee, and objection to the proposed alterations was made by the promoters, the 1889 clause remained. The Board of Trade, however, inserted the 1890 clause into the Orders subsequently granted by them, and (notwithstanding the opposition of the Promoters, and the fact that the Telephone Companies did not ask to have the clause of 1890 inserted, but expressed their concurrence in the agreed clause of 1889 being adhered to), declined to make any alteration. Your Committee, however, are informed that in the case of the City of London Provisional Orders, the last two granted by the Board of Trade, during the session of 1890, the Board of Trade, at the request of the Commissioners of Sewers for the City, agreed to the 1889 clause being inserted in the House of Lords in these Orders in lieu of the clause of 1890, which they had inserted in the Orders when granted. For the convenience of the Section, printed clauses of the Sessions of 1889 and 1890 are attached to this Report.

Your Committee understand that the Board of Trade's action in the matter was governed by the following considerations :—They say that in 1889 the responsibility of dealing with the question *had been taken out of their hands* by the agreement come to between the parties. The Board of Trade therefore determined to insert such agreed clause in all orders. They departed from this, however, at the request of a Local Authority, with the result that a Committee of the House settled the clause. The Board of Trade thereupon came to the conclusion that their proper course was to put the Committee's clause into all pending Orders, without reference to locality or to the expressed wishes of the Telephone and Electric Light Companies. At the request of a Local Authority the Board returned to the 1889 clause in the case of the City of London Orders. The Board of Trade have, however, not acted consistently to the course of procedure thus laid down by them. During the present Session some 70 to 80 Provisional Orders are being promoted, and the Board of Trade in the Model Order which they have issued have put forward a third clause on this subject differing from the clauses of 1889 and 1890, and again altering the rights of the two sets of parties.

Your Committee feel strongly that while the Board of Trade are the protectors of the rights of the public in dealing with these matters, and are perfectly justified in altering the conditions which they think necessary to impose upon undertakers in the interests of the public, or of the safety of buildings or otherwise, or as to the prices to be charged, and so on, should not lightly take away from two sets of people the right to contract as to the relative positions of such parties in carrying out their undertakings. It is true that the electric light companies only carry on their operations under statutory authority, and that the telephone companies have no statutory authority. The telephone companies were, however, so to speak, in the field and carrying on a lawful business when the electric lighting companies were promoting their Orders. The Telephone Company, therefore, had a right to say : You shall not injuriously affect our business, but we will be satisfied if you will give us certain clauses for our protection, and the electrict light undertakers had also the undoubted right to say we will give you such protection, but no more. Your Committee moreover admit that in cases where there is a contest as to the proper clauses to be inserted, the Board of Trade was no doubt justified in abiding by the precedent set them by a Committee of the House under similar circumstances. But your Committee cannot understand why the Board of Trade should think it necessary to intervene between the only parties interested, and say that those parties shall not be entitled to settle by agreement the quantum of protection to be given by one to the other. It has been suggested that the Board of Trade in this matter are protecting the rights of the Postmaster-General, as the Telephone Companies carry on their business under a license from the Postmaster-General. The rights of the Postmaster-General are however expressly reserved by the Orders granted, and anything that is arranged between the undertakers and the Telephone Companies can in no way affect these rights.

It would therefore seem to your Committee that the Board of Trade in dealing with this question are unnecessarily curtailing the rights of Electric Lighting and Telephone Companies, to agree amongst themselves how far one is to take precautions against interference with the property of the other. For, as already stated, the essence of the clauses is protection to the Telephone Companies. In the Birkenhead case, moreover, the two parties did not agree, and the Committee was asked by the parties to settle their dispute.

Your Committee feel that it is most desirable that steps should be taken by the Chamber of Commerce on the question of principle, as they feel it is most desirable in the interests of those who have invested and are investing capital in these undertakings, that they should not be put to the continual expense of discussion every Session, both with the Board of Trade and Parliament, how far one of them is or is not to be protected, that there should in fact be some finality to the discussion, and that the rights of the parties to contract with each other should not be disturbed.

Your Committee feel that it is not for them to suggest what steps the Section of the Chamber of Commerce should take upon this report, but

Digitized by Google

they do feel very strongly that the representations should be made to the Board of Trade based upon the principles to which they have here referred.

The CHAIRMAN stated that the report was signed on behalf of the Telephone Companies by Colonel Jackson and Mr. William Winterbotham, and on behalf of the Electric Light Companies by Mr. Sydney Morse and himself. The report rendered it unnecessary for him to say anything on the subject beyond this, that they were both agreed that the 1889 clause would meet their case, and that the Board of Trade were proposing to adopt some other course. It therefore devolved on them to consider what they would do on this report of the Committee. It might be convenient, in discussing this matter, that the further developments which had occurred since the report was drawn up should be communicated to them, and he would therefore ask Mr. Sydney Morse to address the meeting.

Mr. MORSE read a letter which he had received that morning from the Board of Trade, which, he said, was evidently a circular which had been sent to all promoters of Electric Lighting Provisional Orders this Session. In pursuance of the agreement come to by the report which the Secretary had just read, he wrote to the Board of Trade on the Orders in which he was interested. Seeing that they contained the clause known as the clause of 1891, as in the Model Order, and not the clause of 1889, he wrote to the Board of Trade and stated that there was an agreement existing between the telephone companies and his clients that the 1889 clause should be inserted, but not the 1891 clause. The Board of Trade thereupon stated that they had considered the matter, that they could not insert the 1889 clause, and that they must insert the clause of 1891. Now, this was a refusal to the electric light companies to insert an agreed clause. Probably they were aware that it was a common practice in private legislation for the opponents of a Bill to approach the promoter, and say: We will withdraw our opposition if you will agree to certain clauses, and when that is agreed to the petition of the opponents is always withdrawn, and the clause is then inserted in the Bill when it comes before the House, unless it is something contrary to public policy. He had, therefore, concluded that the Board of Trade would follow such a course in connection with these Provisional Orders. He would like to mention that the promoters of an electric light Provisional Order were in a great difficulty when they came to the House. The Board of Trade granted it in such a form as seemed best to the Board of Trade, and the promoters were unable to alter any word in the Order, whereas anyone else could come and oppose the terms of the Order. He went to the Board of Trade and said there was an agreed clause; but the Board of Trade said they did not care—that he was only a promoter. The telephone companies, however, said to the Board of Trade that if they did not put in a clause more satisfactory to them they would oppose every Order that came before Parliament, which meant 70 or 80 oppositions of Bills. The Board of Trade then said: As the telephone companies can oppose us, we must do what they ask us to do. We won't even go so far as to give the electric light companies the clause which the telephone companies have agreed to give them, but will only give a clause which is satisfactory to the telephone companies." When the Board of Trade sent the Model clause to him as the promoter of an Order for this year, he took the trouble to get full instructions, and he wrote fully to the Board of Trade, but they absolutely paid no attention to the letter beyond adhering to their original clause. Having regard to the alteration made by the clause of 1891, as compared with the clause agreed upon in 1889, he stated that the telephone companies had signed the report which had been read, and were prepared to join with the Chamber of Commerce in approaching the Board of Trade and pressing for the 1889 clause being inserted. The telephone companies, however, most unfortunately, as he thought, had already intimated to the Board of Trade that the Model clauses of this year would satisfy them.

Colonel JACKSON said that it would be almost suicidal for the telephone companies to say to the Board of Trade: Now that you have altered the Model Order so as to suit the representations first made, we still decline to accept that Order. The telephone companies indeed thought that the Board of Trade should accept the clause agreed upon between the electric light and the telephone companies in 1889, and if the former could induce the Board of Trade to adopt that generally the telephone companies were prepared to do so; but he did not know that Mr. Morse could ask them to do more than this. What argument could they advance in Committee when they were offered the clause which protected their interests as thoroughly as the clause they had asked the Committee to insert? They quite agreed that the Chamber should be entitled to use its influence in the direction agreed on between them, and the telephone companies could do the same, but the latter could not refuse to accept the Orders. They would probably lose both the Model Order and the new Order by such a course of action.

The CHAIRMAN: I think it is a pity that the position has been somewhat complicated by the telephone companies approaching the Board of Trade practically at the same time as this Committee was sitting.

Colonel JACKSON: No; we approached the Board of Trade before the Committee took up the matter at all.

The CHAIRMAN: Probably the right course then would have been to stay negotiations with the Board of Trade pending the report of the Committee in view of joint action, if the report of the Committee was to have any effect at all.

Colonel JACKSON: I do not see how we could refuse the clause, which gives us all the protection we require.

The CHAIRMAN said he thought they now recognised what the position of this important but complicated clause was. It seemed that the Board of Trade were now suggesting that which was satisfactory to the telephone companies but not by any means to the electric light companies. It was now for the meeting to decide on the course that should be adopted. He was glad to hear Colonel Jackson say that, notwithstanding what had taken place, he would use his influence in the direction of this report.

Colonel JACKSON: Certainly.

The CHAIRMAN: The electric light companies did not desire any more than Colonel Jackson did that there should be any opposition to the promotion of Orders. He would have thought that their going on a common course of action would have avoided that.

Colonel JACKSON: We had hoped so, too, but we cannot control the Board of Trade. If the Board of Trade refuses to adopt the clause of 1889, and insists on an Order of its own, we cannot alter that, and that is the position in which we are placed. We say still that we would prefer the adoption of the clause of 1889.

The CHAIRMAN said it seemed to him that the best course that could now be pursued was to ask the Chamber of Commerce to take some step with a view to this report being made effective; and if Colonel Jackson would not object, he (the Chairman) would propose a resolution asking the telephone companies to support the report by joint action with the electric light companies before the Board of Trade.

Colonel JACKSON stated that he had no objection to a resolution being passed to that effect—speaking for himself; but he had several colleagues on their Board, though he had no doubt they would confirm his action.

The CHAIRMAN pointed out that this was a course which Colonel Jackson, as member of the Committee, had suggested. For the rest, the question at issue afforded only another illustration showing how great were the difficulties of the electric lighting companies before the Board of Trade. He did not believe that any other industry had been hampered in the same way.

After a short further discussion,

Mr. C. J. WHARTON moved the following resolution:—

*"That the report of the Committee of January 26, 1891, be hereby adopted, and that the Council of the Chamber be requested to embody the substance of the report to the Board of Trade by letter, supported by a deputation attended by both interests."*

Colonel JACKSON seconded the resolution, which was adopted.

The CHAIRMAN stated that the next matter on the agenda paper was to consider the desirability of co-operation between the telephone and electric light companies, for the purpose of placing wires underground in future. He had understood that Mr. Crompton had desired to bring this matter before the meeting. He did not know whether any other gentleman would take up the question.

Colonel JACKSON stated that the telephone companies would be ready to discuss the subject with the representatives of the electric light companies, but the Section could not do more than bring the interests together. To give effect to Mr. Crompton's suggestions, certain negotiations would have to take place between the electric light and the telephone companies.

It was decided to postpone the consideration of the question.

The CHAIRMAN stated that the report on overhead wires from the Sub-Committee was on the agenda paper. He believed that the report had been circulated. It was a very long report, and it was not necessary to read it. Those who had read it would recognise how very unfairly the electric light companies were treated by the Board of Trade in this matter. He thought they could only pass a resolution in the same sense as in the case of the telephone wire—that they should make a strong representation to the Board of Trade on the subject.

The proceedings shortly afterwards terminated.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *March* 13, 1891.

**Electric Motor Accident.**—Yesterday another was added to the list of fatal accidents from electricity that have attracted an unfortunate amount of attention in this city. The present, however, is unique, in that the fatal contact was received from a defective motor. The scene of the accident was a silver-plating establishment, recently started in this city. A 6 H.P. Baxter motor for arc circuits had been put in for operating the necessary machinery. It was comparatively a new machine, having been sent from the factory a little over a month ago. Like other similar establishments the factory has a sheet-iron floor for the readier collection of silver dust. The first sign of trouble appeared yesterday morning, when the superintendent of the factory went to the motor to measure its speed, and although he was standing on a board his feet were damp, and on approaching the speed indicator to the armature spindle he received a severe shock. This put him on his guard, and all the *employés* were warned not to go near the machine. As the factory was shutting down for the evening, a lad employed as bookkeeper attempted, contrary to instructions, to shut off the current from the motor. The machine is at about the level of one's head, and as the young man, standing on the iron floor, reached for the switch, he accidentally brought his forehead in contact with the flange of the motor pulley, and was instantly killed by the shock received. The newspapers are only too quick in taking up such a case and gloating over its details.

Digitized by Google

**Electric Railway Activity.**—There is promise of great activity in electric railway circles as soon as spring opens and the weather is sufficiently good for construction work. All the large companies are overburdened with orders, and probably even a larger number of roads will be equipped during the coming season than last year. Several long roads are talked of, two of them 50 miles in length. Neither of these, however, proposes to be anything more than an exaggerated street car line connecting a considerable number of towns. It is to be hoped that before long some steps will be taken towards a genuine electric railroad operated at sharp speeds. The Weems Electric Railroad Company, under whose auspices Mr. Crosby's beautiful experiments with high speed traction were tried, is said to be preparing to carry out an extensive experiment that was postponed by unfortunate financial embarrassments. One or two other high speed schemes are on the *tapis*, but whether anything practical will come from them remains to be seen.

**Rapid Transit in New York.**—The rapid transit excitement in this city has not in the least abated its fervour, and plans are constantly being brought before the rapid transit commissioners for their careful consideration. The general consensus of opinion now seems to be that a viaduct is impracticable on account of the enormous expense, if the route should be laid through the central portion of the city, where it is needed. The public will no longer tolerate the elevated roads, and consequently the only refuge is underground roads. The two underground systems that are most favourably looked upon are the Greathead, too well known in London for me to say anything further about, and the Reno, which has some strong advocates on account of its great simplicity. The Reno plan is to run in beton side walls for the tunnel, from narrow open cuttings, keeping as near the surface as possible, and then to roof it in with steel channel irons resting on the tops of these walls, and shielded by cement. A cutting edge bearing on the top of the walls will be forced ahead to clear away the material, and the proposed tunnel is large enough for four tracks, two express tracks below, and two way tracks above. This form of tunnel is said to cost less than a four track tunnel of the Greathead system, which latter loses much of its characteristic advantage in working in rock, through which any underground system in New York will have to be cut almost continuously above Fourteenth-street.

## CORRESPONDENCE.

### ELECTRICITY IN RELATION TO THE HUMAN BODY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My colleague (Dr. Harries) and I would esteem it a favour if you will grant us space to reply to the remarks of the unknown correspondent whose letter forms the subject one of the leaderettes in this week's issue of your journal.

The tone of the extracts from his remarks appears to us to lack both courtesy and good taste. He commences by a covert sneer at our experiments relative to "cataphoric medication," goes out of his way to insult the Society of Arts, and finishes up by misquoting our words. On his misquotation he bases an inference that we had no ground for speaking of the "indifference, suspicion and conservatism" of the medical profession.

1st. As to the cataphoric medication experiments—their "crudeness" consists, we suppose, in the fact that they are (so far) qualitative and not quantitative. We only put them forward as evidence of an early stage of an investigation confessedly incomplete, but we have good reason to suppose them conclusive as far as they go. If they be in any sense true, it can hardly be denied that they form a very important advance in the uses of electricity to the body, and we are therefore justified in bringing them forward. Should your correspondent be able to prove that we are wrong, we will not hesitate to acknowledge our error; but till he has at least attempted to do so we think a more courteous tone of criticism would have been more becoming. From the wording of the communication it seems probable that your correspondent was present when the Paper was read, in which case it seems strange that he should have failed to avail himself of the opportunity of relieving his feelings in the discussion which followed.

2nd. We did not make the statement attributed to us, "that the health of the body *is* largely dependent upon electricity." Our words (taken from the official journal of the Society) were, "The health of the body *seems* to be intimately connected with, and *perhaps* to a large extent dependent upon, electricity, or the immediate results of electrical action both internal and external." We specially guarded against expressing any such absolute opinions, and confined ourselves to stating the probabilities based upon such information as we have been able to obtain from others and to observe for ourselves.

His other quotation, "very probably life does not exist without electricity," is rendered unnecessarily bald by being robbed of the remainder of the sentence of which it forms a portion only. The complete sentence is: "Electricity is useful to us in health; it is so closely connected with vital function and sensation that very probably life does not exist without it; it is capable of producing such changes in the body, that it takes rank as one of the best remedies in disease, and it is also of immense value in many branches of surgery." In support of this conclusion we had brought forward a fair amount of evidence, but that we laid no claim to complete proof thereof is clearly shown by the next sentence, which runs:—

"The true relationship between this marvellous and many-sided agent of Nature, and the various complicated phenomena which together make up the sum of our individual existence, *has yet to be found*." We have no desire that medical men (or any others) should, in considering our work, accept as proved what we do not claim as such, but we are surely justified in drawing conclusions from our experiments and observations, and in setting forth those conclusions before such a body as the Society of Arts in order that they may be criticised and discussed, and thereby established or destroyed.

Our reference to the "indifference, suspicion and conservatism of the medical profession *as a body*" was made a ground for complaint not because they declined to accept any theories we may have put forth, but because they have so strangely ignored the whole subject of the uses of electricity to the human body. On this point we spoke strongly, because we feel strongly, and we are further quite prepared to stand by and show evidence for all that we said thereon.—Yours, &c.,

March 23, 1891. H. NEWMAN LAWRENCE.

### CAPACITY MEASUREMENTS OF CABLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: An examination of Mr. Dearlove's recently published Paper, illustrating a correction for capacity tests, calls for the following remarks.

The method of correction in question, as described in Messrs. Glazebrook and Muirhead's communication to the British Association last autumn, would appear to include an allowance for leakage, as well as for absorption, in the comparison of condensers; but we fail to see how it applies to a submarine cable in respect to leakage. In this case the charge lost by leakage cannot be measured. For, supposing, for the sake of argument, that in the figures given in Mr. Dearlove's Paper there is *no* absorption effect, but only leakage on the cable side, then there ought to be no correction deflection on earthing the point K (*The Electrician*, March 6th, p. 537) and discharging the point J through the galvanometer to earth. Consequently, the value of the capacity obtained would be wrong. The results on the cables cited are perhaps not wholly conclusive, but have a general tendency to too high a value for the corrected capacity, as might be expected from the operation of leakage on the cable. This tendency seems to have been accentuated when the "earthing period" was made more commensurate with the time of charge.

We are of opinion that it is necessary in all capacity tests to apply the formula we published in *The Electrician* of 12th

Digitized by Google

December last, or some similar one, except where the loss of charge can be measured by accumulation. But, as we remarked in the same place, in connection with the absorption effect, if the time of charge does not exceed about three seconds the only correction which need be taken into account is that for leakage. We also ventured to point out that if by "capacity" be understood the instantaneous charge, then no existing cable would require more than three seconds for the establishment of a practically uniform potential throughout its conductor.

We note that Mr. Glazebrook, in his Paper referred to, speaks of "instantaneous" and "full" capacities. Would it not be more satisfactory if, when dealing with the subject of capacity, it were decided whether the former or the latter of the two values is to be understood? In practice it often happens that by varying the conditions of measurement, especially as regards time of charge, neither one nor the other is arrived at.—Yours, &c.,

Harold W. Ansell.
Julian E. Young.

Cable steamer "Chiltern," London, March, 1891.

## TRADE NOTES AND NOTICES.

Tenders Wanted.—The telegraph authorities at Stockholm require tenders for the supply of telegraph and telephone insulators, iron, copper, bronze, bimetallic and insulated copper wire, line connections, glass tubes, hooks, &c. Particulars will be found in our advertisement columns. Tenders must be in by noon on April 4.

——— The Urban Sanitary Authority of Harwich require tenders for the public lighting of their district by Electricity, gas, oil, or any other method, from August 1, 1891. Particulars may be obtained from Mr. A. J. H. Ward, town clerk, to whom tenders must be sent by April 4th.

Tenders Received.—The following tenders have been received for the wiring of the Blue Posts Tavern, Old Bond-street, London, W. The number of lamps was 52 of 16 c.p. and 2 of 200 c.p. The estimates were made to the specification of Mr. R. Willy, F.R.I., B.A. Crompton and Co., £111. 14s.; Strode and Co., £99. 14s.; B. Verity and Sons, £97; Brush Electrical Engineering Company (Limited), £96; Woodhouse and Rawson United (Ltd.), £61. 3s.; Dobson and Co. (accepted), £47. 10s. It may be noted that the average of the first four is £101. 2s. The highest exceeds this average by only 10½ per cent., while the lowest falls 5 per cent. below it. The two other tenders differ from it by about 40 and 53 per cent. respectively.

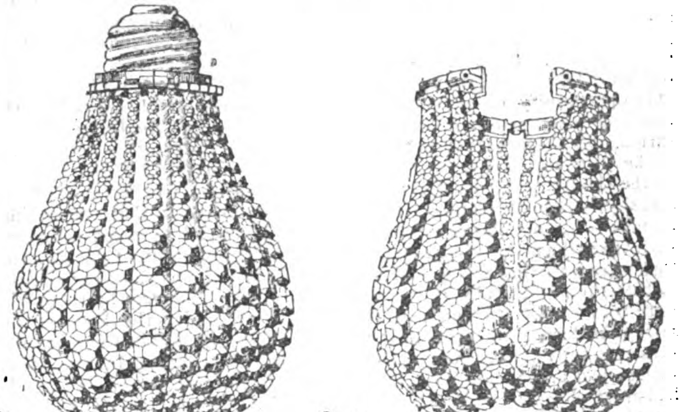
——— The following tenders have been received for laying electric bells between police station and residences of members of fire brigade, Coventry:—Radcliffe, Birmingham, £139. 14s. 3d.; Blenheim and Co., Egham, £85; Matthews, Ball, and Preston, Leicester, £80. 10s.; Gillett, Richmond, £68; National Telephone Company, £20.

Measuring Instruments.—MM. Richard Frères send us their catalogue of measuring instruments. Their *specialité*, as is well known, is for recording apparatus, and these, with a revolving drum, they apply to a very large number of purposes. Among others, we find recording ammeters and voltmeters. The latter appear to be the most useful, since they are only required to work through a small range. They are in use in many central stations for recording the insulation of the mains by showing the volts between the mains and the earth. The ammeters cannot be expected to register correctly with small currents. All these recording instruments would be much improved by the addition of a simple parallel motion. The power absorbed by the Richard meter described in our last issue is 2 watts, not 20.

Livonia Flashing Letters.—We were recently shown a working model of Messrs. Cox, Robinson & Co.'s "Livonia" flashing letters, specially designed for outdoor advertising purposes. These letter signs and devices are thoroughly weatherproof. The inside of the letters consists of a number of various coloured incandescent lamps which can be changed at will. The body of the letter consists of an iron case, in the base of which is placed an insulated lining for mounting the lamps upon. The outer iron bodies are lined throughout with reflecting sides arranged at an angle enabling each lamp to be multiplied. The whole is enclosed in a case having a transparent front which is hinged to the body of the letter, forming a weather-tight cover for the lamps. The connections are made inside the body of the letter, and are brought to insulated terminals. Taking the letter "A" as an example, 12 lamps are sufficient to light up the letter with considerable effect. The motor (a combined gravity clockwork and electro-motor, very simple and having few working parts) by which the alternations are worked permits the whole of the main circuits to be made and broken without sparking. At 60 feet from the ground 30 watt lamps, we are assured, have been found quite sufficient to ensure a good light. The cost of running is small, and, considering the effect, after the initial expense only a very trifling outlay per lamp is entailed. We understand that Messrs. Cox, Robinson & Co. put up these flashing letters and maintain them by the hire system, if necessary. They certainly make an effective advertisement. In London they are used at the Trocadero, Piccadilly-circus; in Manchester at Messrs. Lewis's; and in Liverpool at Messrs. Lewis's and at the Prince of Wales Theatre.

Turbines.—The catalogue of Mr. F. Nell, of 16, Mark-lane, contains a great deal of useful information about the Victor turbines. These are arranged on horizontal or on vertical shafts, and are well adapted for low heads of water.

The Bead Ray Diffuser.—Those who like cut-glass shades for electric light, should examine the very ingenious fitting to which we alluded in the description of the St. Pancras Electrical Exhibition, and which is illustrated by the accompanying figures. The makers claim a little too much for it, as they imagine that no light is wasted. The loss is probably less than with ground glass, as there are spaces between the beads. The chief merit of the invention appears to lie in the compact manner in which the bag of beads encloses the lamp. In a large room, and with a number of lights,



With Electric Lamp Ray Diffuser Attached. Sketch Showing Simplicity of Attachment.

where the spotty shadows which are inevitable with such an arrangement would not be noticed, these diffusers would be excellently adapted for use with cut-glass chandeliers.

Munro's Electrical Manufacturing Company.—We are notified that this Company have made arrangements with Messrs. Höfler and Company, 45, Jewin-street, E.C., to act as their sole representatives for London and district.

A Printers' Exhibition.—There is now being held at the Agricultural Hall, Islington, an exhibition which will probably interest many of our readers. A number of labour-saving machines are on view, and gas-engine makers are, as usual, well to the fore. Messrs. Crossley Bros. have on show several of their most recent makes, and, in particular, have a very fine 9-horse engine exhibited. The Trent Gas Engine Company have on view some good engines, but the absence of anything electrical is again noticeable.

The Opening of the Mutual Telephone Exchange.—In reference to our note on the subject of the opening of the Mutual Telephone Exchange, in which we stated that the transmitters were of Messrs. Siemens' manufacture, we are asked by the International Electric Company to state that they also have supplied the Mutual Telephone Company with their spoon-shaped receivers, which have proved a decided success, and for which they have recently received a very flattering report as to efficiency, &c.

## COMPANIES' MEETINGS.

### Brighton and Hove Electric Light Company (Limited).

The annual meeting of this Company was held on Wednesday at the offices, Gloucester-road, Brighton, under the presidency of Mr. Robert Hammond, the Chairman of the Company.

The CHAIRMAN, in moving the adoption of the report and balance-sheet (an abstract of which appears below), said it was a very gratifying thing to point out to the shareholders that the system which the Company adopted some two years ago, the alternating current high tension transformer system, was now almost universally acknowledged as the only possible system for supplying electricity over an extended area by the

Digitized by Google

leading electricians not only in this country but throughout the world. All the new work in America was being carried out on this high tension system, and practically one might say that only very old-fashioned engineers, who had not kept pace with the times, found themselves advocating the low tension system, which had its day and finished its career in the minds of serious people some six or eight years ago. For instance, during the past few months the City of London decided to grant powers to two companies, and in both cases the system which was practically worked out by this Company in Brighton had been adopted. The same remark applied to Dublin, Cambridge and Bristol. He, therefore, did feel that he was safe in speaking very confidently as to what would take place if they were forced to go into competition with the Corporation. Of course the Corporation purse was a much longer one than theirs, and if it came to a question as to who could lose the most money he quite acknowledged that the ratepayers of Brighton would be able to beat them on that score but in actual and fair working competition they (the Company) would gain the victory. The Company were doing their very best to come to an amicable arrangement with the Corporation, and he personally had felt confident for some time past that it was greatly to the Corporation's interest to come to an arrangement with the Company. By the system which the Corporation had adopted it was only possible to supply a limited area. By the Company's system a very extended area could be supplied, so that by coming to an arrangement with the Company the Corporation would have the advantage of having a pioneer system by which they could put on customers in the most distant parts of Brighton and Preston, while they were gradually consolidating their business in the choice area they had carried out in the front of the town. If the Corporation were to meet a committee of this Company, he was quite certain that the result would be a friendly arrangement which would be to the advantage of both the Company and the Corporation. It would be noticed that the amount of capital at present invested in the Company was £17,500, of which £2,500 was held in debentures. It was proposed to increase the debenture capital by a further £3,000, bringing up the total to £20,500. He would like to take this opportunity of correcting a misapprehension which existed in the minds of many ratepayers of Brighton, and which had been referred to in various observations that had been made in the Corporation with regard to the Company. There was an impression that the £17,500 share capital of the Company was largely made up of promotion money, and did not actually represent plant. He could only say in reply that the original founders of the Company bought a limited amount of plant compared with that which the Company at present held for the sum of £2,000, and that after a further £2,000 had been spent upon it it was valued at £8,000, so that the profit made in the formation of the Company by those who were bold enough to purchase the old concern under the hammer was £4,000 in shares. But the plant that was taken over by the Company was valued at fully the £8,000 paid for it. Since then various important additions had been made, bringing up the present total to £17,500, and he had great pleasure in assuring the shareholders that during the past year the plant had been kept in repair out of revenue, and that for every penny that appeared on the balance sheet the Company could show a satisfactory asset.

Mr. CASH seconded the motion, which was carried.

Mr. Kimber having been re-elected a Director, and Messrs. Ball, Baker, Rowe, and Co. reappointed auditors, the CHAIRMAN, replying to a vote of thanks, said that he hoped to continue Chairman of the Company for a very long time. Some folk had tried to drive them out of the field, but, considering he had the honour of having founded in Brighton the first electric light company that took up the industry of the house-to-house supply, they could easily understand that he felt a much greater interest in Brighton than that which would depend on his share of the small Directors' fee which the Company paid. He had felt very keenly the opposition of the Corporation in view of that fact. At a time when the distribution of electricity from house to house was an absolutely unsolved principle in England—he might say in any part of the world, for Brighton was the earliest place in the world where the distribution of electricity by means of high tension currents was carried out—that system, which ten years' experience had proved to be the best, was founded in Brighton, and history no doubt would write their names very large. The item of £3,361. 11s. 9d. (net revenue from supply of electricity) did not by any means represent the total amount of revenue which they could have obtained from the plant they had at work. Although for the greater part of the year they were completely full, yet during the past two or three months they felt a falling off of revenue, inevitable from the cessation of those customers who preferred to wait for the Corporation supply, and refused to enter into a three years' contract with the Company. These adverse circumstances caused their business to be temporarily reduced in the winter quarter, when it should have been the largest. He was glad, however, to say that the lights released by the recalcitrants were being rapidly taken up, and there was every reason to believe that their net revenue from the supply of electricity in the year ending December, 1891, would be largely in excess of that which figured in the present balance sheet.

---

The following is an abstract of the Directors' report:—

"The Directors have pleasure in submitting to the shareholders the report of the operations of the Company from January 1st to December 31st, 1890. The profit and loss account, after writing off an ample sum for depreciation of plant (which has, however, been kept in thorough repair out of revenue), shows a balance of profit for the year of £768. 2s., from which has to be deducted interest on debentures £123. 6s. 7d., leaving a net amount of £644. 15s. 5d., which, with the balance brought forward from last year's accounts, makes the sum to the credit of profit and loss account £1,202. 15s. 1d. The Directors recommend that this shall be dealt with as follows:—Written off from 'Suspense Account, Garman Case' (one third of £697. 6s. 10d.), £232. 9s.; dividend, 5 per cent., £750; carried forward, £223. 6s. 1d.; total, £1,202. 15s. 1d.

"The Directors greatly regret that in consequence of the continued opposition of the Corporation of Brighton they were last year again disappointed in their efforts to obtain a Provisional Order under the Electric Lighting Acts, 1882-1888. They have, however, this Session applied to the Board of Trade for power to lay underground mains in that portion of Brighton which is not embraced in the area which the Corporation at present proposes to supply. In the event of this Provisional Order being granted they are willing to withdraw their overhead wires from the Corporation area. Should the application for the Provisional Order not be successful the Company will continue to supply throughout the whole of Brighton, including the area served by the Corporation, by means of its overhead wires; and it hopes to be able, by means of its greater economy of working, to make satisfactory headway against the competition of the Corporation. During the past year every effort has been made by the Company to come to terms with the Corporation, and the Directors cannot help feeling that eventually the Corporation will acknowledge the desirability of making some arrangement with the Company. The Company has during the past year proceeded with the alterations referred to in former reports, and at the present time the whole of the Company's supply is on the most modern system known, *i.e.*, The Alternating Current High-Pressure Converter System, by means of which the excessive waste connected with the use of accumulators is avoided, as well as the heavy cost in mains, necessitated by the low-tension system. Failing coming to an arrangement with the Corporation, it is the intention of the Directors to lay down additional plant in order to cope with the pressing demand from consumers outside the Corporation's proposed area of supply, and the attention of those shareholders, who wish to subscribe a portion of the additional capital, is drawn to the advantages offered by the Company's debenture stock.

"The Hove Commissioners, who now hold a Provisional Order, have decided not to do the work themselves, but to let it out to a company;

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.

Digitized by Google

and in view of the fact that this Company is already meeting all the present demands for electric lighting in Hove, the Directors hope to get the preference with the Hove Commissioners for any extensions of electric lighting which the Commissioners may require.

"During the past year, Mr. Albert Gay has resigned his position as manager, having been offered the important post of manager of the House-to-House Electric Company's Works, West Brompton. Mr. Gay gave the Directors great satisfaction, and they are sorry to part with him. Mr. Alfred Hodgson, who has been for the past four years secretary of the Company, has been appointed manager in his stead. During the past year, Mr. Frank Wilden Bentley has ceased to be a Director, and the shareholders are invited to nominate some one—a local gentleman by preference—in his place. If the Company obtains its Provisional Order, or comes to a fair working arrangement with the Brighton Corporation, it will be desirable and agreeable to your Board to invite the Corporation to appoint a Director to represent its interests and those of the ratepayers generally. The retiring Director is Mr. Arthur Kimber, who offers himself for re-election. The meeting will have to elect an auditor or auditors for the ensuing year."

## The Telephone Company of Egypt (Limited).

The eighth ordinary annual general meeting of this Company was held on Tuesday at the offices of the Company, 14, Austin Friars, under the presidency of General Alex. Fraser, C.B., R.E.

The SECRETARY (Mr. A. B. Chalmers) having read the notice calling the meeting,

The CHAIRMAN said: I assume, gentlemen, that the report and accounts having been already before you may be taken as read. The business has during the past year been kept up to a fair point of prosperity, though, in fact, so far as the accounts are concerned, the profit in this last year has been about £340 less than in 1889, but the benefits from the establishment of the exchanges at Port Said and Assiout will only be felt in this and following years, while the working expenses have necessarily increased on this account. Any large extension of the business must wait on the reviving financial condition of the country. Our wires are for the most part being renewed with phosphor bronze, and the replacing of some very large poles has also added to the expenses which have all been charged to revenue, and as the manager reports all the lines in excellent condition the Directors have not thought it necessary to charge anything to depreciation. It may be that the charges against revenue may from time to time be large on account of maintenance, but so long as the lines and instruments are kept in perfect order from revenue there is no reason for making another charge for depreciation. You are, no doubt aware that much of the trade has been transferred from Alexandria to Port Said and Suez, and as a consequence our business at the former place has to some extent fallen off, but from what I know of the Port of Alexandria I should say it will always remain a place of importance, and any falling off there will be fully compensated by increasing business at Port Said and Suez. We have already as you are aware opened at Port Said, and we hope to conclude negotiations for opening at Shez this year. We have had, from time to time, negotiations with the Egyptian Government as to the establishment of telephonic communication between Cairo and Alexandria, but considering the circumstances of the latter, to which I have alluded, the Directors have not been able to come to the conclusion that such a line, which would cost not less than £12,000 to be efficient, would give even a moderate return to the Company. Perhaps, as the financial condition of the country improves, it may be worth while for the Government to erect the line, retaining the Company to work it in connection with its exchanges at either end, or to make some arrangement whereby the expenditure shall not be altogether at the Company's risk. The matter will continue to have your Directors' attention. Your Directors believe that our service is carried on with the greatest efficiency. We have had, at all events, no complaints on that score, and as this is due to the careful supervision of Mr. Evans and his staff, I hope the shareholders will be able to express their satisfaction with the services of the Egyptian staff. Our staff and expenditure in Egypt is also kept on a most moderate scale by our able secretary, who is quick to bring any abnormal outlay to the notice of the Board, and your Directors are not dilatory in requiring full explanation before authorising it. While our expenditure is at the lowest point consistent with efficiency, and our dividend remains at the moderate sum of 6 per cent., our subscribers in Egypt cannot fairly expect that the moderate charges for the services rendered can be reduced. The Committee in Egypt lend their aid to our superintendent in any matters of importance which may arise in which their advice is desired by the Board, and our thanks are due to the members of the Committee for thus giving their time. I beg to propose—

"*That the report and accounts for the year ended December 31, 1890, b and are hereby approved and adopted, and that a dividend be paid of 6 per cent. on the preferred shares, free of income-tax.*"

Mr. HENRY GREWING seconded the motion, which was carried unanimously.

The CHAIRMAN next moved:—

"*That Henry Grewing, Esq., be and he is hereby re-elected a Director of the Company.*"

Mr. LLOYD seconded the motion, which was carried unanimously.

On the motion of Mr. ADDISON, seconded by Mr. HENTSCH, the auditors, Messrs. Price, Waterhouse, and Co., were reappointed; and the Chairman having been thanked for presiding, the proceedings terminated.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended March 20th amounted to £6,174.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended March 21st amounted to £766.

**ELMORE'S FOREIGN AND COLONIAL PATENT COPPER DEPOSITING COMPANY (LIMITED).**—The Directors have called meetings for April 6th, to alter the articles of association to enable them to distribute amongst the shareholders the assets held by the Company, and represented by shares and debentures of the French and Austrian companies. If these clauses are altered so as to enable the Directors to distribute the above securities as though they were dividend in specie, they will immediately propose a distribution equivalent to £6 per priority share and £5 per founders' share, reckoning the securities to be divided at their par value.

**THE NEW YORK BELTING AND PACKING COMPANY.**—The first ordinary general meeting of this Company will be held on Tuesday, April 7th next, at the Cannon-street Hotel, E.C., at 2 o'clock.

**STOCK EXCHANGE.**—The Stock Exchange Committee have appointed Thursday, April 2nd, a special settling day in Elmore's Austro-Hungarian Patent Copper Depositing Company (Limited), shares Nos. 1 to 50,000.

**TELEPHONE COMPANY OF AUSTRIA (LIMITED)**—This Company have declared the usual half-yearly dividend to the 30th inst. on the preference shares, at the rate of 6 per cent. per annum, payable, less income tax, early in April.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended March 20, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £5,105.

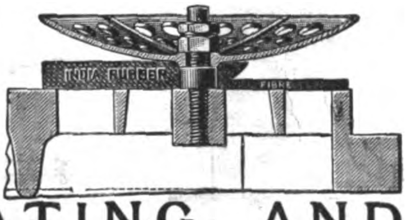
## NEW COMPANIES REGISTERED.

**ALEXANDER MATHIESON AND SONS (LIMITED).**—Registered in Scotland, with a capital of £120,000 in £10 shares. Object, to purchase and carry on the business of the firm of Alexander Mathieson and Sons, merchants, manufacturers of planes, mechanical and engineering tools and machines at the Saracen Tool Works, East Campbell-street, Glasgow, as well as in Edinburgh, Liverpool, and elsewhere.

**JARROW FORGE AND ENGINEERING COMPANY (LIMITED).**—Registered with a capital of £80,000, in £10 shares. Objects: To carry into effect an agreement made Feb. 27th, between "The Jarrow Forge Company (Limited)," of the first part, Matthew Dent and Edward Wilson, of the second part, and John Price, on behalf of the Company, of the third part, and to carry on generally the business of forge proprietors, engineers, shipbuilders, mechanical engineers, &c.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"13, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 672.—Vol. XXVI. FRIDAY, APRIL 3, 1891. Price Fourpence.

## NOTES.

Attention was called on a recent occasion in the House of Commons to the small attendance at the British Museum in the evening, and it appears that while 7,224 persons visited the galleries on Easter Monday, only 342 went there after eight o'clock, when the Museum was reopened. It is a great pity that the lighting was not thoroughly done at first, since one may go there with the intention of studying early English sun-dials, and have to put up with mummies; for only one portion is lit at a time. A far more serious mistake has been made in closing the Museum at dusk and reopening it from eight to ten. We recently visited the gallery in which a most interesting selection of drawings from the Print Room has been arranged. There was a very fair attendance, but at five o'clock the politely-worded cry of "All out!" resounded through the rooms, and the whole place was cleared forthwith. As an evening paper says, the visitors cannot be expected to cool their heels from five till eight o'clock. There is no apparent reason why a large attendance *should* be looked for on a Bank Holiday evening. Those who are bent on some form of entertainment at the end of a holiday can hardly be expected to turn out at eight o'clock to go to a museum. It was obvious enough on the occasion of our recent visit that many others besides ourselves would have stayed if permitted, and the electric light being very well done as far as it goes, they would have gladly continued to instruct or to amuse themselves.

To call a Society "International" which regularly year after year chooses all its officers from a single nation, is obviously a misnomer; yet a glance at our columns will show that this is the course pursued by the Société Internationale des Electriciens. A genuinely International Society might serve as a sort of permanent International Congress, and would possess considerable influence. As it is, the Société Internationale remains a purely French institution with little or no prestige.

In the January number of the Royal Society's *Proceedings*, Prof. J. J. Thomson describes some experiments to determine the velocity of the electric discharge through rarefied gases. It is strange that, since Wheatstone's first attempt, in 1835, to measure this velocity by means of a rotating mirror, no experimenter seems to have thought the matter worth re-investigation. Not only does the knowledge of the velocity render it necessary to discard at once several theories which could be advocated in explanation of the phenomena of electric discharge, but any method of measuring it must also show whether the discharge starts from the positive or negative electrode. The velocity found by Prof. Thomson by the revolving mirror method, is approximately half the velocity of light, and is given as $1{\cdot}6 \times 10^{10}$ centimetres per second. This is so great that the discharge cannot possibly take place by mere convection of the luminous molecules of the gas; for, if this were the case, the velocity of the molecules would be enormous, and the spectrum of the gas, when analysed with the telescope pointing along the direction of discharge, would, according to Doppler's principles, exhibit lines displaced from their proper position in the spectrum. No such phenomenon is found to occur, so that a different explanation must be sought. The idea that discharge takes place by the successive interchange of atoms between adjacent molecules is equally untenable, as the average distance between the molecules is far too large.

If one could regard the phenomenon of gaseous discharge as being mainly due to an action in the ether, there would be nothing extraordinary in such a high velocity as is actually found. The velocity with which an explosion travels in an explosive mixture of gases, such as hydrogen and oxygen, is known to be about the velocity of sound; and, from analogy, one would imagine that anything in the nature of disruptive discharge, would be propagated with the velocity of light, since that is the velocity appropriate to the ether. Prof. Thomson, however, takes the view that the passage of electricity is always effected by the dissociation of molecules, and ingeniously accounts for the high velocity by assuming that chains of contiguous molecules are formed, capable by electrolytic action of transferring an atom, and hence an atomic charge, from one end of this chain to the other, practically instantaneously. The spaces between the chains are traversed more slowly, but, by supposing them comparatively short, it is easy to account for the high velocity. This assumption leads at once to an interesting theory of the well-known striæ occurring in vacuum tubes, and the fact found by Prof. Thomson that the discharge proceeds from the positive to the negative electrode, can be shown to imply certain properties of the striæ which they are known from experiment to possess.

In the March number of the *Philosophical Magazine* appear two valuable Papers dealing with the subject of specific inductive capacity. The determination of this quantity is of interest, from both a theoretical and a practical point of view.

Digitized by Google

In the first place, it is a well-known deduction from MAXWELL's theory, that the square of the index of refraction of a substance is equal to its dielectric constant. This law is far from holding good in many cases, and it is accordingly desirable to test substances by various methods, to determine the influence of secondary actions in altering the apparent value of the inductive capacity. In view, also, of the prospective importance of condensers in alternate-current work, it is specially desirable to thoroughly examine the behaviour of the dielectrics under the action of alternating potentials; because the differences found in the value of the dielectric constants of bodies, when tested by different methods, correspond with the waste of energy which would occur in condensers formed with these substances as the insulating medium. Thus, the phenomena of residual absorption, when occurring with alternating currents, must produce effects closely analogous with those caused by hysteresis in iron, and must give rise to a loss of power and heating in the condenser.

MR. LECHER, the author of the first Paper, investigated the constants of ebonite, glass, petroleum oil, and water, by three different methods, in which the time of charge was varied from half a second down to one hundred millionth part of a second. For the high frequencies HERTZ oscillations were used, while an influence machine, and an induction coil were employed for the slower charges. The result, contrary to the experience of Prof. J. J. THOMSON, who had also determined dielectric constants by HERTZ oscillations, is to show that the inductive capacities apparently increase with the rapidity of charging; and the author considers that the electric oscillation method is unreliable, owing to the great damping which occurs. The second Paper on this subject is by Mr. ROSA, of John Hopkins University, and deals more especially with conducting electrolytes. The inductive capacity was calculated from measurements, by a torsion balance, of the force exerted between two balls immersed in the fluid under test and charged to various potentials. The voltage applied, the frequency of alternation, the temperature, and the conductivity of the liquid, were all varied to test their influence on the constants found. The method of test was specially suitable for eliminating the effects of conduction; and the result of the numerous measurements made, is to show that a conducting liquid has a definite specific inductive capacity independent of the current flowing through it. The values found for the specific inductive capacities of water and alcohol are extremely high, being 75·7 and 25·7 respectively.

**Societe d'Encouragement.**—This Society has published a long list of small prizes for electrical inventions to be awarded in 1892-93-94.

**Brussels.**—The municipal authorities have requested M. Wybauw to draw up a specification for tenders for the erection of a 20,000-light plant.

**Honours.**—Sir F. Abel was invested by Her Majesty, on the 18th March, with the insignia of the Civil Division of the Second Class of the Order of the Bath.

**Portsmouth.**—At a recent meeting, the Town Council decided to undertake the electric lighting of the borough, and that Mr. Shoolbred should be engaged to prepare plans and specifications.

**Telegraph Extension in Orkney and Shetland.**—The Government have agreed to the extension of the telegraph to Westray Island, Orkney, and to two places in Shetland. It is expected that the cable will be laid very shortly.

**Capacity Measurements of Cables.**—Mr. Dearlove informs us that he proposes to reply next week to the criticisms of Messrs. Ansell and Young, which appeared in our last issue, upon his communication which was published on March 6th.

**The Manufacture of Submarine Cables in France.—A Correction.**—In our last issue, on p. 648, we were made to say, owing to a printer's error, that the Société des Téléphones accepted a £3,200,000 order for cables. The figure should, of course, be £320,000.

**Institution of Electrical Engineers.**—A general meeting of the students was held on March 20th, when the following Papers were read :—"Gutta Percha," by Mr. H. C. Haycraft; "Commutators," by Mr. J. H. Garret. At the next meeting, on April 10th, a Paper will be read on "Photometry," by Messrs. Matthew and Seaman.

**Royal Victoria Hall.**—The following are the arrangements for science lectures at this hall during April:—Tuesday, 7th, Prof. Rupert Jones on "Minute Things in Nature;" 14th, Dr. Crosskey on "Extinct Volcanoes of France;" 21st, Mr. Dent on "Mountain Exploration in the Caucasus;" 28th, Mr. Kennedy, "Fighting the Indians" (experiences of a war correspondent).

**The Old Students' Association.**—On Wednesday, March 25th, an interesting Paper on "Coals, Coal-Mines, and Coal-Mining," was read before this Association at Finsbury Technical College by Mr. Albion T. Snell, following which an interesting discussion took place. A Paper has been promised for this session by Dr. Silvanus Thompson on "Recent Advances in Optics."

**Electric Traction in Berlin.**—At the recent general meeting of the Grosse Berliner Pferdebahn an exhaustive report was submitted regarding the financial and technical results of electric street railways on the overhead, underground, and accumulator systems of traction in Europe and America. The directors are negotiating with the Berlin municipal authorities for a concession to work experimentally one of the above-mentioned systems on their tramways.

**Reduction of Telephone Charges.**—It is announced that the charges to the public for the use of the Post Office Telephone Exchanges in various towns throughout the country have been reduced. For subscribers within a quarter of a mile of the exchange, £8 a year; half a mile of the exchange, £10 a year; three-quarters of a mile of the exchange, £12 a year; one mile of the exchange, £14 a year. At the same time a reduction has been made in the charges for ordinary private wires.

**Presentation to Mr. A. D. Stevenson.**—The partners and *employées* of the firm of Messrs. Drake and Gorham on Thursday last week presented a Wheatstone bridge and a stationery cabinet to Mr. Stevenson on his resignation of the post of manager. We understand that Mr. Stevenson has been compelled to resign on account of failing health, and has been recommended by his medical advisers to go to South Africa, where he will start in business in partnership with Mr. Edlin, for some years the representative in this country of Messrs. Lacombe and Co.

**The Telegraph Revenue for 1890-91.**—Although the receipts from the telegraph service continue to show an increase, it is by no means so large as that of the preceding financial year. The receipts for the year ending March 31, 1890, amounted to £2,320,000, or £240,000 more than the previous total. The receipts for the year ending March 31, 1891, are £2,380,000, an increase of only £60,000 over the previous total. All the quarters of the year 1890-91 show an increase, when compared with the corresponding quarters of 1889-90, except the last, in which there is a decrease of £45,000.

**Societe Internationale des Electriciens.**—The Council of this Society have decided that all presidents shall be nominated one year in advance. The Council's candidates for 1891, elected at the annual meeting on Wednesday, were as follows: President, M. Joubert; Vice-Presidents, MM. H. Baron, H.

Digitized by Google

Menier, de Romilly; General Secretary, M. R. V. Picou; Treasurer, M. Dumoulin-Froment; Secretaries, MM. Hospitalier, Max de Nansouty; Members of the Committee, MM. E. Cael, J. Carpentier, Chapron, Clérac, Darcq, Ducretet, Gariel, Harlé, Huet, Magne, Mouchel, de Parville, Pellat, Rouart, Sartiaux, Sciama, de la Touanne. The President elect for 1892 is M. Carpentier.

**Electric Lighting in Connection with Railway Disasters.**—The electric light is used to a large extent on American railways for lighting up "wrecks" or night construction work. For this purpose the Pennsylvania Company and the Cumberland Valley Company have a car fitted up with boiler, dynamo, engine, water tanks and coal bunker, and all the tools necessary for a central station. After the Johnstown flood six men put up six arc lamps, ran the wire, coupled up the lamps, and had the lamps going in 35 minutes from the time the car, lamps, poles, and wire arrived on the ground. The lights were distributed some distance, one being about one third of a mile away.

**Exports of Telegraph Apparatus.**—The Board of Trade Returns continue to show very irregular movements in the value of our exports of telegraphic wire, and of apparatus connected therewith. The February exports were small, but the aggregate this year is still large compared with the corresponding figures for 1889 and 1890. The following are the details for the two months:—

| | 1889. | 1890. | 1891. |
|---|---|---|---|
| January ......... | £113,230 ...... | £71,686 ...... | £238,223 |
| February ......... | 32,086 ...... | 201,594 ...... | 22,306 |
| Total......... | £145,316 ...... | £273,280 ...... | £260,529 |

**Electric Light Mains in the West End.**—At a recent meeting of the St. George's (Hanover-square) Vestry, Lord F. Fitzroy called the Surveyor's attention to the irregularities of the electric light companies who had been engaged in laying cables in the more fashionable parts of St. George's for some months past. One company, he said, would take up the paving-stones, and directly they were re-laid the other corporation would lift them again. He asked if the Vestry could take no action in the matter to put an end to the inconvenience inflicted upon the public?—The Surveyor said he was sorry to state that the Vestry was almost powerless in the matter. The companies had left several streets and squares in a very bad condition.

**Accumulator Traction.**—On p. 563 of our issue of March 13th, we stated, on the authority of the *Elektrotechnisches Echo*, that the firm of Hostmann and Co., of Hanover, who had been carrying on traction experiments with Schoop gelatinous accumulators in the neighbourhood of Hildburghausen, had decided to abandon the use of these accumulators. This is an error, and the real facts are as follows:—The experimental line at Hildburghausen was regularly worked from August last until the end of March, when the charging station was dismantled and the accumulator car was got ready to be taken to Frankfort. During the Exhibition this car, and a large 34 passenger car will run regularly. Messrs. Hostmann and Co. state that the results of their experiments have so far been satisfactory.

**The Victoria Patents Office.**—The Commissioner of Patents for the Colony of Victoria has issued the following circular to inventors, manufacturers, and others:—"With a view to obtaining the fullest information for the library of the department, I have the honour to solicit a copy of catalogues, leaflets, &c., with sectional illustrations, describing and illustrating as fully as possible your products and manufactures. It is hardly necessary to point out that, as a means, not only for the better dissemination of knowledge and information for the public, but also for protecting manufacturers and inventors, to whom letters patent have been granted, and thus preventing the piracy of inventions already published or in operation, such documents are invaluable, and are necessary as evidence of publication prior to an application being made to this office for letters patent.

**The Westminster Electric Supply Corporation.**—All the three Stations of the Westminster Electric Supply Corporation are now at work. The Millbank Street Station was permanently started in November last. The station at Eccleston Place was started on the 2nd March; and that at Davies Street, which supplies Mayfair (down to Piccadilly), was started on the 24th March. In the two cases last named the permanent machinery is enclosed in a temporary iron building, covering over a portion of the engine and boiler rooms, while the building of the rest of the station proceeds. The time which elapsed between the signing of the building contract and the delivery of current from permanently installed plant, was seven months and three days in Eccleston Place, and exactly six months in Davies Street, although work was practically stopped for nearly two months in the winter, owing to the severe frost.

**"The Optician."**—A copy of the first number of this weekly paper has been sent to us, and it certainly has a useful field before it. "The ordinary dealer," says this new journal, "with a few notable exceptions, is profoundly ignorant on all optical questions affecting his photographic apparatus, although his assurance will never fail him in replying to any inquiry involving the optics of photography, or the principles of the lantern. . . . . . We shall endeavour, by providing scientific articles, written in a comprehensive and popular style, to educate him up to a higher standard. . . . . . The day will be welcomed by all when the covert sneer contained in the epitaph 'Shoptician' shall have been, once and for all, wiped out." A few hints as to the choice of batteries for particular purposes, and the use of vacuum tubes and coils and other electrical playthings would be useful also.

**The Telephone in Spain.**—The Spanish Government has published the conditions under which tenders will be received for the construction and working during a certain number of years of a complete network of telephonic lines, to be established between the principal towns in Spain. For this purpose the country will be divided into four districts. Telephonic communication must be established between the principal towns designated in each district, within ten months after the date of the concession; with other towns of less importance, within a year from the same date; and with other places, within three years. All the apparatus employed must be of the most perfect description. The maximum charges to the public are fixed by Government, and the holders of the concessions will pay an annual sum to the State for each kilometre of line. The full conditions under which tenders will be received are published in the *Madrid Gazette*.

**A French Electrical Mining Plant.**—The Compagnie Continentale Edison installed an electric haulage plant last year in the Mines de Marles, and it has given such satisfaction that the original plant is now about to be considerably enlarged. The generator is a 26 unit Edison machine, giving 400 volts at 900 revolutions. The pit is nearly 1,000 feet deep, and the line runs along a gallery 1¼ miles in length. The locomotive is 7ft. 3in. long, 2ft. 4in. broad, 4ft. 11in. high, and weighs 2 tons, 6cwt. The motor, a 10 unit machine, is arranged lengthwise and drives on to both axles through double helicoidal gearing. A speed of over 9 miles an hour is attained, and 10 B.H.P. is developed when hauling a train of 25 fully loaded skips, each weighing 14cwt. The conductors in the gallery are two Vignole rails suspended from porcelain insulators fixed in the roof, and the current is taken off by two travelling carriages fitted with brushes and connected to the locomotive by flexible conductors. The plant efficiency is stated to be 75 per cent.

**The London Electric Supply Corporation.**—"Probably no Board of Directors ever had to bear a heavier responsibility than has weighed upon Mr. Forbes and his colleagues during the past year; and no engineer," says the *Journal of Gas Lighting*, "has ever had either greater difficulties or a finer opportunity than their young Engineer, Mr. S. Z. de Ferranti. But the Directors believed in their Engineer, and stuck to him through everything; and he has justified their confidence by triumphantly doing what nearly all other electricians have declared to be impossibilities. Whether or not the Company will ever make a good profit, of course remains to be seen; but, in the meantime, the splendid spirit displayed by both Board and Engineer in grappling with their troubles, and agreeing to sink

Digitized by Google

or swim together, deserves recognition. If they were gas people, we should be proud of them; and we do not see why we should not cordially admire them because they happen to belong to a different industry."

**Underground Telephone Cables in the City.**—Colonel Haywood has reported to the Commissioners of Sewers upon the application of the National Telephone Company for permission to place some telephone cables beneath the public ways of the City. At present, he states, all their cables are overhead, and what is immediately sought is permission to lay underground trunk lines to connect the principal exchange with the smaller exchanges. About 31 streets altogether, and many of them important and leading streets of the City, would be disturbed for the purpose. The total length of public way sought to be opened was nearly three miles. Colonel Haywood points out that the inconvenience caused to the public by carrying out the work would be considerable, and in some cases the laying of additional tubes in the network of gas, water, and telegraph pipes would be impossible. He advises the Commissioners to defer their consent until the conductors for lighting the City by electricity are laid. At the same time he expresses a strong opinion in favour of all wires being placed under the streets in subways of ample size. This report will shortly come up for consideration.

**The Dawn of Telegraphy in France.**—The use of the electric telegraph, says *l'Electricité*, was first thrown open to the public on March 1, 1851, the first official recognition of its existence having been a royal decree, dated November 13, 1844, placing £9,600 at the disposal of the authorities for experiments on the line between Paris and Rouen. Three years later every departmental capital was in telegraph communication with Paris. In 1852 the receipts amounted to more than £20,000; in 1853 they had increased to £60,000, and in 1854 they exceeded £80,000. An early cause of the inferiority of the French telegraph service, was the endeavour of the authorities to use a method of signalling similar to the time-honoured semaphore system, in order that the staff might have little new to learn. It is needless to say that the tariff was exorbitant, 4fr. being the minimum charge for a message to Rouen, and no rebate was given to pressmen. Tedious proofs of identity were also demanded from every individual who despatched a telegram. A noteworthy feature of the early days of French telegraphy, was the great relative importance of the Paris receipts. In 1852, 43 per cent. of total receipts were due to Paris; in 1853, 40 per cent.; in 1854, 41 per cent.; and in 1855, 40 per cent.

**The Founders of Electric Lighting.**—The following remarks made by Prof. Elihu Thomson in his "Pioneers' Day" address to the National Electric Light Association, may be of interest:—"It was my privilege in 1889 to visit the Royal Institution in London, and there inspect the original manuscript records made by Sir Humphrey Davy and by Faraday—the two great names lying, as it were, at the foundation of the sign, at least, of electric lighting—to inspect also the apparatus and even to handle the apparatus which Faraday used in his early experiments. I can say that I did it reverently. These two names are coupled with the beginnings of our great industry. Sir Humphrey Davy was the first man who ever saw the electric arc; the first man who put two wires together tipped with carbon, drew them apart and got the flame which we now call the electric arc. He called it the electric arch, I believe, or an arch of flame. I saw the record of this in Davy's rapid hand, that this was a gorgeous experiment. It was quite a contrast—the difference between Davy's style of recording his experiments and Faraday's—and there is that contrast even to be seen in their work. Davy was, as it were, brilliant, jumping from one thing to another and getting thereby a great leap; while Faraday's was the painstaking work of the scientific investigator, who thought out carefully what he was about, and when he had concluded his experiments, wrote out just as carefully what he had obtained. The records of Faraday's are models of neatness; they are models of precision in every way."

**Magnetic Rocks.**—In a letter to *Nature* the following instance of extraordinary local magnetic disturbance, due to the presence of magnetic rocks, is cited by Commander Creak:—In September, 1885, when H.M. surveying vessel "Meda" was passing Bezout Island, near Cossack, North-West Australia, a steady deflection of her compass of 30deg. was observed. This remarkable result has, however, since been exceeded by observations made in the "Penguin" on November 6, 1890, the "Penguin" being two miles N. 79deg. E. from Bezout Island, a deflection of 22deg. was observed. The ship was immediately anchored, and some hours of the next day were spent investigating the matter. On Bezout Island itself the absolute values of the variation and dip were normal, the dip being 50deg. 1'·7 S. But at a position N. 79½deg. E. distant 2·14 miles from that on Bezout Island, the observed dip on board was 83deg. S., with a very small deflection of the compass. At 900 feet to the westward of this the dip was normal, and it decreased rapidly as the centre was quitted in any direction. At about 100 feet south of the centre of disturbance, the compass was deflected 55deg. This was the largest deflection observed, but the compass was disturbed over an area of about a square mile. The general depth of water in this area was nine fathoms, and the quality of the bottom quartz sand. The observations of the magnetic elements at Cossack and the neighbourhood showed little or no disturbance from local magnetic effects. It is therefore evident that the disturbances were due to magnetic minerals at the bottom of the sea.

**Night Signalling at Sea.**—Experiments in new methods for night signalling at sea are now being conducted on board the ships of the United States Navy. With the present system, there are three electric lights, green, red, and white, of 16-c.p. each, fitted in a vertical line on a jackstay, about six to eight feet apart. They are worked by an ordinary telegraph key, one of the long line keys of the Western Union Company being employed. The green light means a dash, the red a dot, all three lights briefly a space, or all three for a more extended period signify the end of a word. The distance at which this system can be used is about three miles. To communicate beyond three miles the "Very" system is used. This consists of pyrotechnical displays of red and green stars, by combinations of which certain numbers are represented, having their own signification in the code. The English Navy system, as is well known, is on the flashing plan. Another system for long-distance signalling at present under experiment in the United States Navy, and frequently employed with success in the Chilian-Peruvian war, is to throw the electric search light directly overhead and make dashes and dots with it against the sky, so that they may be read for many miles by the whole fleet. A new French system, called the "Ardois," has been fitted on the "Chicago" for experiment on her present cruise, and will be tested on favourable occasions. This system is made up of 10 lamps which hang vertically from a backstay, thus forming combinations which, being interpreted, make up the code. The combinations are worked from a keyboard having 62 different letters and signals.

**Hampstead Vestry.**—At the Easter meeting of the Hampstead Vestry, the Electric Lighting Committee presented a report on the subject of electric lighting for Hampstead. The committee stated that it had consulted Mr. W. H. Preece, who estimated the cost of installation for street illumination and private purposes at £81,000. He recommended the Vestry to undertake the work rather than permit a company to come in and do it, and to undertake the full scheme for the whole parish rather than the lighting of portions only. He estimated the working charges for a year as £15,800, yielding a revenue of £19,500; and after deducting £1,400 as the increase cost of public lighting over gas, the net result would be a profit of £2,300, while the total required to repay the loan and interest in 30 years would be £3,455. His figures were based on the supposition that the Vestry would charge 6d. per Board of Trade unit, as against a probable 7½d. charged by a company, and that 24,000 16-c.p. lamps would be rented by the ratepayers. The committee, in concluding the report, stated that, all other things being equal, it was evident that there would be this solid advantage, that the Vestry could, at any time, adopt any scientific improvements, and that the ratepayers would always have the means of procuring the redress of a grievance, and of insisting on efficiency of management. In the absence

Digitized by Google

of Mr. Baines, chairman of the Committee, a communication from that gentleman was read, as also another, offering special terms, from the Tottenham Company, and the Vestry finally decided to receive the report, but to postpone any decision to May 7th. An urgency proposal that a poll of the ratepayers should be taken was rejected.

**Aluminium.**—If anyone ought to know what aluminium is, and what it is good for, it should be, says the *Engineering and Mining Journal*, one of the leading manufacturers of this metal; and if such leading manufacturer deliberately and publicly says that aluminium is not the extraordinarily good metal that it is popularly believed to be, then we have good reason to suspect that he is right, and that popular belief in the matter wrong. According to our contemporary, Mr. A. E. Hunt, President of the Pittsburg Reduction Company, summed up the disadvantages of aluminium in a Paper recently read before the Boston Society of Arts. The *pure* metal is very soft, and not so strong as the impure. It becomes pasty at a temperature as low as 550°C., melts at 720°C., and loses its tensile strength and much of its rigidity as low as 200 or 250 deg. It is inferior to copper as a conductor of electricity, being in fact only half as good. Its lack of rigidity and hardness is an obstacle to its use for many purposes, such as castings. Alloys of the metal increase in brittleness more than they do in hardness. Its tensile strength per square inch is not greater than that of common cast-iron, and only about one-third that of structural steel, while its compressive strength is less than one-sixth that of cast-iron. The modulus of elasticity of cast aluminium is about 11,000,000, being only about one-half that of cast-iron, and one-third that of steel. It combines with iron in all proportions, but none of its alloys with that metal are of value, except those with very small percentages of aluminium. Other elements than aluminium can be better employed to harden iron, and its presence in iron is to be regarded as deleterious, and to be avoided if possible. The addition of aluminium does not lower the melting point of steel, as has been claimed, nor does it increase its fluidity.

**Specific Inductive Capacity.**—The following measurements of the specific inductive capacity of various media have been published in *Wied. Ann.*, Vol. XXXVI., by Herr Tereschin. The method used was that due to Cohn and Arons, and the temperature at which the observations were taken was in all cases about 14° centigrade.

| Substance. | K | Substance. | K |
|---|---|---|---|
| Methyl alcohol | 32·65 | Amyl acetate | 5·2 |
| Propyl ,, | 22.8 | Methyl benzoate | 7·2 |
| Amyl ,, | 15·9 | Ethyl ,, | 6·5 |
| Methyl formate | 9·9 | Isobutyl ,, | 6·0 |
| Ethyl ,, | 9·1 | Amyl ,, | 5·2 |
| Isobutyl ,, | 8·4 | Ethyl propionate | 6 |
| Amyl ,, | 7·7 | Ethyl butyrate | 5·3 |
| Methyl acetate | 7·75 | Ethyl valerate | 4·9 |
| Ethyl ,, | 6·5 | Aniline | 7·5 |
| Propyl ,, | 6·3 | Carbon tetrachloride | 2·2 |
| Isobutyl ,, | 5·8 | Xylol | 2·35 |

For water, the value of K found was 83·8.

Several measurements of specific inductive capacity have been lately published in the *Philosophical Magazine*. Herr Lecher finds that the value of K varies with the time of charge, the value of K for plate glass being 4·67 when the time of charge was half a second, and 7·3 when the charging was effected by electric oscillations occurring $10^8$ times per second. The values of K for ebonite varied under the same circumstances from 2·64 to 3·01. Mr. E. B. Rosa gives the following numbers for various conducting liquids:

| Substance. | K | Temperature. |
|---|---|---|
| Water | 75·7 | at 25°C |
| Alcohol | 25·7 | ,, 25°C |
| Sperm oil | 3·09 | ,, 20°C |
| Benzine | 2·45 | ,, 21°C |
| Turpentine, Commercial | 2·43 | ,, 18·°6C |
| Petroleum, "Neutral" | 2·26 | ,, 21°C |
| Headlight oil | 2·11 | ,, 24°C |

**Pioneer Electric Traction.**—The following are some of Mr. Frank Sprague's pioneer experiences, as related by him at the recent meeting of the National Electric Light Association at Providence, (R. I.) The contract for the road in Richmond was taken in 1887. I had never seen the road. When I went to Richmond I saw a grade of 10 per cent. My heart fell within me, and I said it was utterly impossible for any car to climb that hill. I came back to New York. Mr. Johnson then said, we had better find if we really could not get up the grade. Back to Richmond I posted. We started and mounted the hill. When we got to the top we had settled the question of traction on a 10 per cent. grade. It was settled likewise that the motors we had were too small and too light, they were hotter perhaps than the furnace in an electric welding apparatus. I was now brought face to face with the fact that it was necessary to make a complete change on sixty machines in Richmond in the matter of gearing. In the course of four or five weeks we started again in Richmond on February 2, 1888. The next thing we found was that the armatures were too large, and so we had to resort to electrocution—we had to cut off their heads. The machines were covered with water and mud. Every field-magnet had been wound and rewound three or four times. Our next experience was that our commutators were going to pieces. We had tried no less than 65 different kinds of trolleys and had not got one that would work reasonably satisfactorily. We were attempting to run motors in both directions. After trying a great variety of brushes, we finally settled upon square bars of brass about three-eights of an inch square. Subsequently we used carbon. That inside history of some of the work at Richmond has not been told before. I think the time has come now when there is no harm in its being made public. I think that people would have looked on electric railways as out of the question if they had known of the straits we were going through.

**The Cultivation of India Rubber.**—In a recent letter to *Nature* Mr. W. R. Fisher gives some interesting particulars with regard to rubber cultivation in Assam. After some preliminary experiments, the Government of Assam in 1873 determined to plant caoutchouc in the Charduar Forest at the foot of the Himalayas. This district is essentially damp, and the moist hot atmosphere in the summer months resembles that of a forcing house. The plan of concentrating rubber-trees in artificial plantations was carried out as follows:—At first attempts were made to propagate by cuttings, but it was soon discovered that rubber-seed germinated freely on well-drained beds covered with powdered charcoal or brick-dust, and that the seedlings, though at first small, became about 2ft. high in twelve-months, and were much hardier against drought than plants produced from cuttings. In order to imitate nature as much as possible, some strong seedling rubber-plants were placed in the forks of trees in 1874, but by 1885 only a few of them had reached the ground and were growing. Large nurseries were ultimately formed, in which the plants were retained until they were 10ft. high and then planted out in belts of 40ft., separated by alternating strips of untouched forest 60ft. wide. It was found that the rubber-plants did not get sufficient light with lines less then 40ft. broad, whilst the strips of forest kept the soil and atmosphere moist, and afforded side shelter to the plants, forcing them to grow upwards. As this method involved considerable expense in clearing the lines, and wasted the wood, which was frequently unsaleable, the Chief Commissioner of Assam, in 1874, directed that plantations of *Ficus elastica* should also be made in grass-land near Tezpur. The trees, however, when tapped yielded scarcely any rubber. An area of only eight acres was therefore planted out near Tezpur, whilst the area of the Charduar plantation in 1889 was 1,106 acres, and contained 16,054 plants, besides large nurseries with 84,000 seedlings. The present average annual growth in height and girth, taken from 350 plants, are respectively 5ft. 2in. and 8in. The up-keep of the plantation consists chiefly in clearing the lines round the plants, but four years after planting the under-growth is well kept down by the shade of the rubber-trees. Experimental tappings were made in 1883 and 1884 on 50 natural grown rubber-trees in the Charduar Forest, the total yield being 438lb. in 1883 and 206lb. in 1884, giving an average yearly yield of 6½lb. per tree.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 636.*)

§ 47. The waste of power may be obtained from the diagrams by taking the product of E and C at short intervals of time, and using these products as ordinates in a power curve, the

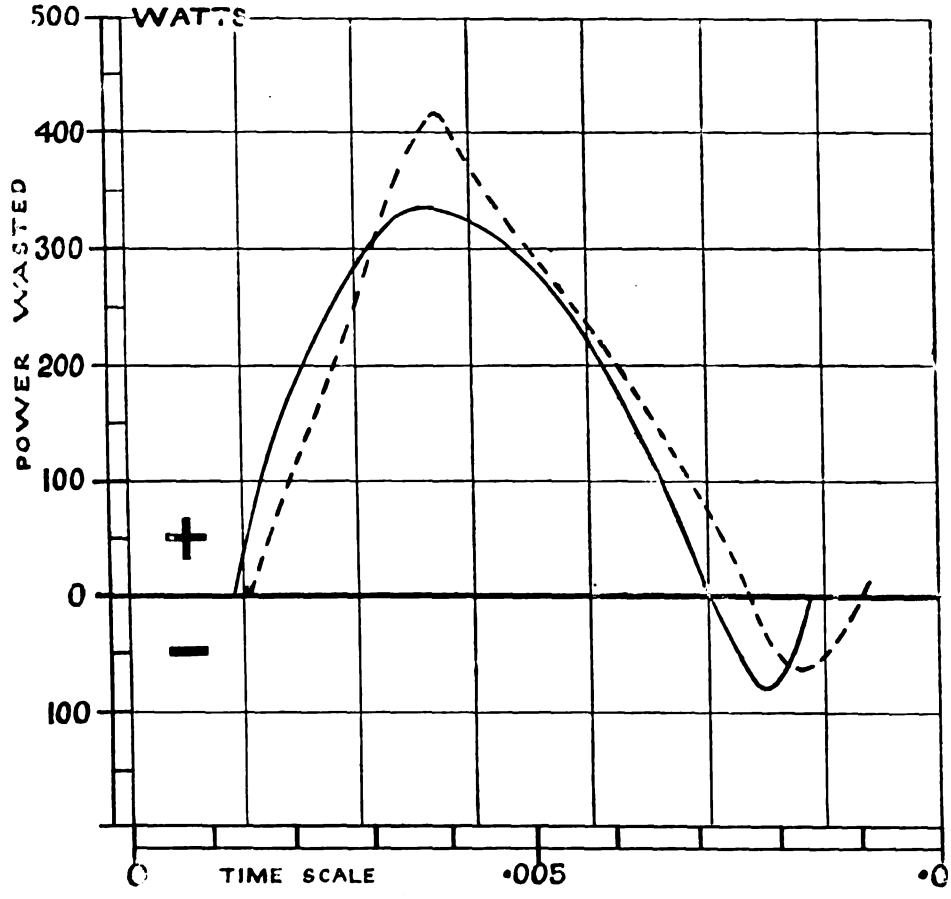

FIG. 13.—Curves shewing power wasted in the core of No. 2 Closed Transformer. The full line corresponds with sine E.M.F., and dotted line with zig-zag E.M.F.

area of which—best taken by a planimeter—divided by the time, gives the mean power wasted in the transformer core at *no* load. The power curves for No. 2 closed transformer run by a sine and a zig-zag E.M.F. will be found in Fig. 13. In each there is a time during which the power is negative the core giving back to the circuit a small

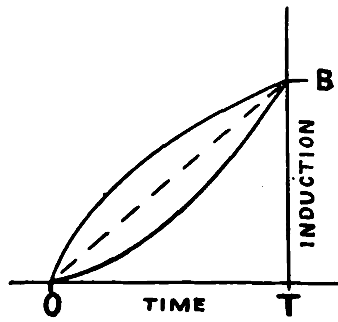

FIG. 14.—Three modes of raising the induction threading a circuit to value B in time T, that indicated by the dotted line wastes least power in eddy currents.

part of the energy previously put into it. The negative area must be deducted from the positive area before dividing by $\frac{1}{2}$T to obtain the mean power. These curves show that the *shape* of the E wave has very little influence on the total waste of power in the core, a result which the reader has doubtless foreseen from the beginning of this investigation, for the hysteresis loss depends only on the maximum induction and number of reversals per second, and the former having been kept constant and the latter only slightly varied, the variation in waste power from this cause can only be small. The hysteresis loss then varies *directly* as the frequency other things remaining constant. The eddy current loss for a given shape of E.M.F. wave also varies directly, but as the *square* of the frequency, for it will be remembered, that the expression for the power wasted in eddy currents contains the factor $\dot{B}^2$, which is proportional to the square of the maximum induction and square of the frequency. But the eddy current loss depends on something besides frequency. When a given total change of induction takes place within a certain area in a given time, the waste power in eddy current in conductors surrounding the

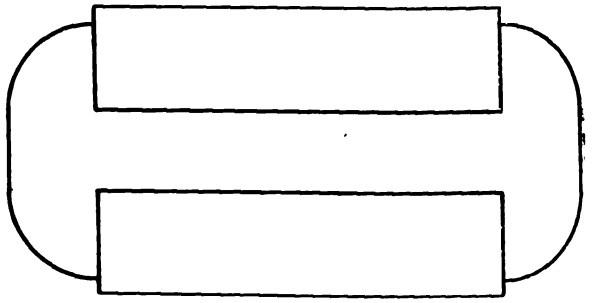

FIG. 15.—No. 2 as an Open Transformer, with small Hedgehog ends. One-tenth full size.

area depends on the law governing the rate at which the induction varies during the whole time occupied by the change.

§ 48. Let us examine this a little more closely. Imagine a bar magnet to be thrust into a conducting ring, causing eddy currents in it. In Fig. 14 the law by which the induction

Digitized by Google

threading the ring varies with the time as we push the magnet in is indicated by two curves, either of which is represented by the equation :—

$$B_t = \frac{\beta}{T} t + \frac{B' - \beta}{T} t^2,$$

where $\frac{\beta}{T}$ is the tangent of the angle made by the tangent to the curve at $t = 0$; and $\beta$ is obviously the value B would have when $t = T$, provided the induction continued to increase at its initial rate from 0 to T. The curve is convex or concave

into heat through the medium of electric currents in the ring—is

$$W = \int_0^T \frac{\dot{B}^2}{r} dt,$$

and, if the value of B is obtained from the equation just given for $B_t$, and the integration performed, we arrive at the following value for the work done :—

$$W = \frac{1}{rT}\left\{ B'^2 + \frac{1}{3}\left(\beta - B'\right)^2 \right\}.$$

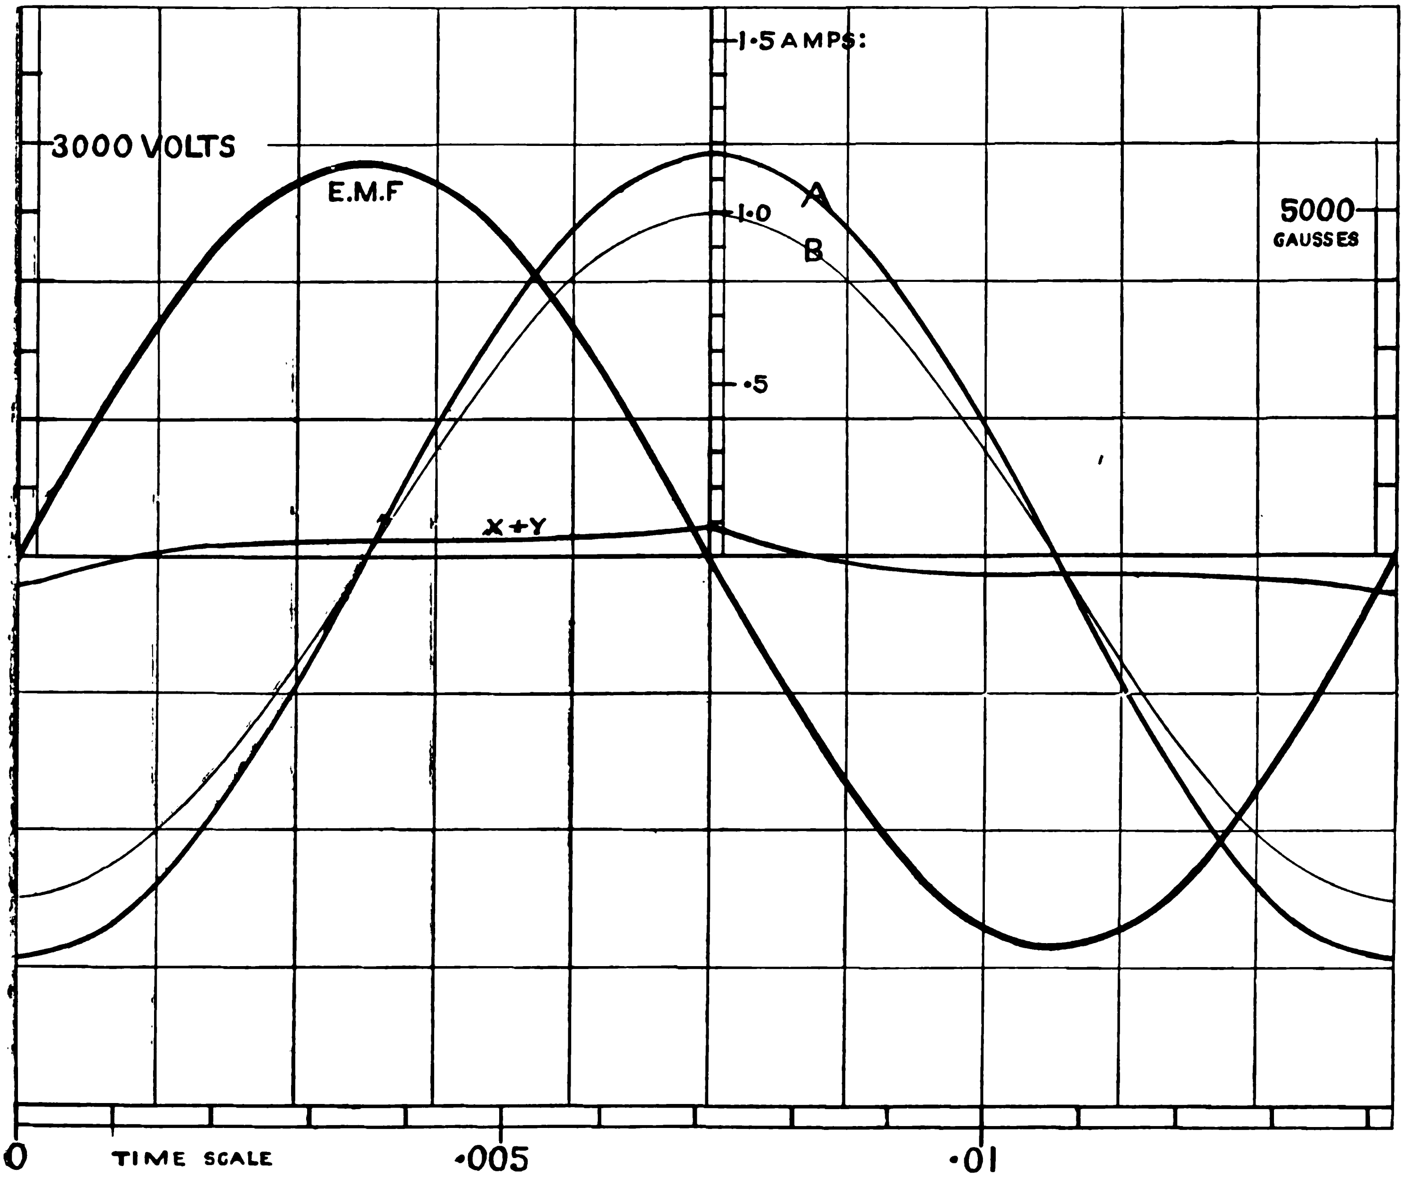

Fig. 16.—No. 2 as an Open Transformer with Small Hedgehog Ends (Fig. 15) run by a sine E.M.F.

X + Y = Total Exciting Current required by the Core.
A = Exciting Current required by the Air Path.
B = Induction Density in the Core.

F = 700.
Output = 0.
E = 2,000 volts.

to 0 T, according as $\beta$ is less or greater than B′, and when $\beta = B'$ it becomes a straight line. We can vary the rate at which we push the magnet into the ring in any way we please and so make B increase according to any law, and the problem being to determine which law will make the energy wasted in currents in the ring a minimum, we start by choosing an equation which practically represents any regular law. The electromotive force in the ring during the motion of the magnet is $\frac{dB}{dt} = \dot{B}$, the resistance of the ring being $r$ the irreversible work done by pushing the magnet into it—the work turned

Now as $(\beta - B')^2$ is always positive whatever value is chosen for $\beta$, it is clear that W is a minimum when $\beta = B'$; the second term then vanishes and the minimum work done is

$$W = \frac{B'^2}{rT},$$

and this is evidently when the law of increase of induction is

$$B_t = \frac{\beta}{T} t = \frac{B'}{T} t,$$

that is to say when the rate of change of induction is constant; a result entirely in accordance with our sense of the fitness of

Digitized by Google

things. To push the magnet in in *no* time would only end in melting the ring, and would require an infinite amount of work.

§49. Other things being the same then, the eddy current waste in a transformer, and generally in all parts of an alternate current apparatus, will have the least possible value when the *induction* follows a zig-zag law. Fortunately, large eddy current waste is usually so easily avoided by judicious lamination of conductors, cores, and other conducting parts of alternate current machinery, that there is no occasion to attempt the realisation of any alternator giving E.M.F. waves of the shape assumed in Fig. 12. The point was worth notice however. In most transformers the loss from hysteresis is so much larger than that arising from eddy currents that there is a distinct gain in efficiency when the impressed E.M.F. follows a zig-zag law, and the alternators would run at a slightly lower speed, so that in spite of the dictum of a well-known professor, to the effect that "if an alternator does not give a sine curve, it must be *made* to do so," the fact remains that there is a very small balance of advantages in favour of the zig-zag wave. It is obvious that the one essential condition for general efficiency of an alternate-current system is that the induction should be always *changing*; if it is constant during any fraction of the period, that fraction of time is wasted. So long as this condition is fulfilled the actual shape of the E.M.F. and current waves is of practically no importance.

§50. The broad lesson to be learned from the diagrams Figs. 10, 11, and 12, is that in studying the losses in the cores of transformers, we may neglect the slight differences due to widely differing E.M.F. wave forms; so that such diagrams may be drawn according to any simple method involving little labour. The zig-zag and the sine diagrams are about equally easy to work out, each being slightly more laborious than the alternating constant E diagram. As nearly all alternators gives wave forms something between a zig-zag and a sine function, preference must be given to them, and in drawing a diagram for No. 2 as an open transformer we shall choose the latter, but before doing so it will be best to make the modification alluded to in the note on page 599. It appears from the corrected figures for the dimensions and exciting currents for Hedgehog transformers, that the total effective surface of the spherically-spread wires of the core is considerably greater than our original estimate, and the exciting current correspondingly less—a fact which will be further discussed when comparing the results of our more or less theoretical investigation with actual results of observation.

§ 51. In actual work No. 2, Fig. 8, would require about ·7 ampere to excite it, so that the daily waste as $C^2R$ for exciting current would be $7{\cdot}6 \times {\cdot}7^2 \times 24 = 90$ watt hours nearly, instead of 182 as previously calculated; but the core waste was 2,470 watt hours per diem, so that it would evidently pay to cut down the spherical ends and save on the larger loss. If the total length of the core is reduced from 93 to 74 cms., the volume being proportionately diminished, the waste of power in the core becomes 82·3 watts; the exciting current will be about ·9 ampere, and the efficiency on the six hours load at 4,000 watts is as follows:—

**Table XV.**—*No. 2 as an Open Transformer with small "Hedgehog" ends.*

Maximum $B = 5{,}000$. $F = 70$.

Load as in Table V.

| | | |
|---|---|---|
| Total output | 24,000 | watt hours. |
| 24 hours' waste in core at 82·3 | 1,975 | ,, |
| 24 hours' waste $C_p^2 R_p$ for exciting current | 148 | ,, |
| 6 hours' waste $C^2 R$ for load | 372 | ,, |
| | 26,495 | |

$$\text{Efficiency} = \frac{24}{26{\cdot}5} = 90{\cdot}5 \text{ per cent.}$$

Resistance drop = 2·8 per cent. at full load.

§ 52. The diagram given in Fig. 16 is obtained in exactly the same way as was explained in connection with the closed transformers, but it is convenient in dealing with open transformers to divide the magnetising current in two portions, one being that required for the core alone, including anti-eddy current; the other being that required to magnetise the air-path from pole to pole. The total maximum induction being 5,000 x area of core, and the so-called magnetic resistance of the air-path being approximately calculated, the necessary air-magnetising component of the exciting current is easily ascertained and plotted in. It is, of course, co-phasal with the induction, and therefore exactly a quarter-period behind the counter E.M.F. The exciting current for the core is calculated and plotted just as in the case of the closed transformer, the same **B H** curve (Fig. 9) being used, and indeed the only change made is in the length of core, which is now 74 cms. as against 147 cms. for No. 2 closed transformer. In Fig. 16, the hysteresis and eddy current, X and Y components, are added before plotting in order to prevent confusion. The scale to which current is plotted in Fig. 16 is one-fourth that used in the previous diagrams.

§ 53. As has been noticed above, the exciting current for the air-path is exactly a quarter period behind the counter E.M.F. It is, therefore, very nearly $\frac{1}{4}T$ behind the impressed E; it would be exactly so but for the resistance of the primary coil, which leads to a little potential difference between its ends being required to maintain the exciting current in it. But the maximum value of C R is only $7{\cdot}6 \times 1{\cdot}26 = 9{\cdot}6$ volts, and this is entirely negligible compared with the maximum counter E—2,860 volts—so that the latter must be almost precisely in step with the impressed E. For every practical purpose the air-exciting current may be treated as being exactly $\frac{1}{4}T$ behind the impressed E, and consequently though "full of sound and fury" it signifies next to nothing, when reckoned as waste of power. It is, apparently, for this reason Mr. Swinburne speaks of it as "spurious" current. This is a needless epithet, for after all it is a real current, and it will be preferable to speak of a current which is $\frac{1}{4}$ T out of step from E as an *idle* current—a current that is, which does no work and requires no power to maintain it, beyond that wasted in heating the conductors. We have already noticed that the one defect introduced when transformer No. 2 was converted into a Hedgehog, was the large exciting current. It is now clearly established that a very large proportion of the whole of the exciting current is idle. The additional efficiency of an open circuit transformer costs nothing—less than nothing, for the material used is somewhat less, and the labour would also be diminished to some extent. But there is a useless encumbrance given away with the bargain, namely a large idle current, which may quite conceivably lead to a new metamorphosis. A supply company after putting in highly efficient open-circuit transformers over the whole of its system, might discover that it was harbouring white elephants disguised as hedgehogs.

*(To be continued.)*

## PHOTOMETERS.

Practical photometry does not enter into the ordinary work of an electrical engineer. Most of our readers are familiar with the general principles, and every technical college is provided to a greater or less extent with photometers "for educational purposes," and occasionally with a properly-fitted photometric bench. The eye is utterly unable to estimate illumination quantitatively. We cannot tell whether one light is twice as bright as another, or if it is only once and a-half times as powerful. Every electrical engineer knows that eight-candle lamps are more easily distinguished from sixteen-candle by the size of the bulb than by the light yielded. Photometrical measurements are therefore always made by the comparison of illuminations, and a null or zero method is adopted; the skill of the observer being directed to the adjustment of the apparatus until the two illuminations appear to him to be identical. This amounts to a relative

Digitized by Google

quantitative estimate of two sensations. Our various senses are very keen in detecting small *qualitative* differences. Thus the eye can detect, according to Aubert, at least one thousand different simple colours, while, allowing for mixtures, there must be between two and three million distinguishable tints. A practised ear, according to Weber, can recognise one sixty-fourth of a semitone, or a difference of one vibration in a thousand; but for all that it is impossible to say whether one sound is half as loud as another. The exactness of quantitative estimation becomes, then, generally merely a matter of the limit within which two sensations appear to be identical. If an unpractised observer puts two equal lights at the opposite ends of a photometer bar one hundred inches long, and places the screen one inch from the centre, he will probably fail to see any

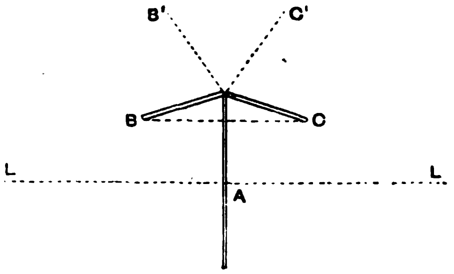

Fig. 1.—Arrangement of Bunsen Photometer. Plan.

difference in the two illuminations. The actual difference is equal to the difference between $49^2$ and $51^2$, or 8 per cent. Practice will soon reduce the limit or error to rather less than half this, but no elaboration of apparatus, whether as to facilities for adjustment, sensitive screens, or accurately standardised sources of illumination, will make the measurements more accurate. A large number of readings from different directions, with the graduated scale hidden from the observer until he has made the adjustment, will give an average to an imposing number of decimals, but the probable error must still remain large, as compared with most scientific measurements.

Photometric measurements up to about 6 to 10 per cent. are very easily made, and the apparatus required is of the most simple character. A greater accuracy is only to be attained by carefully-screened instruments or the use of a dark room, together with considerable practice and training.

The two most simple photometers are those of Bunsen and Rumford. The essential part of the former is generally a piece of white paper with a grease-spot. When this is brightly illuminated on one side, the grease-spot seen from that side appears to be darker than the rest of the paper. Seen from the other side, it appears brighter. In the former case the difference in tint between the spot and the surrounding paper

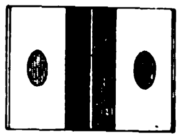

Fig. 2.—Images of Bunsen Screen as seen in the Mirrors.

is practically the same from whatever angle it is seen; but in the latter the spot appears brighter as the eye is brought into a line with the light behind it. It would seem at first as though the grease-spot would disappear when the illumination is the same on both sides. But it is clear that the light falling on the paper screen is affected in three different ways—reflection, absorption, and transmission; and it is the absorption which introduces the difficulty. In practice it is usual to arrange two mirrors inclined at such an angle that the two sides of the screen may be seen simultaneously. Then, whatever may be the relation between the reflection, the absorption and the translucency, it is sufficient to adjust the screen until the reflected images appear to be identical.

The plan of the arrangement is shown in Fig. 1. A is the screen, L L the axis of the light, or the line joining the two sources of illumination. B and C are two mirrors, in which reflections of the screen appear as if at $B^1$ and $C^1$. The projecting sides of B and C throw a shadow on the screen. Fig. 2 shows the appearance of the reflections, the two images of the grease-spot being separated by the shadow. In order to avoid this a prism has been used. Two images of the screen A (Fig. 3) are seen through the prism B, as shown by the dotted lines. The images are, however, necessarily very much foreshortened. In either case the arrangement is symmetrical, and the images are equally inclined to the eye.

For ordinary laboratory work the screen is enclosed in a blackened tube, which shuts out all stray light; and this tube is mounted upon a carriage sliding or running on wheels on a graduated bar. A pointer for reading the scale is covered by a hinged door, in order that the observer may not be biassed while making an adjustment. If the scale be visible

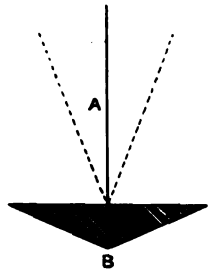

Fig. 3.—Prism for showing both sides of Bunsen Screen.

there is always a temptation to look at it and to make the reading approximate to a previous one, or to some preconceived value.

The illumination varies inversely as the square of the distance of the screen from the light. If the screen is found to make a balance when it is situated at 25 inches from one end of a 100-inch bar, the lights being 100 inches apart, one is nine times as powerful as the other, the screen being, of course, nearer the lesser light. If a balance was found at 20 inches, the ratio of the lights would be as 16 to one, or as the square of 80 is to the square of 20.

The Rumford photometer is not so common as the Bunsen, but it possesses several important advantages. It consists of a screen and a rod (Fig. 4). The two lights to be compared are so arranged that they cast two shadows side by side upon the screen. The distance of the rod from the screen does not affect

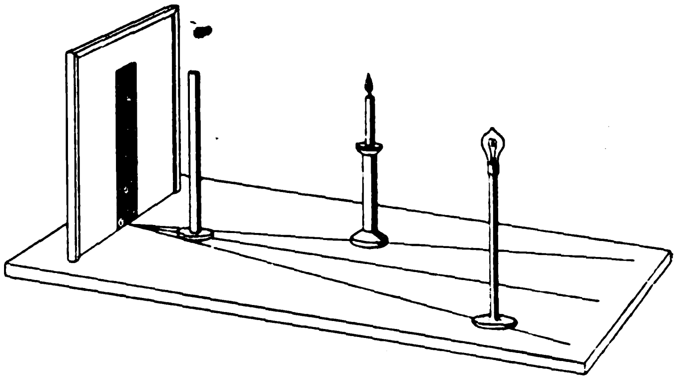

Fig. 4.—Rumford Photometer.

the calculation, and it should be so arranged that the shadows exactly meet without overlapping. The two tints to be matched falling next to each other, a considerable degree of accuracy is possible, and the observation does not depend on the angle at which the screen is seen, nor are any mirrors or restricted view necessary. A modification of this is the Bouguer or Foucault photometer, in which the rod is replaced by a partition, which allows one side of the screen to be illuminated by one light only. The partition is capable of adjustment, by which the junction of the shadows may be arranged. The screen is translucent, and may be made of opal glass or paper.

The Bunsen photometer is undoubtedly the favourite in England and Germany, while until recently the Rumford and Foucault was the most popular in France. One advantage possessed by the former is, that a diffused light can be compared with one of high intrinsic brilliance without difficulty. Indeed, it is impossible to tell, on a Bunsen screen, if the light is diffused

Digitized by Google

or not. Shadow photometers are easy to work with, since the screen can be observed directly, but if one light be more diffused than the other, the edge of one shadow will be more soft than that of the other. Instead of a round grease-spot, a star-shaped spot is often employed with a Bunsen photometer, and this may be easily made by soaking blotting-paper uniformly in white wax or paraffin. When cool, the blotting-paper may be cut into a star or other shape, and placed on a sheet of white paper, covered with another, and pressed with a hot iron. With a little practice very sharp-edged spots may be produced. With suitable paper a very perfect disappearance can be obtained, and so sensitive is an elaborate star-spot, owing to its extent of edge, that greater accuracy and certainly greater speed may be attained than with the mirror method. Complete disappearance,

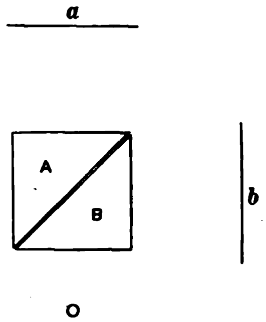

Fig. 5.—Elementary arrangement of Lummer and Brodhum Photometer with Prisms and Screens.

however sensitive the spot may be, does not mean a balance, and the photometer scale must be empirically graduated by means of two equal lights. The disadvantage of this method is that the graduation will differ with differerent spots and different papers. A very good screen, and one which may be easily reproduced if injured or soiled, can be made from two pieces of very translucent paper with an opaque white piece, having a star-shaped opening, between them. The middle piece of paper may be replaced by a sheet of tinfoil.

The principle of the Bunsen photometer is sufficiently obvious, but some mathematics have been expended on it. The spot is more or less transparent, the rest of the screen is more or less a reflector. Both the transparency and the reflection are necessarily imperfect or diffusive. A silvered glass with a portion of the reflecting surface removed, could not, under

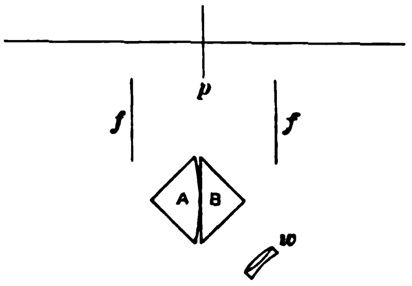

Fig. 6.—Practical arrangement of Prisms and Screen with Mirrors.

ordinary circumstances, be used as a Bunsen screen. But the imperfections of such a screen, the absence of simultaneous disappearance of the spot on both sides, the uncertainty of the line of separation on the edge of the spot, and the necessity for the use of mirrors, have led MM. Lummer and Brodhun, of the Physico-Technical Institute, of Berlin, to design a very sensitive photometer, in which they retain the main principle of Bunsen, but avoid the difficulties arising from the imperfect translucency and reflection.

In its most elementary form the photometer consists of two screens, *a* and *b*, Fig. 5, which may be either translucent or opaque. The former would be the best for very powerful lights, the latter would be suitable for ordinary purposes, and it would be much more easy to ensure the equality of their reflecting power than equality in the transparency of opal or semi-opaque screens. A pair of glass prisms, A and B, are placed face to face, and are united by a drop of Canada balsam or other transparent cement of about the same refractive index as the glass. From the direction O, the screen *a* is observed direct through the prisms, since they are brought into optical contact by the cement. The screen *b* is seen by reflection from the inner surface of the prism B. This surface may be silvered, and the silvering removed at the centre. A more perfect arrangement is shown in plan in Fig. 6, and a general view is given in Fig. 7, which is reproduced from an article by M. Palaz in *La Lumiere Electrique*.

The direction of the light through the prisms is such that total internal reflection takes place in prism B. The face of prism A is rounded, and is pressed firmly against B, bringing the surfaces into optical contact. To avoid Newton's rings a

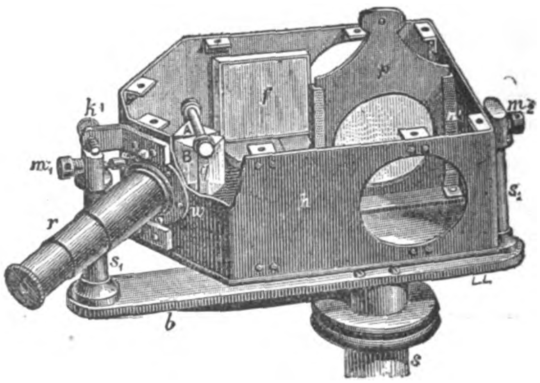

Fig. 7.—Lummer and Brodhun Photometer.

little Canada balsam may be used. A telescope is hardly necessary, but one has been provided by the inventors, and through it the prisms are seen. Instead of two screens, as in Fig. 5, a single screen, *p*, is employed. This is opaque, and should have a high reflective power, but this reflection must be diffusive. At *f* and $f^1$ are two mirrors placed symmetrically with respect to the screen *p* and the prisms A and B. The screen is placed on the usual photometric bench, the light from the two sources falling perpendicularly on it. The diffused light from the screen falls on the mirrors, and is thence reflected perpendicularly on the prisms. In its practical form the mirrors and prisms are enclosed in a box, *h*, mounted on an axis. The two pillars, *s* and $s_2$, support the box by means of the set-screws, *m*, allowing it to swing in a horizontal plane. The prisms A and B are pressed together by a clamp, *q*. The opaque screen, *p*, slides in a frame, and passes through a slot in the cover of the box. The light falls on the screen through the side openings. This photometer, on account of the absence of absorption, and the exact balance which can be obtained, is very much more sensitive than any form of Bunsen.

## A METHOD OF SIMULTANEOUSLY REGISTERING THE WAVE OF ELECTRICAL EXCITATION AND THE RESULTANT MUSCULAR CONTRACTION.*

BY A. D'ARSONVAL.

Currents of brief duration (condenser discharges, induction currents, etc.) are constantly employed in physiology and medicine, to excite the nerves and muscles. The reactions which follow from these excitations are intimately connected with the shape of the wave emanating from the electrical apparatus, as I have shown by numerous experiments, since 1881, to my classes at the Collège de France. It is, therefore, of extreme importance to be able to ascertain the shape of this wave which I have termed the *characteristic of the excitation*, and to be able to vary this characteristic at will. The curve which represents the *characteristic of excitation* is a function of three variables:—(i.) The maximum potential of the discharge; (ii.) the rate of variation of the potential; (iii.) the quantity of electricity traversing the organ excited. Each of these three factors modify the excitation in proportions which it is indispensable to study separately. Now, the method which I am about to

*From the *Comptes Rendus*, vol. cxii., No. 12.

Digitized by Google

describe, enables us to isolate each of the three factors in a continuous manner, and to combine the variations in twos or threes. It is a general method, by means of which it is possible to inscribe the electric wave-curve directly on a registering cylinder, and immediately under it, the curve of the muscular shock caused by the excitation. The comparison of cause and effect is thus rendered extremely simple.

In the accompanying diagram let P be a constant source of electricity (accumulators), the circuit of which is closed through a vertical column of mercury contained in a glass tube. The current enters at the top, and leaves at the lower end by means of appropriate nickel-copper contacts. The negative pole of the battery and the bottom of the column are connected to the earth at T, and are consequently at zero potential. On the other hand, the upper end of the mercury column is at a positive potential of, say, 10 volts. The potential decreases regularly from +10 volts to 0 volts down the mercury column according to a well-known law. Let us suppose that a metallic wire P′, insulated down to its lower extremity, can move up and down in the mercury. If the point is at the bottom of the tube, its potential will be zero; but, on lifting the wire, its potential increases regularly from zero to +10 volts. If, now, we attach this wire to one end of a lever, movable about the point L, the other end moving up and down a smoked cylinder F, it is easy to see that the displacements of the point of the lever L, along the cylinder F, will register the phases and amounts of variation of the potential of the plunger P′. In order to obtain a determinate curve, cause the lever L to be oscillated by the rotation of an eccentric E, the section of which is shown. In practice I attach the wire P′ either to a vibrating rod or to a pendulum, which gives me a sinusoidal variation

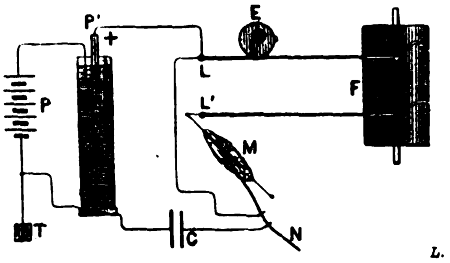

Diagram of Apparatus.

of potential. I can obtain any shaped curve by attaching this wire P′ to a spring which is more or less stretched (an indiarubber band), which I move mechanically in order to produce the necessary excitation. If the wire P′ were connected direct to the nerve N, which is in communication with the earth, it would be always traversed by a derived current, and this would impair its excitability; moreover, we should have no means of regulating the quantity of electricity passing through it. I avoid this by passing the current through the primary of a Du Bois-Reymond induction coil, or, as is shown in the diagram, I interpose a standard condenser, C, in the circuit. Thus, when P′ is at rest, no current traverses the nerve N, and for the same displacement of P′, that is to say, for the same variation of potential, the quantity of electricity traversing the nerve N is rigorously the same, and is known in advance. The muscle M, actuated by the nerve N, is attached to the myographic lever L′, which traces the curve of the muscular shock immediately under the *characteristic of excitation* traced by the first lever L.

The curve inscribed by the lever L gives, therefore, (i.) The quantity of electricity traversing the nerve at each excitation; (ii.) the variation of potential; (iii.) the phases of this variation; (iv.) the rate of variation. Moreover, it is possible to vary each of these factors independently; (i.) Quantity, by altering the surface of the condenser C; (ii.) Potential, by altering the movement of the lever L, or the number of cells of the battery P; (iii.) Mode of variation of potential, by altering the eccentric E; (iv.) Rate of variation, by altering the rapidity of the oscillations of the lever L.

The nerve is traversed by alternating currents, corresponding to the charge and discharge of the condenser, and it cannot therefore polarise. In the case of unidirectional excitation, I avoid polarisation by discharging the condenser C into the primary wire of an induction coil, in the way I have previously described to the Academy.* In a future communication I shall publish the results obtained with this method.†

## TO ADVERTISERS.

*"THE ELECTRICIAN" offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "*THE ELECTRICIAN*" Printing and Publishing Company, who are proprietors of the well-known "*ELECTRICIAN*" Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## ENGINEERING AT CAMBRIDGE.

A report has been recently communicated to the Senate of the University of Cambridge by the Mechanical Workshops Enquiry Syndicate, on the proposed Engineering Laboratory. To those who are not familiar with University doings, the word "senate" is uncommon, but easily understood, while to business men the word "syndicate" is well known, but conveys a very erroneous meaning. A Cambridge syndicate has this in common with a City syndicate, that it is not unfrequently the precursor of an important undertaking; but in ordinary language it is a committee. The foundation of a school of engineering at a technical college or minor University is happily not an unusual matter, but there are several reasons why the development of such a school within the University of Cambridge presents considerable interest both to the educational world and to the profession, the principles of which it is intended to teach. Engineering at Cambridge may be said briefly to have been first taught by Prof. R. WILLIS. It was he who, having been appointed Professor of Natural Experimental Philosophy in 1837, first formulated and rationalised mechanical knowledge; and teachers are greatly indebted to him for putting lecture experiments and laboratory demonstrations on a solid and practical scale; while every intelligent patternmaker is familiar with the simple implement by means of which he is enabled to set out the teeth of gear wheels. The scope of Prof. WILLIS's teaching cannot be compared with the courses of to-day; but it was a great step to introduce experimental lectures among those who were wont to busy themselves with inextensible cords on frictionless pullies.

The next step was made by Prof. J. STUART, who was appointed Professor of Mechanism and Applied Mechanics in 1875, and under his auspices the workshops were started some 18 years ago. In a little shed, hard by the Cavendish Laboratory, undergraduates used to make scribing blocks after a given pat-

Digitized by Google

tern, and this scribing block differed from the ordinary tool, in that it was designed on a principle which required the student to use every tool in the workshop in order to construct it. This principle had its merits educationally, perhaps, to the disadvantage of the scribing block as a useful tool, when made. The workshop struggled on under peculiar circumstances into which it is not necessary to enter. One or two very clever workmen were employed, and their duties were divided between teaching the students and making scientific apparatus. The latter portion of the work was of a potboiling description, for it was intended to assist in defraying the expenses of the educational portion. At first some very good work was turned out, but the system was an impossible one, and it is well that it has been abandoned. The workshops were gradually extended, some good tools were provided and several were presented, and the teaching formed a valuable supplement to the courses of lectures which were given in one of the Botany lecture rooms. But for some time past it has been acknowledged that the place which the subject of engineering holds at Cambridge, cannot be compared with that which is given to it in many other places. It might well have been expected that this University would treat engineering as a mere practical and professional application of that which is taught there *as* science, and it might have met with the indifference with which practical science was regarded until quite recently at Oxford.

So far, however, does the progress of the outside world affect that donnish circle which sometimes seems so narrow, that not only do the authorities feel that they must advance with the age, but they show in their report that they do so in no grudging spirit, and with the best possible motives. It is indeed a sign of the times to find the following sentence with the *imprimatur* of a Cambridge syndicate: "The study of mechanics gains much in utility and loses nothing in educational value by being approached from the standpoint of the engineer." Admitting this, there is but one objection that can be raised, and, unfortunately, there is some reason in it. It has been common among a few establishments, where instruction has been given in engineering, to endeavour to turn out ready-made engineers. Sometimes this is done openly, and if we may say so, with audacity; and sometimes a particularly proficient pupil or two passes straight from the lecture-room to a good berth in some engineering firm, and it is consequently suggested to intending students, and more particularly to anxious parents, that the system of training in the works and in the office is out of date. The old term of seven years of apprenticeship gave place to that of three years, and this again to two years, preceded by a year at a technical college; and now, the fact that some students are found capable of earning a living at once is put forward as a proof that they are engineers, and that to follow them is the cheapest and quickest course. Cambridge has at no time encouraged this, and is not likely to do so. "Without attempting to supersede the practical training which a pupil must receive in the office of an engineer, or in engineering works," says the report, "several English Colleges have striven, with much success, to supplement this professional training by offering a course of scientific study, chosen so that it may have as direct a bearing as possible on professional requirements. The need on the part of engineers of such a scientific basis in their training is now generally admitted." The lecture-room naturally came first, the workshop followed, and the laboratory on a small scale will be begun at once. Its objects are well set forth in the report:—"The uses of such an engineering laboratory are four-fold. It makes the student's knowledge of mechanical principles more real by bringing him into contact with material examples. It gives him practice in those kinds of experimental work which he may afterwards have to perform in professional life. It teaches him how investigations are to be conducted, and gives him some experience in this higher work. And, lastly, it endeavours to contribute to the common store of knowledge by affording opportunities and appliances for original research." The first of these, dealing with knowledge of principles and with material examples, places them in the proper order. In the old way, the pupil was confronted in the workshop with the examples, and he had to consult his books in the evening, after his work, in the hope of discovering some principle which would account for them. The second item contains a careful reservation, and is, perhaps, a little too modest, offering, as it does, practice only in experimental work, while many a technical college promises practice in real professional work, encouraging the idea that the training can be thus completed. Such a system is as absurd as would be that of an art school which should undertake to teach the painting of Academy pictures, or a school of medicine which should attempt to qualify its students as physicians without walking the hospitals. The two latter uses of the higher order would, in themselves, justify the foundation of such a laboratory, although they are placed after the primary ones connected with teaching. The fascinations of original research are accompanied by an enthusiasm which is felt by others who are not directly engaged in it. The laboratory, says the report in conclusion, "will probably draw not a few men of mathematical ability into a profession they would otherwise not enter."

All that is wanting now is the money to carry out the complete scheme. An excellent site has been acquired near the Physical and Chemical laboratories, and the other scientific departments. The University has made an annual grant for demonstrators and current expenses. It is proposed to include a laboratory of practical or applied electricity. The resources of the University cannot do more for some time to come, the colleges being already laid under heavy contributions, and the funds not admitting of any considerable augmentation from increased fees of students. As our educational establishments are wholly free from any connection with the State, help must be sought from private individuals. Some £20,000 for buildings and plant are needed. Owen's College has been well provided for; £28,000 has recently been spent on the department of engineering at University College, Liverpool. What the Duke of Devonshire did for the Cavendish Laboratory may well be repeated by some generous benefactor, and with more certainty of success than, perhaps, in any of the similar undertakings that have done so much for technical education in this country.

---

**Superimposed Magnetisations.**—Experiments by M. Jamin have shown that two longitudinal magnetisations of inverse polarity may be imposed on a piece of steel without mutual neutralisation. The same has been shown by M. Decharme to be true for transverse magnetisation; and in a recent communication to the Académie des Sciences, M. Decharme describes the result of magnetising the same piece of steel successively, longitudinally and transversely. The specimen of steel was 100mm. long, 28mm. broad, and 3mm. thick. If the conditions were favourable and care was taken, it was found possible to obtain an iron-filing sketch, showing two simultaneously existing magnetisations. In most instances, however, the two magnetisations were merely superimposed, and by making the proper passes the longitudinal and the transverse magnetisations could be made to predominate in succession, and with increasing strength, until saturation point was reached. A bar magnetised first longitudinally and then transversely, would thus appear to be in a state of magnetic instability.

## REVIEWS.

**Decorative Electricity.** By Mrs. J. E. H. Gordon. With a Chapter on "Fire Risks" by J. E. H. Gordon, B.A., M.I.C.E. [London: Sampson Low and Co.]

A book dealing with the decorative treatment of electrical fittings is much needed, and the present work, handsomely got up and well illustrated, goes some way towards meeting the want. The subject has not yet become a branch of decorative art, and the authoress has not attempted to treat it as such. The other extreme has been reached, for the book simply describes existing fittings, and these not from various sources, but from one house.

An article recently appeared in our columns in which the beauty and comfort of ordinary electric light fittings were criticised, and the criticism was warmly resented by a correspondent. Mrs. Gordon, however, goes much further than the writer then ventured, and says, "modern *bright* brass-work should be avoided. I have seen a great deal of it used with electric light, but never with success." "There is a lamentable want of good and simple designs for hall and staircase electric lighting; those to be found at present are ungraceful and too heavy for the light lamps that they support." "Most of the electric light found at present in dining-rooms is very glaring and disagreeable, and fully justifies the remark I so often hear made by ladies, 'I never will have the electric light in my house, as it gives me a headache whenever I dine by it.' . . . There was a round table seating ten guests, and ten lamps with lemon-yellow shades were hung just above their eyes, so that the light was focussed into the eyes and face of everyone sitting at table. . . . showing up every wrinkle and line in the face. No one over the age of eighteen should be asked to sit beneath such a light." "I went to see some friends this winter, who were staying in an electrically-lighted hotel. They had switched off the electric light altogether, and they were reading with a shaded paraffin lamp, which they had asked the proprietor to procure for them. I inquired the reason, and they told me that they found it impossible to read by the bright, glaring, unshaded light of the central electrolier." Knowing that electric light lends itself with the utmost readiness to every possible artistic treatment, we give the utmost publicity to these quotations, in the hope that some efforts may be made to prevent such abuse, and to bring about more gracefulness and simplicity in fittings.

The subject is both worthy and capable of careful and systematic treatment; but the owner of a very beautiful old house is now having a private plant put down to save the trouble and nuisance of oil lamps, and he does not propose to introduce the light into the finest rooms, which are hung with old tapestry, because he has not found any fittings which will harmonise with the decorations.

The present book recommends carved cupids and tall bronze storks, while most lamps are shrouded in silk or lace handkerchiefs. The writer is a little too exacting in deciding which tints are permissible and which are to be avoided, and, in spite of her protestations, errs in over-elaboration. One or two unfortunate ideas are put forward, *e.g.*, sham candles "coated with *real* wax." Taste cannot be taught, and though its principles may be formulated, decorations must be carried out by artistic feeling, and not by rule. Some of the suggestions are excellent, and several practical hints contained in this book will be found very useful.

**Die Elektrischen Verbrauchsmesser.** By Etienne de Fodor. (A. Hartleben, Vienna, Pesth, Leipzig. 1891.)

The author of this little book, particularly in dealing with electrical and other units in his introduction, is perfectly sublime in his disregard of the element of time. This may, perhaps, be partly due to a looseness akin to that which is responsible for the term "wattmeter" as a name for an instrument performing the operation indicated by $\int V.A.\,dt$; but it is not on that account any the more excusable. Of the errors into which he is consequently led, some, such as the statements that a watt is energy, and that the work done by a *current* is equivalent to a certain number of kilogram metres per second, are so frequently met with, that they do not excite surprise, but one cannot help being startled by reading that a 16 c.p. lamp at 110 volts consumes ·5 ampere *per hour*, and in another place that half an ampere is equivalent as regards cost and light to a fifth of a cubic metre of gas. Instances of similar mistakes occur continually throughout the book.

To the 15 points enumerated by Prof. Forbes as desiderata in electric meters, the author adds three, based upon his practical experience at the Athens Central Station. These relate to the desirability of measuring the whole current, and not a fraction only, of eliminating the effects of residual magnetism, and double registration. The first two of these seem to be included in the first of Prof. Forbes', viz., "accuracy," though, as practical hints, they are certainly valuable. The descriptions which the author has compiled of the various types of apparatus are brought well up to date, and these, as well as the regulations with regard to meters that are adopted in various central stations will make the book useful to those who are not liable to get confused in their ideas as to what an electric meter is intended to measure.

**L'Annee Electrique.** By Ph. Delahaye, Septième Année. (Paris: Baudry et Cie.)

The aim of this publication is to give within the compass of some four hundred pages, a resumé of the principal electrical discoveries, inventions and applications chronicled by the technical press during the past year. The book is divided into ten chapters dealing respectively with electric lighting, batteries, telegraphy, telephony, atmospheric electricity, medical electricity, electro-metallurgy, electricity applied to railways, electric transmission of power, measuring instruments. Care and discrimination in the choice of subjects for notice and in the space allotted to them, would render M. Delahaye's annual volume a more useful and reliable authority than it can at present claim to be. Thus, in the section devoted to dynamos, the Polechko, and the Reignier and Bary machines are mentioned, but nothing is said about the Westinghouse constant-current alternator. Again, a quarter of the chapter on Medical Electricity is devoted to "La Première Electrocution," while the chapters dealing with electrical railway devices and the electric transmission of power are respectively almost entirely taken up with MM. Sartiaux and Weissenbruch's voluminous report to the Congrès International des Chemins de Fer and Mr. Reckenzaun's O.S.A. Paper. The remaining chapters, on the other hand, exhibit more sense of proportion. The idea of the work is excellent, but its execution cannot be recommended for imitation.

**Annuaire pour l'An 1891.** [Paris: Gauthiers, Villars et Fils.]

This is an official publication emanating from the Bureau des Longitudes, and is replete with tables intended for use by the physicist and astronomer. Some twenty pages are devoted to Terrestrial Magnetism, and seven only to Electricity, out of a total of nearly 800.

## THE ELECTRIC CURRENT AND ITS LAWS.—V.

BY JOHN T. SPRAGUE.

(*Continued from p. 609.*)

§ 42. We may now consider the actions which take place in an electric "source," and follow them into the "circuit," in order to see how electric energy and electric current are related to each other. I should first lay down a general principle, which, probably, no one will dispute, though they will practically set it aside. It is this. If we wish to get a clear comprehension of phenomena, we should trace them in their simplest forms, if possible, where they alone are operative, leaving the more obscure cases, in which disturbing or distinct agencies are at work, until we can clearly see the fundamental principles.

The galvanic battery is clearly the simplest form of source, because it is complete in itself. The dynamo and thermopile are both complicated with supplies of energy external to them. They are like the steam engine, not real sources of energy;

Digitized by Google

they only transform the energy supplied to them. But the galvanic battery not only supplies its own energy, it also makes clear the mode of transformation into "electric energy" and its relation to current. Once we get a clear insight into this we can more readily see our way to understanding how the same principles are working, in the same general manner, in cases where the operation is not itself apparent, and where the inventive genius might devise other explanations.

§ 43. The contact and chemical theories long disputed the explanation of battery phenomena; but the contact theory is now utterly dead. The thing which is occasionally mentioned now-a-days as the contact theory, contact potential, or E.M.F. of contact, is purely the chemical theory. The contact theory, as a real mental existence, died when the notion of "contact of heterogeneous substances" generally, was substituted for the definite doctrine that the mere contact of different metals set up a transfer of electricity, and was the cause of chemical action in the battery. The make-believe contact theory of to-day is only a mathematical ghost; the reality is that the bringing into contact, or close neighbourhood, of heterogeneous substance, brings their chemical forces into operation.

All this has been fully cleared up by the study of thermo-chemistry, the science of the relations of energy to material structures. Let us consider this a little.

Every one who has given even a casual attention to chemistry knows that the actions of change take place in "equivalent proportions;" the modern chemical notation, with its atoms containing more than one equivalent of matter, rather obscures this fundamental fact, but when we bring electricity into connection with chemistry, it brings the old fact into prominence; we have to recognise that, whether the modern "atom" has or has not an actual existence, the equivalent, which used to be called the atom, cannot be ignored.

Those who have gone a little deeper, know that energy plays its part concurrently with matter; that, when any equivalent of chemical action occurs, it either sets free a definite measureable quantity of energy, or that quantity of energy must be supplied to it, and stored up in the product ready to be released at a future time. This is, in fact, the real work of vegetable life, the breaking up of the fully oxidized water and carbonic acid, unburning them in fact, and storing the sun's energy in the new vegetable substances, which give it up again when burnt, and in a myriad other ways.

This, also, is what is done in a metal reducing furnace: we take oxides, carbonates, sulphides of zinc, and unburn them into the metal zinc, which contains a large quantity of "energy" which it will release in the act of oxidation. We can release it direct as heat, for zinc will burn, or we can release it, still under bondage, as electric "energy," and this is the function of the battery.

§ 44. I trust it will not greatly disturb Mr. Evershed if I say that I cannot well dispense with a few new terms, because the development of ideas is often checked when conveyed in words which have other uses, and many of our familiar electric terms imply a theory or physical basis which is really a nuisance. *Current* is one of these; the electric conductor has many important analogies with true currents of water, &c., but we do not know that any analogous thing exists in them; it introduces confusion as to the meaning of velocity, while we have no real evidence that there is any proper transmission, or any true velocity. I shall have to return to this, but at present I am going to suggest that, as "voltage" has found definite acceptance, "amperage" may prove a good substitute for current; indeed, it is occasionally used. We need only substitute "ohmage" for what is now absurdly called resistance, to have a complete formula freed altogether from theory.

$$\frac{\text{voltage}}{\text{ohmage}} = \text{amperage}, \qquad \text{and } \frac{V}{O} = A.$$

We all know that so-called ohmic resistance is not a resistance in any true sense; how can that be a *resistance* which accepts indifferently large and small currents? The term simply misleads the partially informed, and obscures the fact that the real resistance is as the square of current, and corresponds to what is known as resistance in mechanics. Ohmage is simply the reciprocal of "conductance," expressible in sizes and lengths of wire of given physical properties.

§ 45. *What is Amperage?*—It may be said to be merely an arbitrary measure of a hypothetical current. I am going to show that it is something very much more important; that it is the expression of the physical fact of nature, which is, or underlies the current itself; most unfortunately it is arbitrary and accidental, related to the facts by a troublesome fraction, instead of an integral figure, and that figure unity.

On p. 451 the new definition of the ampere value is given as a deposit of silver 0·001118 gramme per second. I may as well note an important omission—the *density* should be fixed—that is, the surface area on which the unit deposit is to be formed. Now, practically, silver is the best agent for actual determination; its equivalent is high (108), which minimises errors; its salts are easily obtained pure, and there is not much liability to subordinate actions. But theoretically speaking of silver simply hides the real fact. We must divide by 108 to get the real relation of the ampere to nature, and to the structural actions of matter. This gives us the value of the ampere in hydrogen, the unit and basis of all equivalent actions; and this, multiplied by the proper equivalent values, will give the relation of the electric current to all substances which take part in its transmission.

This value H = ·0000103518 is the *equivalency of the ampere*, or let us call it the "amperage equivalence." Had fate so arranged our energy system of units that this figure had been simply ·00001, what a clearance there would be of mathematical abstractions and metaphysical cobwebs! No one would have needed to poke about eolotropic and isotropic media for imaginary explanations of a fact which would be self obvious,—that electric current is purely a function of the structure of matter, and that amperage is purely the expression of the relation of what we call electricity, to the same equivalency of matter which governs all chemical actions whatever. But we have now to clear up the relation of energy to this equivalent.

§ 46. Chemical workers commonly represent the intrinsic or specific energy of reactions (§ 43) in terms of "calories per gramme equivalent;" it may be as truly expressed in foot-pounds per grain equivalent, as I did years ago, when very few electricians had even a glimpse of this side of nature. I then devised a unit of energy, and called it the "equivolt," which defined the relation of electromotive force to the equivalency of matter, and to the intrinsic energy specific to each kind of matter. The term has not caught on; I fear it indicated too absolute a barrier to the extension of abstract and visionary ideas. But the thing itself is now generally recognised, viz., a constant, which, used as a divisor on the calories per gramme equivalent, *gives us the voltage* which the chemical reaction sets up.

The unit or constant may be arrived at in various ways; the simplest is to take the time of an ampere current doing one equivalent of chemical action, which is the reciprocal of the amperage equivalence, or 96,601 seconds; multiplied by the energy $C^2R$, expended in that time under unit conditions, that is, in one ohm, we have the energy expended by the source in setting up unit voltage, and maintaining unit current. That is the constant (equi-volt) which, when applied to the chemical energy of the reaction in the source, gives the voltage of the source.

§ 47. It will be seen now, why I propose to give a name to this vague and general "specific energy." I propose to call it the "voltance" of the chemical reaction. As it sets up an opposing or "counter E.M.F." in any decomposition cell, any one who pleases may express this $-e$ as the re-voltance. We have now in view the two distinctive features of all sources, the "amperage equivalence," § 45, related to the structure of matter, and the "voltance" which is the density of the energy associated with that structure.

I may say that all that precedes this was written at intervals while recovering from a sharp illness, and was in the editor's hands before the issue of the number of March 27th, which I have just read with some surprise at finding Mr. O. Heaviside dealing, § 40, p. 633, with the very points I have been working out. I need scarcely say that I entirely differ from his opinion as to the superior value of abstract theory. I

Digitized by Google

take it that our only mode of attaining truth, is to find out what Nature does, not to invent mere imaginary schemes about her works. As to our relative knowledge of matter and ether, I have already spoken my mind, and will simply quote myself, p. 434. "I repudiate all ideas about what is called the essence of matter, or any interest in the question of what it really is. All this is of no concern to us. It belongs not to science, but to metaphysics." Mr. Heaviside says: "No one knows what matter is any more than ether, and we should rather explain matter in terms of ether than go the other way to work." I deny it in *toto*. We do know what we mean by matter; no one knows what they mean by ether. I may as well quote a reply of mine from elsewhere to this same erroneous statement: "We are often told that we do not know what matter is, and that we have no right to object to the ether notions on the ground that we do not know what ether is. Now this is pure cant; it is mere juggling with words. We know a great deal about the properties of the thing we mean by the word matter, and we can examine and test those properties. Nothing of this is to be said of the ether. The word 'matter' connotes a mass of natural obvious records of our cognition. The word 'ether' connotes nothing but our difficulties of defining some of those facts. What an infinite difference this is." Ether is one of these spirits called from the vasty deep, and, like Hotspur, I want proof that they will "come when you do call."

§ **48.** I fear the writer of the article, "Electromotive Force," p. 606, thinks there is some difference in our views. I agree with nearly everything he says. "Why should not a cell be said to liberate energy." That is what I do say. I use E.M.F. only as a phrase in common use, which is known to mean energy. Now, let us see what goes on in the source.

Zinc is consumed, an equivalent of zinc in each cell; that is, at each cross-section of the circuit, for each amperage equivalent. The equivalent of zinc being 32·6, we have gramme ·00033746 as the zinc representing one coulomb, *i e.*, one ampere second equivalent. We have now this fact to consider. This quantity of zinc is all that affects the question; it is of no consequence what is the nature of the cell, or what the energy of the reaction. That zinc generates its current equivalent, and cannot be made to generate more. It is a purely material relation.

§ **49.** Now turn to the energy. Energy of chemical action is within a material limit of the active substances. When released freely as heat, it becomes radiant, and distributes itself as conditions permit. To convert it into electric energy, which is linear, we must provide a line of force within and along which that transformed energy operates.

*What is a line of force?* Is it an abstraction or "concept," or is it a physical reality? That "thin red line" which has carried the might of England through so many "fields," is a veritable line of force, and whether it is an eolotropic medium or not, it distributes its energy at right angles to its linear formation. But it is built up of physical units—British men—each doing his own work in his own place, but standing "shoulder to shoulder" to form the line, which organisation converts into a unity pervaded by one living will.

It is the same with the "lines of force," magnetic and electric; these are built up of units—equivalents of matter; it is by the natural forces of these material units, not merely by an externally impressed force, that the lines are constituted; the lines are the organisation which combines the individual forces into one agent.

Every particle of matter possesses many forces; gravitation, chemical attraction, capacity for heat, and the two polar forces, which we know as electricity and magnetism; each of these—atomic functions of matter itself—is manifested by the capacity to assume a "polar" order; the electric polar order + −, + −, corresponding to the column or marching formation of troops, + and − being, as it were, the front and back of each unit of which the column is built.

Magnetic polarity N S, N S, corresponds to the linear formation of the same troops ranged "shoulder to shoulder;" it is the force manifested radially from an electric current, which becomes parallel lines in opposite directions on the two faces of a row of parallel currents, and this at once gives us the explanation of the functions of "ampere-turns" in magnetisation. Just as the insertion of sources into the electric polar order accumulates their energies within the electric circuit, so the accumulation of the lateral magnetic forces of that circuit in turns around a magnetic substance, adds to the stress on the magnetic lines of force set up in that substance, at right angles to the linear direction of the electric circuit.

The two sets of polar lines and forces are each capable of their own development, and employ and distribute energy each in its own way; but none the less they originate in the atomic forces of matter itself; they are both based upon the equivalence of matter, both propagated by physical lines of material equivalents, and excepting in those lines, so related to the "structure of matter," no man has ever witnessed electrical or magnetic phenomena.

*(To be continued.)*

## ON HYSTERESIS IN PRESENCE OF ALTERNATING CURRENTS.

BY DR. GEORGE FINZI.

As "we are to-day in the midst of a conflict which touches the very root of the matter," I shall be perhaps allowed to enter this conflict, as the bringer of some facts, not as the supporter of any theory; I hope far abler hands will prosecute and discuss the consequences of my experiments.

I cannot help thinking that the simple fact of the magnetisation of a piece of iron is still far from being thoroughly investigated or well understood; and, though these uncertainties and misunderstandings do not prevent us from magnetising tons of iron, or from covering the world with lines of force, they certainly hinder us from many important improvements in the magnetic circuits of dynamos and tranformers. From the first researches of Lenz and Jacobi (1839), to the latest of Ewing, the doctrine of magnetic induction has grown more and more complicated; the time has perhaps come to look for simpler phenomena. I need not recall how epoch-making Ewing's discovery of hysteresis has been; but to study hysteresis independently from any actual magnetisation, or magnetisation from any actual hysteresis, is a double method not yet adopted. The first of these two problems seems to me to be much easier than the second; it is the second, however, which has been first attacked by Prof. G. Gerosa and myself, in a Paper, now before the "Istituto Lombard di Scienze e Lettere," the conclusions of which I will now briefly explain.

To announce that a simple Faraday iron disc may transform alternating currents into mechanical power or into continuous currents, would be a striking but not a convenient starting-point. It is preferable to begin with the magnetisation curve, which has been a faithful looking-glass for all the successive phases of the question. There was, firstly, a straight line. Joule then obliged it to bend, and said, *Ne plus ultra*. Next came Wiedemann, who, laying down his arguments on the first part of the curve, impressed upon it an incurable distortion. At last, under Ewing's conduct, the curve has untwined itself, and an infinity of other curves have at once appeared. Moreover, every physical force acting upon the iron mass, influences the curve in the most strange and disappointing way. But let us consider Fig. 1: two curves of first magnetisation are drawn there, both belonging to the same sample of charcoal iron wire. The curve marked X is the usual well-known curve; the curve marked Y is regularly obtained when an alternating current of a sufficient strength passes through the wire. The corresponding X and Y curves of Fig. 2 relate to a cyclic variation of the magnetising force. (The current-density through the iron was, roughly, three amp. per square mm.) It is scarcely needful to translate the curves into ordinary language; everyone sees that the alternate current destroys the hysteresis, and the shape of the magnetisation curve is at the same time wholly changed. On the signification of the word "destroys" I shall return later. I must say now that the results of our experiments could perhaps be foretold; since Ewing's researches, we

Digitized by Google

know that hysteresis is much affected by mechanical vibrations; and we know besides, that alternate currents through an iron wire produce such vibrations, *ergo* . . . . The fact, however, had never been proclaimed, and besides, I think it is more likely that what we have observed is a direct consequence of the alternate current (which produces an alternating transverse magnetisation), no sensible vibration having been ever heard or felt.

Mathematical clothes have vainly, though perseveringly, been tried on the usual magnetisation curve. May we exclaim to-day, *Si scopron le tombe* . . . ? Even mathematical functions have their luck; Lamont's, Müller's, Sohncke's formulæ did not indeed shine a long time; but what a brilliant career has Frölich's (Robinson's) formula! After Frölich and Clausius, Prof. S. P. Thompson brought it before the world. And now it is the only one which agrees very well with our curves Y, equally well for iron, steel, and for every portion of the curves; no better agreement could be anticipated. This is, I think, very fortunate both for the physical meaning and the simple shape of Frölich's formula. In fact, let us remember Ewing's admirable theory of induced magnetisation; let us now consider the particular condition of a piece of iron when hysteresis has disappeared, as a *free state*, then every magnetisation will be represented by the single general formula:

$$k = k_m\left(1 - \frac{I}{I_m}\right),$$

where $k$ is the co-efficient of susceptibility, $I$ the intensity of

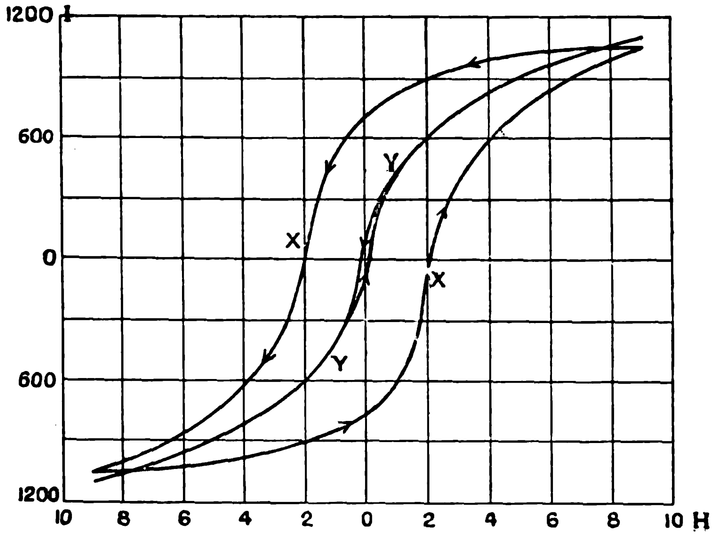

Fig. 1.

magnetisation, $k_m$ and $I_m$ the maximum of $k$ and $I$. Moreover, $I_m = 1750$ both for iron and steel. The well-known relations between $k$, $I$, magnetic resistance, and induction make the formula immediately useful in every problem of induced magnetisation (in the free state).

The iron cores of dynamos are sometimes, and those of transformers are generally, on account of the eddy currents, much more in the free than in the normal state; this consideration, I think, makes the theory of these systems a little different from the actual one, but I cannot enter into this now. I may say, however, that the core of a working transformer is in a peculiar condition; its permeance is greater than if no currents passed through the coils, load or no load, this or that frequency will also make considerable changes. I have spoken of "destroyed hysteresis." Of course, I do not think that hysteresis is no longer there. I only assert that if two cyclic magnetisations of very different frequency take place at the same time, the slow one does not show any hysteresis. As for the hysteresis loss, this is more likely to be transferred than abolished; but experiments are wanting on this point, as on many others, of this interesting question.

The extraordinary value of the initial permeance, which is one of the characteristics of the free state, may lead to the construction of a very curious machine. Once more the Sturgeon-Barlow-Faraday disc comes, and proves to be, if not a successful industrial machine (though the day may still arrive for it), at least a suitable system for electrical transformations of all kinds. Let us imagine an iron disc split radially into a multitude of narrow strips or filaments, all welded to the axis, but insulated from each other for the remainder of their length. A permanent horse-shoe magnet embraces a section of the disc. Then let us suppose that an alternate current passes through the filaments of a sector unsymmetrically placed in with respect to the magnet; this sector will increase its permeance and will accordingly be attracted by the magnet; but then another sector will take the place of the first, and so on; and thus the disc will set up a continuous movement of rotation. That is not all; if, whilst from an arc of the circumference to the axis, an alternate current is passing, and the disc is revolving, and the remaining arc or a portion of it is put into communication with the axis, a continuous constant current will flow through this circuit. Thus, our disc is performing a double transformation of energy, quite different from all those that take place in our ordinary dynamos and transformers. As to the efficiency of such a machine, nobody could, perhaps, attempt to foretell it; at least, to grasp at a molecular question of this kind is far above my power; but I hope to soon be able to submit it to experimental proof.

The few things I have said will, perhaps, be of no use in their actual state to electrical engineers; but this portion of electrical science is so interesting, and our experiments are so

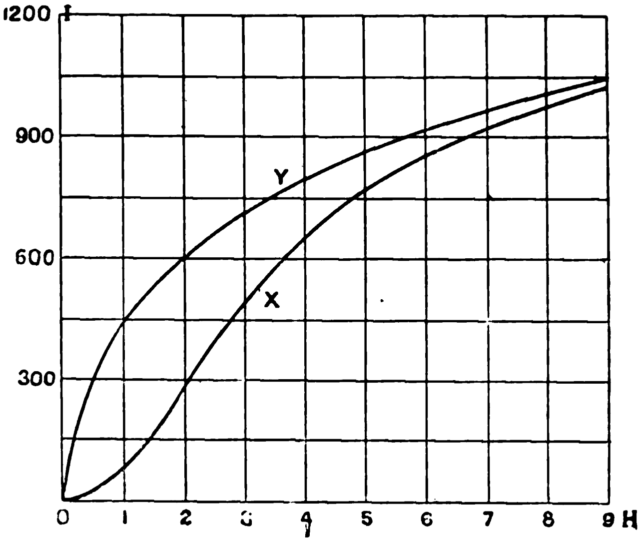

Fig. 2.

easy, that I hope they will soon be repeated and varied; and then many things may arise that we cannot even perceive now.

## METERS—GAS AND ELECTRIC.

A Paper, which was recently read before the Eastern Counties Gas Managers' Association by Mr. W. Barratt, and the discussion which followed it, contains several statements which are of interest in connection with the supply and measurement of electrical energy. Quoting from his own remarks at a discussion in 1875, on the testing of meters, the author said that he had never found one dry meter that would register the same under all circumstances. Take a two or three-light meter, and test it under $\frac{5}{10}$ths pressure, and it might be found to register within five per cent. of the quantity it was marked to pass. But pass through that meter from 12 to 18 cubic feet of gas and it would vary. If 18 cubic feet were passed, it would be from five to six per cent slow; if the same quantity of gas was passed through at a slower rate, it would be found to be what it was alleged to be when sent out from the manufactory. On

Digitized by Google

one occasion he wrote to Mr. Joseph Adamson, one of the first Presidents of the British Association of Gas Managers, stating there was not a dry meter that had come under his observation through which he could not get as much gas, without any registration, as that meter was sent out to pass. A dry-meter maker undertook to make a 10-light test-meter that should be absolutely correct under all circumstances. The meter came and was put through several tests; but, before the the testing was over, there was a variation of registration, as against the gas company, of no less than 7½ per cent. When he first went to Grantham, he tried to ascertain the leakage in the place, and, to his astonishment, found it to be 25 per cent. He was certain that this 25 per cent. could not go through the mains in the streets, and he therefore proceeded to discover the proportion of dry meters to wet throughout the town, and found a large proportion of dry meters. The inspector's book showed that out of 1,400 meters, there had been stopped, in six or nine months, no less than 30. On the other hand, during the whole of the time, very few wet meters had come under his notice which were not within two or three per cent. of being correct.

Since making the foregoing statement, he had seen no reason to alter his opinion, except that a more extended experience had caused him to have less faith than ever in dry meters.

In the discussion, it was stated that the gas unaccounted for at Yarmouth had been reduced from 30 per cent. to 7 per cent., no wet meters being used except the station meter, and this had to be wrapped up in winter and kept warm with a gas stove. A speaker who alluded to the delicacy of construction of dry meters, thought that wet meters should be attended to at intervals of six weeks, or at least once a quarter; and in the case of dry meters, after the first five years, they should be taken out and tested periodically—at least once in two years. The gas unaccounted for at Dereham was four per cent.

At Chesterfield the meters were visited eight times a year, and if, the manager said, he could afford it, he should visit them every month. The larger meters, in fact, were inspected every month, and very large and wet ones each week. Watches are not expected to keep perfect time without attention, and no one could expect a meter, which had to pass through all the vicissitudes which were alluded to during the discussion, to go on for ever without inspection. At Carlisle the meters were inspected once in two months, and once a week in the case of large meters. In the opinion of the manager, it was also desirable that wet meters should be inspected each week.

Mr. J. Barton (Peterborough) said that in discussing this question they had three things to consider: First, the capital charge for meters; secondly, their durability; and, thirdly, their correctness as to the measurement of the gas passed through them. Mr. Barratt had not given them any statistics as to the working of the wet meters in Grantham; and he should have liked to know how it worked out per 1,000 cubic feet of gas sold, for renewals, repairs, and inspection. He had a few figures with him relating to Peterborough, where dry meters were almost entirely used—in fact, he did not think there were a dozen wet meters in the town. During the past fifteen years the highest charge, per 1,000 cubic feet of gas sold, for renewals, repairs, cost of fixing and changing meters, and inspectors' wages, was 0·63d., in 1888, and the lowest 0·38d., in 1886—the average of the fifteen years being 0·46d. During that time the unaccounted-for gas had been reduced from 12·14 to 6·45 per cent. The consumption of gas fifteen years ago was 38½ million cubic feet, and it was now rather more than 67 millions. Thus the gas consumption had nearly doubled, while the cost of maintaining the meters had been reduced, as well as the unaccounted-for gas. Besides this, the price of gas had been reduced from 4s. 6d. and 5s. to 3s. 2d. and 3s. 4d. He thought that dry meters, with proper attention, were thoroughly reliable instruments. In his case they tested at the works one-fifth of the meters every year; so that all of them were tried for accuracy every five years—any meter which was found outside the range being sent to the makers for repair.

The discussion from which we have taken these extracts is interesting because it relates to the present state of gas meters, which were invented immediately after the introduction of gas, and have received very little alteration since. A few details have been modified, but there are only two classes, and all the essential features of these are to be found in the earliest meters that were made.

The figures as to gas unaccounted for show a considerably smaller leakage in the mains than might be expected from the smell which attends the opening up of the streets in which they are laid, and gas managers cannot tell how much is due to leakage and how much to erroneous meters. The leakage to earth from electrical mains can be read at once on an ammeter, and the discrepancy between the readings of the station meter and of the consumers' meters shows at once the mean error of the latter. This error is made up of two factors, want of accuracy in the record, and leakage, or passage of unrecorded current. The want of accuracy, again, may be due to an error in the original determination of the constant, or may have arisen by some mechanical disturbance of the mechanism in carriage or erection, or it may be due to an inherent defect in the principle of the meter, owing to want of proportionality throughout the range. A Board of Trade certificate for a meter, which is liable to alteration by mere handling and carriage, will be valueless. Such instruments must be checked after they are in place, either by a portable meter or by a time-reading. Meters which have not a "straight line curve" will probably fail to receive any certificate.

With regard to the importance of the unrecorded current, Messrs. Ferranti and Co. send us the following statement:—Distributing companies supplying current to 40,000 lamps of eight C.P., or rather their equivalent in various sizes, are now numerous. If these lamps are divided among 800 consumers, and taking only so small a quantity as one ampere for one hour each day, as that which passes unrecorded in each case, the loss to the Company would be £973. 6s. 8d. per annum, the current being supplied at 100 volts, and charged at 8d. per unit. A single one, or perhaps two lamps, are kept alight nearly all day, and sometimes all night, either by design or accident, by a very large number of consumers, consequently, unless their meters record accurately at low readings, the loss to the distributing Company will most probably be greater than that estimated above. Mr. Ferranti has from the first appreciated these considerations, and the success which he has attained in his meters is shown by the fact that the 10 ampere size starts with ·2 amperes, the 40 ampere with ·3, and the 100 ampere with ·5. In the direct current form of the Ferranti meter the magnets are of a special steel, the residual magnetism of which provides the initial field which enables them to start at such exceedingly low readings. In the alternating form this is not possible, but the same effect is attained by the use of a fine wire coil, through which a minute shunt current passes round the iron core, and produces a strong magnetic field relatively to the small current passing through the meter at low readings. The resistance of this shunt is 8,000 ohms, consequently the current passing through it at 100 volts costs the distributing company, at 8d. an unit, under 7s. 6d. per annum, but the great saving which it effects is a two-fold compensation for this.

## VARIATIONS OF CURRENT IN THE PRIMARY CONDUCTOR OF OPEN CIRCUIT TRANSFORMERS.*

BY ROBERT SHAND.

Despite the years during which the subject has received attention from those interested in electrical developments, few subjects are to-day more discussed or receive greater attention than that of the distribution of electrical energy by means of alternating currents and transformers.

Of late interest has been revived to some extent in transformers of the open magnetic circuit type, a revival which is undoubtedly due in great measure to the work done by Mr. James Swinburne in the development of his special "Hedgehog" form of open circuit transformer.

The results of a few experiments made upon an open-circuit transformer, the main object of which was to observe the variations of primary current under different conditions of secondary output, &c., may, therefore, be of general interest and incidentally serve to shed a little light on a statement of Mr. William Stanley, jun.,

* From the *Electrical World* of New York.

Digitized by Google

which appeared in one of his recent contributions on this subject. Mr. Stanley states: "In these transformers (open magnetic circuit) the value of the primary current varies comparatively little with the load derived from the secondary circuit, and when such a transformer is gradually loaded the primary current will remain, roughly speaking, constant, possibly varying 10 to 20 per cent."

This statement is misleading, inasmuch as that, though it may be true when considered in reference to some particular case or cases, it is not so in all. Indeed, it would appear purely a question of design in the construction of open circuit transformers, whether it be true or not; yet upon the unqualified assertion above quoted arguments are based calculated to bias the mind of the reader.

The experiments above referred to were made with the object, primarily, of observing the values of the primary inducing current under various conditions of the magnetic circuit, and the changes produced in such values by changes in the secondary output. While a claim for anything approaching rigid accuracy is not made for these observations, yet it is believed they approximate the truth with reasonable closeness.

The transformer on which the observations were made had approximately the same number of turns and volume of copper on primary and secondary conductors. The resistances also were about the same. Though such a construction would hardly be suitable in the case of a commercial transformer, in this case it suited the means at hand for making the measurements.

The transformer coils T (see Figure) formed a cylinder having an opening through its centre 2in. in diameter, into which the core was introduced, the outside diameter of the coils being 6in., the length 7in., and the weight about 30lb.

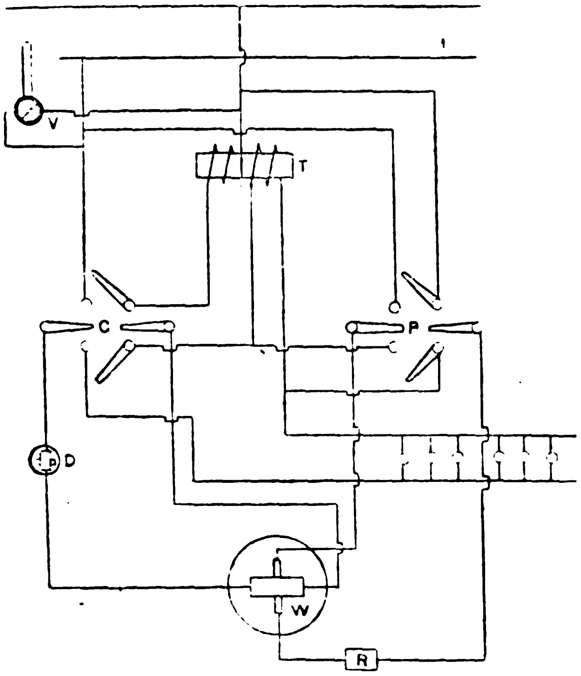

Diagram of Arrangements.

For observing the primary potential a Cardew volt-meter V was employed, for power measurements a watt-meter W having a large additional resistance R in series with the suspended pressure coil, and for current measurements a Siemens electro-dynamometer D. These instruments were disposed as shown in the figure, the commutating or switching devices C and P rendering it easy to connect them in either circuit, and to transfer them rapidly from one to the other. The primary potential varied from 100 volts in some cases to 104 in others. It was, however, kept fairly constant during each set of observations.

The drop given is, in each case, that observed when the secondary output was approximately 1,000 watts. Results given in Table I. were obtained from the copper coils alone, no iron whatever being employed.

In Table II. it will be observed that the energy taken up by the transformer when cold is very near 2 per cent. greater than that taken up after it had been run for some time and thus become heated. This effect was probably due to a decrease in the volume of parasitic currents in the core when the latter became heated.

When the core ends instead of being flattened down on the ends of copper coils were bristled up, and made to project out divergingly, the magnetising current fell to 3·1 amperes. The watts taken up, however (as indicated by wattmeter), remained practically the same.

The iron wire used in the construction of the cores was of poor quality, and was not annealed previous to use, consequently the energy taken up by the cores was, without doubt, excessive.

The quantity $C^2R$ with the secondary circuit open was in Table V. about two watts. If this quantity be accepted as representing the energy consumed over copper resistance, then the consumption of energy by the core comes out about 8,900 ergs. per cubic centimeter per cycle.

At induction taken in Table V., and with iron of the quality employed by Ewing in making his determinations, the energy taken up by hysteresis ought to be about 3,5000 ergs. per cubic centimeter per cycle. Consequently, if the consumption of energy be calculated on the basis of copper resistance and Prof. Ewin's curves, it would come out at about 18 watts, and if a quantity equal to one-third of this be allowed for parasitic currents in the core, &c., the total power with open secondary would still only be about 24 watts. Such a power consumption under the condition named would be quite moderate, even in the case of a transformer having so small an output as 1,000 watts.

Again, referring to Mr. Stanley's statement, it may be stated that on theoretical grounds alone it is difficult to understand how he could expect his statement to be substantiated in practice. The results shown in the test tables certainly do not do so. It would, therefore, appear that the objections which he raises to the employment of transformers of the open-circuit type are in reality non-existent as such. So far is it, indeed, from being the fact that the primary current will not vary more than 10 or 20 per cent. from light to heavy load on the secondary, Table V. shows it to vary nearly 500 per cent.

**Table I.**—(No iron used; drop = 3·4 volts.)

| Primary potential. | Primary current. | Primary watts. | Secondary current. | Secondary watts. | Efficiency per cent. |
|---|---|---|---|---|---|
| 100 | 52 | 657 | ... | ... | .. |
| 100 | 53 | 1,630 | 11·30 | 960 | ·59 |
| 100 | 54 | ... | 19· | 1,564 | ·68 (?) |

When secondary load was 1,564 watts the primary power was beyond the capacity of wattmeter.

**Table II.**—(Small iron wire core same length as coils; induction per centimeter of core, 23,000; drop = 3·5 volts.)

| Primary potential. | Primary current. | Primary watts. | Secondary current. | Secondary watts. | Efficiency per cent. |
|---|---|---|---|---|---|
| 104 | 16·5 | { 110 (cold) / 108 (hot) } | ... | ... | ... |
| 104 | 16·7 | 339 | 2·2 | 220 | ·65 |
| 104 | 17·2 | 531 | 4·14 | 410 | ·77 |
| 104 | 19·4 | 1,115 | 10·1 | 972 | ·87 |

**Table III.**—(Core of iron wire 7in. long; induction, 14,000; drop = 3·5 volts.)

| Primary potential. | Primary current. | Primary watts. | Secondary current. | Secondary watts. | Efficiency per cent. |
|---|---|---|---|---|---|
| 104 | 14 | 86 | ... | ... | ... |
| 104 | 14·4 | 300 | 2·1 | 210 | ·70 |
| 104 | 14·7 | 504 | 4·15 | 410 | ·81 |
| 104 | 19·1 | 1,334 | 12·2 | 1,185 | ·88 |

**Table IV.**—(Iron wire core 13in. long, projecting at each end 3in. beyond the copper coils; induction, 6,300; drop = 3·4 volts.)

| Primary potential. | Primary current. | Primary watts. | Secondary current. | Secondary watts. | Efficiency per cent. |
|---|---|---|---|---|---|
| 100 | 7·3 | 45 | ... | ... | ... |
| 100 | 8 | 330 | 2·9 | 280 | ·848 |
| 100 | 13·8 | 1,147 | 11·2 | 1,057 | ·92 |
| 100 | 19·1 | 1,699 | 17 | 1,558 | ·918 |

**Table V.**—(Same iron wire core used as in Table IV. The ends, however, instead of projecting straight out from the centre of the coil, were bent over flat and arranged radially over the ends of the copper coils. Induction, 6,300; drop = 3·5 volts).

| Primary potential. | Primary current. | Primary watts. | Secondary current. | Secondary watts. | Efficiency per cent. |
|---|---|---|---|---|---|
| 100 | 3·27 | 43 | — | — | — |
| 100 | 3·9 | 142 | — | 97 | .68 |

## THE UNIVERSITY TRAINING OF ENGINEERS.*

BY J. A. EWING, B.SC., F.R.S.

The education of engineers is no new subject; it has been so well and so widely discussed that one can scarcely hope to say anything about it that has not been better said before. But the matter has perhaps enough of present interest for us to excuse the repetition of a twice-told tale, for I have to plead for nothing less than the inclusion of a complete school of engineering in that new Cambridge which is fast springing up within the old. Experts have declared, with one voice, not indeed that the system of apprenticeship should be abandoned, but that it should be modified and supplemented. And the universities and provincial colleges are bestirring themselves, often with very remarkable energy, to supply what has been lacking. But the youth who aspires to the profession is still frequently sent directly from school into the office of a civil engineer, or into a great mechanical workshop. His powers of observing and reasoning are little developed; he has no grasp of mechanical principles; his stock of mathematics is scanty at the best, and he is absolutely ignorant of how it may be applied to material affairs. The theory of engineering is a sealed book to him, and in the office or the workshop he finds no one who will break the seal. Even as to matters of practical detail he is left pretty much to pick up what he can; it is the business of nobody to teach him. In time, of course, if he is a man of the right sort, he does learn a good deal, and some of the lessons are lessons that could be learnt in no other school. Before his five years or so of apprenticeship have expired he has seen actual work in all its stages. He has learnt something of the commercial conditions under which it is done. He has been in touch with men; he has learnt their habits and how they are to be managed. He has become acquainted with matters of organisation and business routine. He has come to know what good work is, and what it costs, and what is the time that should be taken for one and another kind of job. These lessons are invaluable; but I submit they are not the whole of engineering. If the pupil, on quitting his apprenticeship, carries away the faintest idea of how scientific principles bear upon engineering practice, he is exceptionally fortunate. The apprenticeship makes no provision whatever for teaching him that. Lest you suspect me of painting too black a picture, listen to a criticism passed on the system of engineering pupilage by an eminent practical engineer. In the evidence laid before the Royal Commission on Technical Education, whose Report was issued in 1884, Dr. Anderson, now director of the Woolwich Ordnance Factories, speaking then as a partner in the Erith Ironworks, said: "I have from 12 to 20 pupils who come chiefly from the great public schools. . . The minds of most of these young men who come to serve their apprenticeship with us are a complete blank as regards any of the sciences. . . Their mathematical knowledge is generally of a useless kind; it is all pure mathematics and they do not know how to apply it. They might just as well know no mathematics at all. They do not seem able to apply their knowledge to the simplest practical questions. . . I have an uneasy feeling that the pupils who leave our establishment know little or nothing except the use of their hands." That is the verdict of a practical man who has studied the system under his own eye, in his own works. It is perhaps severer than anything a professor of engineering could well venture to say. Dr. Anderson's evidence is so representative of what I conceive to be the drift of the best modern opinion on this subject, that I will quote a few sentences more. Dr. Anderson is not merely a destructive critic, he is prepared to point out a remedy, and the remedy he advocates is exactly that which I wish to press upon your notice. Asked what was his ideal of the training of the higher class of mechanical engineers (viz., employers and managers) in the future, he replied: "They ought to have a training such as the scientific colleges can give, and then come and carry out a shorter apprenticeship in the works. Instead of remaining five years at the works, as they do now in a great many cases, it would be better for them to spend three years at college and then come for two years to a practical training. . . I am convinced that that would be better." These, I take it, are beyond question the lines along which we should proceed: not to supplant the apprenticeship but to supplement and shorten it. The chief aim of a University School of Engineering is to give such a training in pure and applied science that when the pupil follows it up by spending two or three years in contact with actual constructive work he is well fitted to begin his professional career.

Before speaking of the work of the English schools in any detail, however, let us glance at what has been done abroad. There is much that is admirable in the foreign technical schools, and it will be admitted that they have fostered industrial development in France and Germany and Switzerland as perhaps nothing else could have done. But when we examine the constructive work that is carried out in those countries, or when we read the expressed opinions of men who have had experience of the system, we find evidence that the highly finished product of the foreign technical school lacks something that is often present in his rough-hewn English competitor. The Report of the Technical Educational Commission contains emphatic testimony on this point. Even those witnesses who are most alive to the inadequacy of our English apprenticeship as the sole means of training engineers give no encouragement to the idea that we should seek a remedy by copying the foreign polytechnic school. Take, for instance, the evidence of the late Sir William Siemens. Asked whether he would recommend us to copy the German Polytechnic School, he replied: "Certainly not. . . . . . I would rather employ a person who had been brought up in practice and who had supplemented his knowledge by study for himself than I would take a young man who had been entirely educated at an establishment like one of the polytechnic schools. . . . . . I think those schools are apt to teach the student details which he mistakes afterwards for principles." In America we find a number of highly organised and admirably conducted engineering schools, forming in some cases an integral part of universities; in others standing alone. In some respects they follow the Continental pattern, but with a difference. If I were to select one for special reference it would be the Massachusetts Institute of Technology. Workshop instruction is given "as an adjunct to the theoretical treatment of professional subjects;" and there is a superbly equipped engineering laboratory for which new rooms covering 15,000 square feet were provided less than a year ago. The work of this school is spoken of in the highest terms, and the fact that it has now 900 students bears witness to the estimation in which it is held in the United States. The Massachusetts Institute carries the college training of engineers to a degree of elaboration which we are perhaps disposed to deprecate; but it seems to me to avoid the most serious fault in the Continental schools.

I turn now to our own country. The University training of engineers as we understand it—the training which it should be our effort to give here—may be said to have had its foundation laid when Rankine was appointed to the professorship of Civil Engineering and Mechanics in the University of Glasgow. His introductory address—a noble vindication of the harmony of theory and practice in mechanics—was delivered just 35 years ago. It will be found printed as an introduction to his text-book of Applied Mechanics, the first of that great series of treatises in which he formulated the theory of engineering with so much of comprehensiveness, of precision, and of philosophic grasp that they hold their place to this day as the most indispensable volumes in the library of the educated engineer. Edinburgh followed 12 years later with the institution of its University Chair of Engineering, of which Fleeming Jenkin was the first occupant. It was my privilege to receive my first lessons in applied mechanics from that most inspiring and sagacious teacher, who succeeded in bringing his subject into close touch with the co-related sciences in the University curriculum, and in securing academic recognition of the course by means of the degree of Bachelor of Science in the Department of Engineering. The work so well begun in Glasgow and in Edinburgh goes on, but for the moment the development of these engineering schools has been outstripped—in respect of material equipment—by some of the younger colleges, which have had the advantage of a greater command of resources. If we wish to see the modern British ideal of a University school of engineering most fully realised, we must rather turn to Manchester, where the genius of Osborne Reynolds, aided as it has been by the wise liberality of the Whitworth trustees, in spending £10,000 upon an engineering laboratory, has achieved results of which Owen's College is justly proud. The Victoria University is indeed peculiarly rich in engineering schools; for besides Owen's it includes the Yorkshire College in Leeds and University College in Liverpool, each admirably furnished for the teaching of engineering. At Leeds the engineers of the district have given unequivocal evidence of their faith in the professional value of a college training by subscribing £10,000 to provide buildings and plant for the department of engineering; and at Liverpool the Walker Engineering Laboratories, recently completed at a cost of £23,000, form the most lavish provision of which any English college can boast. Time would fail me to speak of the many other institutions in this country at which similar teaching is given, with the aid of more or less perfect laboratory appliances—of the colleges at Birmingham, Bristol, Sheffield, Nottingham, and Cardiff; of the comparatively venerable school of engineering at King's College, London; of such special colleges as that at Cooper's Hill; of the laboratory I have just left at University College, Dundee—in the furnishing of which, again, the local engineers gave substantial help; of the great work the City guilds have done in London by founding the central institution in the west, with Prof. Unwin's splendid laboratory, and the Finsbury College in the east, where the suggestive ideas of a most original teacher—Prof. Perry—have taken practical shape. Amongst the London schools there is still one that calls for very special mention — I mean University College, for it was there

* Abstract of an Introductory Lecture delivered at Cambridge January 20, 1891.

that Prof. Kennedy created the first of those laboratories which now fill so large a place in the University training of engineers. To the great regret of all friends of that training, Prof. Kennedy has relinquished professorial work, but not until he has had the satisfaction of receiving, in the laboratories which have sprung up in all parts of the country, the most flattering tribute to his educational methods, the tribute of imitation. It is scarcely too much to say that the engineering laboratory has done for the scientific teaching of engineering what the physical laboratory has done for the teaching of physics, or the chemical laboratory for the teaching of chemistry. Fifteen years ago there was no such thing as an engineering laboratory in any of the English or Scottish colleges. What teaching was given was that of the lecture-room, supplemented only by practice in drawing, and in some cases by field-work in surveying and levelling. To-day, no university or college which professes to teach engineering considers itself complete without a costly laboratory. In promoting this change Prof. Kennedy has done a service to the cause of professional education which, it is safe to say, will not soon be forgotten. He found the engineering laboratory no more than a means of private research. He left it an instrument of education.

I conceive that one of our first aims in furthering the advancement of the School of Engineering in Cambridge, should be to secure the establishment of an engineering laboratory. The work which is done in it is essentially measurement. To carry it out with anything like fulness requires the provision of costly plant; some of it may, however, de done with rough and inexpensive appliances. We may at least make a beginning with them at once, and it is my hope to do so; but in doing that I trust I shall be acquitted of any intention to rest content until a laboratory is provided that will be worthy of the University of Cambridge. In the existing workshops we have a nucleus about which a laboratory may very naturally grow. Whether a University school of engineering ought or ought not to give its students any systematic instruction in the manual processes of the workshop is a question in regard to which experts are by no means agreed. On one hand it is urged that the college workshop is necessarily small, that practice in it cannot (and this all will admit) entirely take the place of pupilage in a manufacturing establishment; that time for it can be ill spared from the more necessary parts of the curriculum, and that the pupil will have a better opportunity of learning the same things in his subsequent experience at the works. On the other hand, it may fairly be pleaded that if the subsequent apprenticeship is to be shortened—as we contend it may—the pupil will do well to learn what he can of the use of tools during his college course; that much that is useful *can* be effectively taught, even in a small way; that the workshops gratify a healthy instinct, and that the time spent in them is an agreeable recreation in the midst of severer studies; that some acquaintance with the ordinary mechanical operations is of service even in the earliest stages of college training; that the workshops are of benefit to students who do not mean to be engineers—a consideration of special weight in Cambridge; and above all that a workshop forms a most important adjunct to an engineering laboratory. In our own case the question, so far as there is any question, is decided by the fact that the workshops exist; one's plain duty is to make the best possible use of them. As to exactly what that use should be I speak with the hesitation natural to one who has not yet had experience in directing this kind of training; but I conceive the workshops will be best turned to account if the pupil is put through a series of systematic exercises in woodwork and metal-work, in chipping and filing, in turning, drilling, planing, forging and the like. It is perhaps instructive in this connection to remark that at the Imperial Technical School of Moscow, where, as I have already said, there are large workshops, these are divided into two parts—practising shops and manufacturing shops. In the practising shops the student gains his first knowledge of the processes of wood and metal-working. The function of the practising shops is probably that which our University workshops may best attempt to fulfil. In any case, it seems to me that the question of the workshops is no more than a detail, and perhaps not even a very important detail, in a much larger question. The larger question is, how are we to secure anything like a fully-organised school of engineering?

The engineering school must be accepted as an integral part of the University system. We must have a department working in the closest association with collegiate tuition and other spheres of University activity, amply furnished in respect of buildings and plant, secure of University favour, and forming an accepted avenue to University distinction. The student who comes here with the serious intention to study engineering must be prepared to follow, and we must be prepared to find for him, a connected course carefully planned to be at once educative and professionally useful, which will engage his full attention during the usual period of academic residence. Without an organised engineering school, Cambridge must lose many good men who intend to be engineers who forego the benefits of University residence and the unrivalled advantages which this University offers to mathematical students, in order to seek elsewhere the special training their profession demands. The schools of mathematics, physics and chemistry will profit by association with a school of engineering. And again, among the men of mathematical bent who in any case would come to Cambridge there must be a few whom an engineering school would draw into a congenial profession which they otherwise would miss. There is still another aspect of the matter, too important to be passed without brief mention. Apart from its service to professional students, an engineering school has work to do in the training of those whose business in life will be to teach applied mechanics. This is a career that now gives occupation t a very great number of men in the colleges, in the technica schools, in the numerous classes that are conducted in all industrial centres under the auspices of the Department of Science and Art. The training of these teachers is a work of national importance in which the University of Cambridge may surely take a share. Is the School of Engineering at Cambridge to be as complete, as well furnished as any existing school? Where are we to look for the £10,000, the £20,000, which has supplied the wants of Manchester, of Leeds, of Liverpool? I was cheered to read in the address of the Vice-Chancellor to the Senate his expression of belief that should the establishment of an engineering laboratory be held to be in itself desirable, pecuniary help from non-resident as well as resident friends of the University was not likely to be refused. I appeal for that help earnestly and confidently, convinced that a laboratory is, not simply desirable, but indispensable.

## THE GUERNSEY ELECTRIC RAILWAY.

As we announced in a recent issue, the contract for the electrical equipment of the line owned by The Guernsey Railway Company has been obtained by Messrs. Siemens Bros. and Co. As this line will be the first in the United Kingdom to be run on the overhead trolley system, the following information, for which we are indebted to the railway company's manager, may be of interest:—

The length of the line is 2 miles 1,430 yards, composed as follows:—1 mile 680 yards of street, with single track, and 1 mile 750 yards single track outside the street. The track is single with 5 turnouts, aggregating 600 yards in length, and there are 28 single track curves, which are mostly very slight. The overhead wires are to be at a height of not more than 25ft., nor less than 20ft. The maximum grade is 2½ per cent., and runs for a distance of 500ft., and there are other grades of 2 per cent. The maximum grade on curve is 2 per cent., and is on a curve of 75ft. radius. It is situated about 1½ miles from the power station.

The line was built in 1879, and is in fair condition. The gauge is 4ft. 8½in., 250 yards of track being paved with granite setts and 1¼ miles macadamised. Nearly 1½ miles is laid with 40lb. steel and iron rails (ordinary railway section), and the remainder with 40lb. rails of tram section. The ground on which the line is laid is chiefly made ground and sea shingle.

The contractors will supply two four-wheeled 50 passenger cars, completely equipped with motor trucks, and the following cars now in use will be converted into motor cars, viz.:—1 double-decked bogie 5 ton 68 passenger car; 1 single storey composite bogie 6¼ ton 42 passenger car. All the motor cars will be lighted by electricity, and will have to run on the level at a speed of 12 miles per hour, fully loaded, under all conditions of weather and track, and with four cars running. The poles are to be of iron in the streets, though outside the town they may be of wood. The power station is situated close to the track, at a point about 2¼ miles from the remote end of the line. The generating plant will comprise a 25 H.P. Marshall compound undertype engine, and a dynamo giving 100 amperes at 500 volts.

The Legislative Assembly of the island having appointed a committee to supervise the work, it will have to be carried out and completed to their satisfaction, and that of their engineer, as well as that of the Directors of the Company and their engineer. The formal sanction of the Royal Court of the island will also be required on completion, before the work is taken over, and passengers allowed to be carried. The electric cars will commence running at the beginning of July.

**The Chicago Exhibition.**—It is stated that Her Majesty's Government have notified to Mr. Blaine, Secretary of State, their acceptance of President Harrison's invitation to take part in the Exhibition, to be held at Chicago in 1893, and that Lord Salisbury has also informed the President that a Royal Commission will be appointed to further British interests in connection with the Exhibition.

## A GRAND TRUNK TELEGRAPH LINE.

The Bengal Chamber of Commerce, says the *Pioneer* of Allahabad, in the course of their annual report, state that they supported a suggestion of the Bombay Chamber that "an early inquiry should be instituted by Government as to the practicability of a land line of telegraphs from Chaman *viâ* Kandahar and Herat to Teheran on the one side and to the Russian system of telegraphs on the other, as affording a cheaper route of telegraphic communication with Europe and the United Kingdom than those now existing." Now, while there can be no doubt that it would be most desirable in the interests of civilisation and commerce to link Chaman with the Russian system of telegraphs in the Trans-Caspian Province by way of Mashad, which is now in communication with Teheran, there are serious difficulties in the way of laying and maintaining the wire through Eastern Afghanistan. The project is not a new one; it was put forward tentatively in our columns some seven or eight years ago, and was freely discussed at the time. Our view then was that the consent of the Amir of Kabul to the scheme might possibly be obtained by the grant of liberal annual payments; that His Highness might undertake to guard the line from attack by the tribesmen; and that trained Mahomedan signallers and line-men might be sent from India to Kandahar, Farrah, Herat, and other points selected for stations. A correspondent, whose opinion commanded the highest respect, at once pointed out that, given the consent of Amir to the scheme, it would still be impossible to maintain the line, as the tribes along the route would to a certainty never allow it to remain intact. The Afghan officials would be lukewarm in carrying out orders which the Amir himself would probably issue in a half-hearted way, for the constant punishment of offending tribes would serve to make his rule unpopular among the turbulent sections of his subjects. There is, we fear, only too much reason to believe that this view is the correct one. Since the time when the project was discussed Abdur Rahman has not shown any desire to open out his dominions. On the contrary, he has almost destroyed trade with India by the imposition of prohibitive duties; and though he has in his own capital availed himself of some of the scientific appliances of civilisation, he is still firm in his determination not to have railways and telegraphs in his dominions. It is but 160 miles from Jamrud to Kabul, and the telegraph line could be laid that distance in a few weeks, but His Highness prefers trusting to the old system of mounted messengers, though during the dangerous phases of Ishak Khan's rebellion in Afghan Turkistan he would doubtless have been glad of a more rapid means of communication with the Punjab. We must, therefore, come reluctantly to the conclusion that he would not support a project for a telegraph line to Herat, and that if his consent was exacted under political pressure there would be but a small chance of the line being maintained in working order.

But if the Bombay and Calcutta Chambers of Commerce desire an overland telegraph line to Europe, they might turn their attention to the Seistan route. Taking Quetta as the starting-point on the side of India a line could be laid through Nushki to Nasirabad, and thence across the Lut Desert to Yezd and Kashan, in the neighbourhood of which town it would join the Indo-European line. The distance by this route to Teheran would be actually less than by way of Kandahar, Herat and Mashad, but against this must be set the fact that the wire already links Mashad with Teheran. On the other hand the line would only be liable to such interruptions as occur on the present Indo-European system in Persia. The nomadic tribes are given to committing wilful damage by using the insulators as targets for rifle practice, but every year offences of this kind become fewer and fewer, and the Persian officials are less obstructive than they were when there is a question of securing the punishment of offenders. The Quetta Kashan line would not pass through any portion of Afghanistan. The safety of the wire could be assured through the Nushki district by the Chief Commissioner of Baluchistan, while the Teheran Government would look after it through Eastern and Central Persia. At present the heaviest expenditure on the Indo-European system is in connection with the cables from Karachi to the Persian Gulf. These have to be repaired from time to time, and even now a large sum has been sanctioned to lay a new cable altogether. A land line is of course immensely cheaper both to lay and maintain than a cable, and with this alternative route from Quetta rates to and from Europe would be considerably lowered. Were Teheran connected direct with the Indian telegraph, traffic would at once be attracted to this overland route; and looking still further ahead to the time when Bhamo is linked with the Chinese Telegraph now laid to Momein, 100 miles from the Burman frontier, it may be prophesied that the bulk of the messages to and from the Further East would pass over what might be called the Indo-Persian line. They now find their way along the Madras-Penang cable, one of the most expensive to maintain in the world and one also which is not uncommonly interrupted. This project of a Grand Trunk telegraph line may seem to be a-head of the times, but the maps will show that Quetta lies almost half between Calcutta and Teheran, and the telegraph wire, unlike the railway, seeks the most direct route when there is a question of through communication between adjoining countries. When the Central Asian question has been laid at rest it may become possible to connect Chaman with Mashed and the Russian line east of the Caspian; but so long as Afghanistan retains its independence it will not be feasible to lay the telegraph to Kandahar and Herat.

## PHYSICAL SOCIETY.

At a meeting of this Society on March 20, 1891, Prof. S. U. Pickering, F.R.S., read a Paper on

### "The Theory of Dissociation into Ions and its Consequences."

According to this theory electrolytes are entirely dissociated into their ions in weak solutions. This dissociation was held by Arrhenius to absorb heat, and although heat is evolved by the dissolution of hydrochloric acid, &c., it is not maintained that dissolution evolves heat, but that the heat absorbed by the decomposition of the molecule into its atoms, is more than counter-balanced by the heat supposed to be evolved by the combination of the atoms with their electric charges. These actions the author considered improbable, and thought that, before being accepted, the theory must give satisfactory answers to the following questions:—How can matter combine with an affection of matter to produce heat? Whence do the electric charges originate? Why does not the opposite electrification of the different atoms make them cling more firmly together instead of dissolving the union between them? And why should an atom which possesses a strong attraction for a negative charge (such as chlorine) go to the positive electrode during electrolysis?

When a dilute solution, which is supposed to contain some gaseous molecules, is further diluted, then, according to the theory, some of the molecules are dissociated, and, if heat is absorbed, it follows that the dissociation, and therefore dissolution, of the gas, must absorb heat; yet, he said, it can be shown that in some of these cases the dissolution of a gas evolves a large amount of heat.

The antagonism between the present and the old electro-chemical theory, according to which the atomic charges are identical with the free energy of an atom, and are the cause of combination, not decomposition, was commented on, as well as the disagreement between the present theory and Clausius' view that there are a few ions or atoms present in a liquid owing to accidental superheating of some of the molecules. Reasons, however, were adduced for believing that the presence of even a few atoms in a solution to be improbable.

A communication on

### "Some Points in Electrolysis,"

was made by Mr. J. Swinburne. Considering a reversible single fluid cell, the author, by a process of reasoning, based on Carnot's principle, and the conservation of energy, arrives at Helmholtz's equation, $E = E_c + \theta \frac{dE}{d\theta}$, where E is the electromotive force, $E_c$ the part due to chemical action, and $\theta$ the absolute temperature. Writing the equation in full, using suffixes *n* and *p* to denote the negative and positive plates, it becomes

$$E_n + E = E_{nc} + E_{pc} + \theta \frac{dE_{ny}}{d\theta} + \theta \frac{dE_p}{d\theta}.$$

He then shows that by having the two plates in different vessels and heating them to different temperatures, the Peltier effects represented by $\theta \frac{dE_n}{d\theta}$ and $\theta \frac{dE_p}{d\theta}$, can be determined separately. Similarly those of a two-fluid battery might be found by arranging the junction of the fluids in a third vessel.

After pointing out the desirability that the conditions under which all thermo-chemical data have been obtained should be clearly stated, he proceeded to show that any cell in which secondary actions occur (as, for example, if zinc oxide, primarily formed by electrolysis, were to dissolve in sulphuric acid) must necessarily be non-reversible. He also contended that in a secondary battery the formation of lead sulphate on both plates is the essence of the cell action, and that there is no intermediate formation of PbO.

On the subject of so-called "nascent" hydrogen or oxygen, he said that, reasoning from the conservation of energy, showed that neither could exist. Taking the case of persulphate of iron in dilute sulphuric acid, which is said to be reduced to protosulphate by the "nascent hydrogen," liberated on putting a piece of metal (say magnesium) into the liquid, he said, a better explanation of the phenomena would be that the metal dissolves, if it either reduces the metal or evolves hydrogen; and, as the former requires less energy, the reduction takes place, and when no reducible salt is

Digitized by Google

available, hydrogen is evolved. Evolution of hydrogen and reduction of the per-salt are thus *alternative* and *not consecutive* actions.

Examining Dr. Lodge's views on the contact E.M.F. between metals, he remarked that, if the tendency of a metal (such as zinc) to oxidise can produce an electric stress or difference of potential which prevents further combination, actual combination must charge the metal if it be insulated. A piece of sodium, however, oxidises continuously, and, therefore, should become charged to such an enormous potential that it would emit sparks. As this effect is not known to occur, the author suggested that the volta effect may be due to films of water; and in support of this view, adduced the fact that metals, when perfectly dry, do not combine with chlorine, and that even sodium is not attacked by dry chlorine.

DISCUSSION.

In the discussion on the two Papers, Prof. PICKERING said the idea of nascent elements had, to a large extent, been given up by chemists, and pointed out that the fact of one reaction taking place rather than another was not merely a question of heat energy, but that a kind of chemical selection was involved.

Prof. S. P. THOMPSON recalled attention to the fact that the products of electrolysis depend on the E.M.F. employed in producing it, and thought the E.M.F. required to produce the various products might be taken as a measure of their affinities. He did not agree with Mr. Swinburne's method of finding the E.M.F. of a secondary battery from thermochemical data, for he failed to see how two similar actions going on at the two plates of a cell could add anything whatever to the E.M.F. of the cell.

The PRESIDENT (Prof. Ayrton) said the question whether the potential difference between two dissimilar substances was due to oxidation or to mere contact, could only be decided by direct experiments made in a vacuum from which all traces of moisture and oxygen had been removed. Without agreeing with Dr. Lodge's view on the subject, he pointed out that the continuous oxidation of a piece of insulated sodium need not necessarily produce a great potential difference, for the combination might produce heat.

After Prof. PICKERING and Mr. SWINBURNE had replied to the points raised, Mr. Walter Bailey took the chair, and Prof. PERRY read a note "On the Variation of Surface-Tension with Temperature," by Prof. A. T. Selby, M.A. Considering unit mass of liquid at constant volume, but variable surface (S), and temperature ($t$), the author expresses the gain of intrinsic energy due to changes of the variables by $dH + dW = k\,dt + (l + T)\,dS$ where $dH$ is the heat absorbed, $dW$ the work done on the film, $k$ the specific heat at constant volume, $l$ the latent heat of extension, and T the surface-tension. This being a perfect differential, it is shown that $T = c - bt$, and $l = bt$, $c$ and $b$ being constants. Supposing $c$ and $b$ to be independent of the specific volume of the liquid, it is shown that at the critical temperature $t = \frac{c}{b}$. Hence this temperature may be determined by finding the surface-tension at two very different temperatures. Since, also, $l = bt$, the latent heat of extension is proportional to the absolute temperature. Reasons for supposing $b$ to be independent of the specific volume are given in the Paper.

Mr. BLAKESLEY described an effect of temperature on surface-tension, which he had observed in sensitive spirit levels. By warming one end of the tube, even by the hand, the bubble immediately moves towards that end. This effect, which might produce considerable error in engineering operations, was, so far as he was aware, not mentioned in the text-books.

Prof. PERRY remarked that, although the volume, temperature, and surface of the liquid had been referred to in the Paper, pressure was not mentioned, and on this point he inquired whether the results arrived at were true, quite independent of the pressure.

Prof. S. P. THOMPSON, D.Sc., then read a Paper on

**"Magnetic Proof Pieces and Proof Planes."**

The distribution of magnetism over magnets has been examined in various ways by different observers, but mostly by observing the force of detachment of either rods, ellipsoids, or spheres used as proof pieces. In all these cases, it was, the author said, difficult to see exactly what was measured, for the presence of proof pieces altered the thing to be tested. The pull exerted must also depend on the permeability of the piece used as well as on its shape and disposition with respect to the magnetic circuit; he had, therefore, investigated the subject by finding the actual distributions by means of a flat exploring coil and ballistic galvanometer, both with and without the presence of proof pieces of various shapes and sizes. The results show that the perturbations produced by the proof pieces are always large, in some cases the perturbed field about a point being four to six times the unperturbed field. In most cases, however, the ratio of the perturbed to the unperturbed field was constant, so long as the former did not exceed 6,000 C.G.S. units. The amount of perturbation was also found to depend on the saturation of the magnet, and on whether it was a permanent or an electromagnet. The numbers obtained in various experiments, and curves plotted from such results, were shown. In conclusion, the author said, that in using proof pieces, much depended on the accuracy of the contact, but in any case, the results obtained were not very reliable. The flat exploring coil, or magnetic proof plane, however, furnished a satisfactory method of examining magnetic distributions.

## THE LONDON-PARIS TELEPHONE LINE.

The London-Paris telephone line, after having been placed for one day gratuitously at the service of the public, came into regular operation on Wednesday, April 1st. The following notice has been issued by the Post Office:—

*Telephonic Communication between London and Paris.*

On and after Wednesday, April 1st, telephonic communication between London and Paris will be open to the public.

Call offices have been established at the General Post Office, West (Bath-street), open always, and the Threadneedle-street branch Post Office (Stock Exchange), open on week days from 8 a.m. to 8 p.m. As soon as possible a call office will be established at the West Strand telegraph office (Charing-cross), open always.

The charge will be 8s. for a conversation of three minutes. Not more than two consecutive conversations can be allowed, except when no other applicant is waiting at any of the offices to use the telephone.

In making appointments for conversations correspondents should bear in mind that Paris time is about ten minutes in advance of London time.

Persons desirous of speaking to Paris direct from their own houses or offices in London can be provided with the necessary wires and apparatus, on terms to be ascertained on application to the Secretary, General Post Office, E.C.

These wires can be used not merely for the purpose of communicating by telephone with Paris, but also for the purpose of sending telegrams for transmission within the United Kingdom or abroad. They can also be used to call a messenger for the express delivery of a letter or parcel.

The speaking cabinet at the General Post Office is situated on the ground floor, near the main entrance, turning out of Newgate-street. It is large enough to contain the speaker, and the walls are padded so as to be sound proof. Numbers of applications for private lines from large firms have been received, and the commercial success of the enterprise is said to be already assured. We may mention that the Roulez transmitter, which is favoured by M. Amiot and the French electricians, is formed by little holes in a carbon block, which are filled with small pieces of carbon filament. The mouths of these holes are covered by the diaphragm, which is a thin disc of charred wood.

## ON THE VARIATION OF VOLUME IN LIQUID DIELECTRICS UNDER THE ACTION OF THE ELECTRIC FORCES ACTING BETWEEN THE PLATES OF A CONDENSER.*

BY EMILIO ODDONE.

Kerr, as we know, has shown that a liquid dielectric submitted to the electric forces acting between the two plates of a condenser has a bi-refractory action on light, and may be compared to a uniaxial crystal, the axis of which is parallel to the lines of electric force. The liquids investigated were ranged under two headings. The *positive* liquids, such as bi-sulphide of carbon, glycerine, &c., behaved like glass stretched in the direction of the lines of force. The *negative* liquids, such as ether, the oils, &c., behaved like glass compressed in the same direction. Quincke endeavoured to show that the action on light arose from a change of volume due to the influence of the electric forces; the positive liquids undergoing an increase, and the negative liquids a diminution, both changes being proportional to the square of the charge of the condenser and inversely as its surface. Others, and even Quincke himself, subsequently recognised that certain experiments were in complete disagreement with this hypothesis, and to settle all doubts the author reinvestigated the whole question of change of volume, employing minute precautions for the elimination of causes of error.

The apparatus used was a kind of glass thermometer with large bulb. In the bulb were two platinum laminae placed face to face and forming the plates of the condenser. The bulb and a portion of the tube was filled with the liquid to be tested.

When the liquid had not been very carefully purified it was a very obvious conductor of electricity. Owing to its conductivity, a current of electricity passed between the two plates of the charged condenser. This resulted in a very sensible heating. The question therefore arises, were not the dilatations observed by Quincke simply due to this heating? If care be taken to keep the whole apparatus at a constant temperature, if the liquids under examination are thoroughly purified, these dilatations always diminish, and become at times almost imperceptible. The author was only able to discover contractions in a few particular cases, with sweet almond oil for instance, and these contractions were accompanied by strong vortical movements, which seemed to point to a mechanical action, completely masking the supposed electrical action.

The author concludes that within the limits of his experiments there is no change of volume of liquid dielectrics under the action of electric forces; the expansion observed being due to heating caused either by the polarisation of the dielectric, or by the passage of a current through the imperfectly insulating liquid.

* The *Rendiconti della R. Accademia dei Lincei*, May, 1890. From an abstract by M. Lucien Poincarré, in the *Journal de Physique*, March, 1891

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *March* 20, 1891.

**Gas and Electric Light Statistics.**—As a rule American public documents are anything except interesting, but a striking exception is to be found in the report of the Board of Gas and Electric Light Commissioners of the Commonwealth of Massachusetts for 1890. It contains a very large amount of important and instructive information, and a very full statistical account of the operation of the gas and electrical companies within that State. During that year there were in that State three fatal accidents from the electric current. All three men met their death from thousand-volt alternating currents; two of them by a leak from line along the guy wire, the other in attempting to take a joint. Gas was responsible for eight fatal casualties in the State of Massachusetts, and nearly 200 in the United States. Eleven electric light companies were incorporated during the past year, operating about 150,000 incandescent lamps and 15,000 arc lamps. In addition there is a motor service of both arc and incandescent circuits aggregating a little over 2,600 H.P., most of it in small machines. As might be expected the prices charged for electric light vary very widely from place to place, the arc lamps furnished for public lighting ranging in price from $60 to $180 per year. Commercial lights are furnished at about the same price. Incandescent lighting ranges from 1 cent. per ampere hour by meter, upward, a common contract price for 16-c.p. lights in commercial service being $10 per year. The dividends reported by 22 companies show that the business pays fairly well, the amounts ranging from 1½ to 10 per cent., and averaging nearly five per cent. The aggregate receipts for electric lighting and power during the year were very nearly $2,000,000.

**Primary Batteries.**—Perhaps the most obnoxiously active of all so-called electrical enterprises are the primary battery companies. There is a large and flourishing crop of them just at the present time, a few engaged in legitimate business, more in promiscuous swindling. One delightful example of the latter class was recently unearthed where the alleged batteries simply acted as a high-resistance shunt across the incandescent lighting mains used to supply the lamps for the edification of prospective investors. This game has been worked more than once, and will probably serve many a time again to extract the hard-earned dollars from the pockets of those who are more greedy than wise. No amount of exposure and abuse seems to have the slightest effect on the vitality of the thorough-going primary battery fraud. I do not know whether they are active with you in England, but here, at times, the number of primary battery swindlers engaged in vigorous work is something almost beyond belief. This state of things makes it very difficult for an honest battery for ordinary purposes to make any headway.

**Lighting of Railway Tunnels.**—The recent disastrous collision in the tunnel that affords entrance for the railroads into New York City has stirred up public opinion to the point of demanding that tunnels shall be properly lighted, especially the tunnel in question. In spite of the fact that for several years the great Hoosac tunnel had been brilliantly illuminated, the railway officials here in New York solemnly aver that it is impossible to light a tunnel so as to be of the least service. This allegation is made for two reasons: In the first place, they seriously object to any expenses that are not forced upon them; and, second, they hope, by frightening the public by keeping constantly before it both the danger of collision and the impossibility of averting it in the present tunnel, to obtain permission to seize bodily upon Fourth-avenue and make an open cutting clear down to the Grand Central Station in 42nd-street. Fortunately their game is a little too obvious, and it will probably lead to no resutls; but meanwhile several railway companies near the city, especially those doing suburban service, are seriously looking into the question of the electric lighting of their tunnels, and it is most likely that the present season will see one or more plants installed for that purpose.

## CORRESPONDENCE.

### VOLTAGE AND ELECTROMOTIVE FORCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The article on Electromotive Force, published in your last issue, raises a question of some interest. The words "voltage" and "electromotive force" are, unfortunately, often used indiscriminately, one for another, as if their meanings were precisely the same, and it thus seems at first sight that the former word, which is shorter and more expressive, could always with advantage displace the latter. It is, moreover, often asserted that the word "electromotive force," besides being a lengthy and round-about term, implies a false idea by leading one to imagine that it is of the nature of a mechanical force. But however this may be, there is still an advantage in having a separate word, like electromotive force, to use exclusively in connection with the electric power *generated* in a circuit, while reserving the word "voltage" to refer to the power used up or *spent* in various ways in the circuit. Both electromotive force and voltage, when multiplied by the current, represent power, but, whereas the former denotes the total power of the current, the latter only refers to a part of it. Thus, a dynamo whose electromotive force is 100 volts, driving a motor which absorbs a voltage of 80, by means of a conductor, whose resistance absorbs 20 volts, gives out power, represented by the number 100, which is divided into two parts—80 and 20—according to the voltages. The E.M.F. of a dynamo, or battery, corresponds with its total electrical output, whereas the terminal voltage corresponds with its useful output. The E.M.F. should be reserved for the energy supplied, while the distribution of energy can be denoted by the voltages. The ideas represented are those of income and expenditure, and though both are measured in the same units, it is desirable to keep the two sides of the balance-sheet as distinct as possible. This can best be accomplished by using different words to describe the items on the two sides. The words "debtor" and "creditor" have been adopted in one case, and the words "electromotive force" and "voltage" should be used in the other.

Voltage can always be measured by a voltmeter, but E.M.F. cannot always be so determined. Voltage must be caused by E.M.F., but E.M.F. may exist without voltage, as when a magnet is pushed symmetrically through a circular ring. E.M.F. is generally local, while voltage is necessarily distributed. One is generally referred to a particular portion of the circuit where the energy is being supplied, while the other is always described with reference to two points. E.M.F. represents a condition of supply which is generally fairly constant, however much power is supplied. Thus, the E.M.F. of a dynamo or battery does not as a rule vary very much as the current is altered. This, however, is not true of voltages, as, for instance, the voltage at the terminals of a battery.

The other question raised in your article about the seat of electromotive force in a battery, rests on an entirely different basis. All that is clear about this matter is, that the energy is obtained from the chemical actions going on within the cell, just as the source of energy in a steam boiler is the heat of combustion of the coal. The "seat" of electromotive force in a cell, or of motive force in a boiler, may, like the source of a man's income, be a very questionable thing, but as long as the condition of supply is fixed and regular, the power of expenditure is perfectly definite.—Yours, &c.,

W. E. SUMPNER.

### CONTROL MAGNETS FOR GALVANOMETERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—In your issue of March 20th, on page 610, a description of Messrs. Nalder Brothers' ballistic galvanometer is given, in which you credit Dr. Mullineux Walmsley, of Edinburgh, with the special form of control magnet applied thereto, and which allows the intensity of the magnetic field, in which the needle moves, to be altered without interfering with its direction.

On July 9, 1883, I read a Paper before the Physical Society, in which I described various improvements applied to my tangent

Digitized by Google

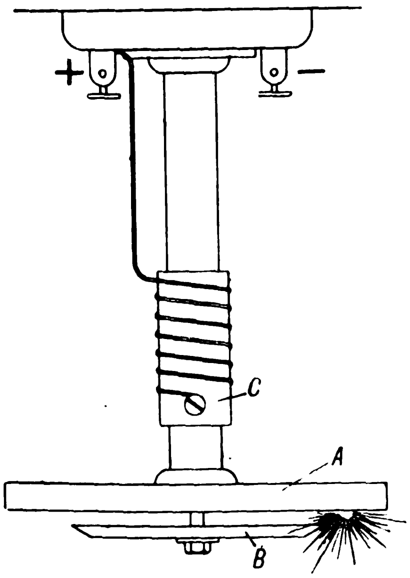
galvanometer with movable coil, and amongst these, the special kind of control magnet you now attribute to Dr. Walmsley. This Paper was afterwards published in the *Philosophical Magazine* for August, and also in the *Proceedings* of the Physical Society, and, with your permission, I will quote the following passages therefrom:—" For that purpose (*i.e.*, to adjust the constant of the galvanometer to a certain value), an auxiliary magnet is placed east or west of the needle in a plane, parallel to the meridian, which can turn round a horizontal axis passing through its neutral point and the centre of the needle, and being at right angles to the diameter on which the coil (of the tangent galvanometer) is turned. This magnet *does not affect the zero position*, and, moreover, if placed exactly vertical with its magnetic axis, it does not alter the original constant, which then only depends upon the horizontal terrestrial component, more or less modified by the surroundings, but if it is dipped, *the horizontal force acting on the needle is either augmented or diminished*, according to the direction in which the magnet is turned, and to the amount of dip given." All the tangent galvanometers with movable coils manufactured by Messrs. Siemens Brothers, since 1883, are provided with these control magnets, which you term "tail magnets," as may be seen from the illustrations of the instruments in various publications, of which I will mention only the following, viz., *Engineering*, August 3, 1883, p. 104; Kemp's "Handbook of Electrical Testing," 4th edition, p. 37; "Kittler's Handbuch der Elektrotechnik," Vol. I., p. 242. Some five or six years ago I made numerous experiments with the new kind of controlling magnet, and completely worked out its theory, but I have hitherto refrained from publishing the results; however, I hope soon to be able to do so.—Yours, &c.,

Woolwich, March 28, 1891. EUG. OBACH.

## AN EXPERIMENT WITH THE ELECTRIC ARC.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The interesting article which you reproduced in your issue of 27th inst. headed "An Experiment with the Electric Arc," recalls to my mind a practical application of the phenomena described which I made in 1879, and patented 11th June, of that year. One form of the lamp and the one which best illustrates the design is as follows:



A, Carbon disc for positive pole. B, Carbon disc for negative pole. C, Iron tube, carrying a coil of wire through which the current to the lamp passes and induces the arc to travel round the periphery of the negative disc.

This lamp and several modifiations of it are described in three patents taken out in 1879 and 1881.—Yours, &c.

J. D. F. ANDREWS.

41 and 42, Parliament-street, London, S.W.
March 28th, 1890.

## TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

TENDERS WANTED.—Our advertisement columns contain particulars of plant and machinery for sale by private treaty, including a vertical boiler 6ft. by 3ft. 6in. disc, three Rigg's patent 3-cylinder engines, a new horizontal steam engine, sliding and screw cutting lathes, slotting, milling, radial and hand drilling machines, shafting, pulleys, &c. Orders to view at 4, Station-buildings, Acton-street, Haggerston, London, N.E., may be obtained on application to Messrs. Wheatley Kirk, Price and Goulty, 52, Queen Victoria-street, E.C., to whom tenders are to be sent.

RESULT OF TENDER.—The following tenders were received for lighting Ballymena with gas or electricity from August 16, 1891, to May 16, 1892:—Ballymena and Harryville Gas Light Company, Limited (gas), £336. 3s.; Messrs. J. E. H. Gordon and Co., Limited, 11, Pall Mall, London, S.W. (electricity), £365. The former tender was accepted.

THE ELECTRICAL ACCESSORIES COMPANY (LIMITED).—Owing to increase in business, it has become necessary to modify the arrangement of the staff, and Mr. C. L. Schwind, son of Mr. Charles Schwind, chairman of Messrs. Handysides, of Derby, has been appointed manager.

THE ELECTRICAL ENGINEERING CORPORATION.—We are informed that Mr. W. Pixley has been appointed by the Court of Chancery receiver and manager of this Corporation, on behalf of the debenture holders.

"THE IRONMONGER."—We have received the Spring issue of *The Ironmonger*, consisting of not less than 500 pages of matter, much of which is of interest to many of our readers.

UNITED ASBESTOS COMPANY (LIMITED).—We are in receipt of a new catalogue issued by this Company, giving full particulars of their various well-known manufactures. The catalogue is neatly printed and fully illustrated, and the particulars given will interest many of our readers A list of the goods manufactured by the Company specially adapted for electrical purposes, are described in page 28. Among the illustrations will be found two excellent photographs of the destruction of the Queen's Theatre, Manchester, by fire in August of last year, on which occasion the drop curtain made of the United Asbestos Company's patent Victor metallic cloth, was the means of saving the whole of the stage scenery and effects. There is also a view of Messrs. Davey, Paxman and Co.'s installation of boilers at the Paris Exhibition, covered with the Company's boiler composition. The Company notify that they have recently opened two additional branches—at 135, Bute-street, Cardiff, and at Provident-buildings, Bristol.

GANDY BELT MANUFACTURING COMPANY (LIMITED).—We have received a copy of the new price list and particulars of the various manufactures of cotton and camel hair belting of this Company.

## PATENT RECORD.

### APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

March 2, 1891.

3,694. F. W. WEBB and A. M. THOMPSON. Crewe. Improvements in electrical switches.

3,738. J. MARX. London. Improvements in and apparatus for electrolysing and bleaching.

3,740. M. KOECHLIN. London. Improvements in electric meters.

3,748. A. MCLEAN. London. Improvements in the production of slabs and blocks for electrical insulators and other purposes, and apparatus to be used in the manufacture thereof.

3,755. B. DUKES. London. Improvements in automatic switches for electric currents (A. Heil, Germany).

March 3, 1891.

3,765. L. H. BUCHANAN. Manchester. Improvements in and connected with electric arc lamps.

3,789. B. J. B. MILLS. London. Improvements in the depolarisation of electric batteries (A. Bellemain, France).

3,799. A. CLARK. A new or improved solution or composition for charging electric batteries.

3,823. S. LEVY. London. Improvements in electric signalling and lighting for the prevention of railway accidents, and for lighting railway and other carriages.

March 4, 1891.

3,867. R. KENNEDY. Glasgow. Improvements in electricity meters.

3,868. F. T. HOLLINS. Leytonstone. Improvements in arrangements and apparatus electrically communicating with engine-drivers of railway trains and others, for signalling purposes and otherwise.

3,893. W. J. GLOVER and G. E. PREECE. Salford. Improvements in electrical cables.

3,895. F. G. CORNING. London. Improvements in apparatus for transferring electric car batteries. [Date applied for, under Patents Act, 1883, Section 103, August 5, 1890, being date of application in United States.]

3,904. J. P. RICHARDS. Penge. Electrical switches.

March 5, 1891.

3,939. W. H. ELLIOTT. Tipperary. Improvements in interlocking of points, signals and electric signals.

3,957. L. B. MILLER and M. W. WOODS. London. Improvements in instruments for measuring electricity.

3,967. J. COAD. London. Improvements in portable electric safety lamps.

3,984. O. PATIN. London. Improvements in and relating to electric arc lamps.

March 6, 1891.

4,005. F. BRYAN. London. Improvements in dynamo electric machines.

4,044. R. H. SIMPSON. London. Improvements in electrical storage batteries or accumulators.

4,064. G. HOOKHAM. London. Improvements in electricity meters.

March 7, 1891.

4,099. W. P. AKESTER. London. Improvements in electric arc lamps.

4,120. W. J. FRYER. London. An improved imitation candle for use with electric incandescent lamps.

March 1891.

4,170. W. H. WILLATT. Hull. An improved method for the distribution of electricity.

4,188. J. A. MAYS. London. Improvements in electrolysis.

## SPECIFICATIONS PUBLISHED.

1890.

3,096. DE FERRANTI. Electric meters. (Price 11d.)
3,193. SWINBURNE. Electric transformers. (Price 8d.)
3,272. FLETCHER. Electric switches. (Price 6d.)
3,937. RAWSON and SNELL. Electric flash signalling lanterns. (Price 8d.)
4,086. BARLEY and STEVENSON. Dynamo machines. (Price 6d.)
4,235. REES. Filaments for electric lamps. (Price 6d.)
4,260. THOMPSON (Young). Electric distribution. (Price 8d.)
4,984. ROBINSON. Electric telegraph apparatus. (Price 8d.)

5,016. BARY. Electric reversible machines. (Price 8d.)
5,678. KALB. Electric tension regulators. (Price 8d.)
5,750. CROMPTON (Fritsche). Dynamo electric machines, &c. (Price 8d.)
5,938. BOETTCHER. Secondary element. (Price 8d.)
6,005. SAYER. Electric lamp adjuster. (Price 6d.)
6,267. MARX. Electrical conductors. (Price 8d.)
6,392. BLÁTHY. Safety fuses for electric currents. (Price 6d.)
6,475. LOWRIE and HALL. Electric safety device. (Price 8d.)
6,495. CLARK (Schuckert and Co.). Electric telegraphs. (Price 8d.)
7,335. MACAULAY-CRUIKSHANK (Ressig and others). Incandescent lighting. (Price 8d.)
13,799. LAKE (Electric Secret Service Co.). Electric signalling. (Price 8d.)
18,266. DAVIES and DUTSON. Conduits for electric tramways. (Price 6d.)
19,496. MUNSIE. Insulators. (Price 8d.)
20,126. DUTTON. Galvanic batteries. (Price 8d.)
20,510. LAKE (Wood). Electrically welding metal articles. (Price 8d.)
20,540. THOMPSON (Coffin). Welding metals electrically. (Price 6d.)
21,143. RHODES. Electric batteries. (Price 6d.)
21,183. MILLS (Ongley). Electric protective and signal systems. (Price £2 2s.)

1891.

536. ATKINSON, C. W. and L. B. Dynamo-electric generators, &c. (Price 6d.)
667. THOMPSON THOMPSON (The Hess Electric Storage Battery Co.). Voltaic accumulators. (Price 8d.)
669. PULUJ. Electric cut-outs. (Price 8d.)
659. LEIGH (Gardiner). Therapeutic magneto-electric machines. (Price 8d.)
1,114. CHURCHWARD (Robertson). Electric railways, &c. (Price 8d.)

## COMPANIES' MEETINGS.

### Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited).

Notice is given that a general meeting of the holders of Priority Shares in this Company will be held at the registered office of the Company, 64, Cannon-street, E.C., on the 6th inst., at two o'clock, for the purpose of sanctioning by extraordinary resolution the alteration or modification of their rights and privileges involved in the proposed alterations in the Articles of the Company set out below. Resolved :—

*"That this meeting of holders of Priority Shares in Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited), hereby sanctions and approves of the following proposed alterations in the Articles of Association of the Company, namely—"*

(a) *That Article 109 shall be cancelled.*

(b) *In place thereof the following Article shall be substituted, namely—"(109).—All dividends shall be payable out of profits only ; but such dividends may be declared and paid either in cash or by the distribution of specific assets taken at their par value, and in particular of shares, debentures, or other securities of any other company, or partly in one way and partly in the other."*

(c) *Article 110 shall be altered by inserting after the words "until they have received a return" the words following, namely, "(either in cash or in shares, debentures, or other securities taken at their par value.)"*

Notice is also given that a general meeting of the holders of Founders' Shares in the Company will be held at the office as above on the same date, at half-past two o'clock, for the purpose of sanctioning by extraordinary resolution an alteration in the Articles of the Company, similar to that set out above.

Notice is further given that an extraordinary general meeting of the Company will be held at the office as above, on the 6th inst., at three o'clock in the afternoon, when a similar resolution to that set out above

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.
The best for overhead Telephone and Telegraph Lines,
AND ALL ELECTRICAL PURPOSES.

will be proposed. Should the resolution be passed by the requisite majority, it will be submitted for confirmation as a special resolution to a second extraordinary meeting, which will be subsequently held.

---

In reference to the matters referred to in the above notices, the Directors of the Company have issued the following circulars —

"March 19, 1891.

"Sir,—In enclosing you formal notices for extraordinary general meetings of the separate classes and the whole body of shareholders, I beg to inform you that the Directors, in compliance with the wish unanimously expressed at the annual general meeting held on January 29th last, have taken Counsel's opinion as to the measures to be adopted in order to enable them to distribute amongst the shareholders the large amount of assets held by the Company, and represented by shares and debentures of the French and Austrian Companies.

"Counsel has at length advised that it will be necessary to modify Clause 109 of the Articles of Association, which in its present shape precludes the payment of dividends except out of profits actually realised and converted into cash.

"It will also be necessary to modify Clause 110, which, as it at present stands, taken in conjunction with Clause 109, would render the proposed distribution of assets impossible until the Priority shareholders should have received a premium of £10 per share in cash.

"If these clauses are altered so as to enable the Directors to distribute the above securities, as though they were dividend in specie, they will immediately propose a distribution equivalent to £6 per Priority Share and £5 per Founders' Share, reckoning the securities to be divided at their par value. The effect of this and of the previous distributions will be that the Priority shareholders will have received back in cash the whole of the original capital invested, and, in addition, in securities a premium of 120 per cent., while the founders will receive securities equivalent at their par value to the original value of their shares. All the remaining foreign patents owned by the Company remain intact, and should prove a source of considerable value to both classes of shareholders, one-fourth going to the Priority Shares and three-fourths to the Founders' Shares.

"The Directors take this opportunity of informing you that satisfactory reports have been received of the progress of the French and Austro-Hungarian Companies. The French Company is progressing rapidly with the erection of its large works at Dives, near Havre, and M. Secretan, the General Manger, confirms his previous statement that he will commence working on a large scale in July next. As to the Austro-Hungarian Company, a factory with suitable buildings and spare land, together with turbines and free water power to the extent of 540 horse power, has been selected, thus avoiding the delay attendant upon the erection of special buildings. The preliminary agreement has been signed, and the property, which is in the neighbourhood of Cologne, will be conveyed to the Company as soon as the consent of the Prussian Government has been received.

"By order of the Board,

"J. SHURMER, Secretary."

---

"Referring to the circular issued on the 19th inst., relative to the proposed distribution of the Company's securities, as dividend in specie, to the holders of the Priority and Founders' Shares, I am directed to state that in consequence of the large number of shareholders who are expected to attend, the meetings will be held at the same hour, at the Cannon-street Hotel, in the City of London (Pillar Hall, on the second floor), instead of at the offices of the Company.

"Some alternative proposals have been brought before the Board, and the Directors deem it well to point out that they do not by any means pledge themselves to carry out the distribution as proposed in the circular, but are anxious in this respect to act only in accordance with the expressed wishes of the shareholders, who, at the general meeting, held on the 29th of January last, unanimously called upon the Board to take steps to effect a distribution of the Company's securities. The Directors confine their recommendation to the Company taking the power to make a distribution of shares or other securities; and they strongly urge upon the respective shareholders to attend the meetings called for April 6th next.

"By order of the Board,

"J. SHURMER, Secretary."

## The British Tanning Company.

An extraordinary general meeting of the British Tanning Company (Limited) was held at Winchester House, Old Broad-street, E.C., on Wednesday, March 25th, when the subjoined resolution, which was passed at the extraordinary general meeting of the Company, held on March 10, 1891, was submitted for confirmation as a special resolution, viz.:—

"*That the Bill now read, entitled 'An Act for rendering valid certain letters patent to Eugene Worms, of Paris, in the Republic of France, and Jean Balé, of the same place, for improved process and apparatus for tanning by aid of electricity,' be, and the same is hereby approved subject to such additions and variations as Parliament may think fit to make therein.*"

Mr. H. MOXON, who presided, explained that the resolution was necessary, inasmuch as a patent for electrical tanning in a similar way had been used by other people, and it was, therefore, needful to get the validity of this Company's process settled by the somewhat unusual course of application to Parliament.

The resolution was confirmed.

## NEW COMPANIES REGISTERED.

**DERMATINE COMPANY (LIMITED).**—Registered by Crosley and Burn, 2, Moorgate-street, E.C., with a capital of 55,000 in £5 shares. Object: To carry on in the United Kingdom, or elsewhere, the business of the manufacture of dermatine, in accordance with an agreement made between the Dermatine Company (Limited) (thereinafter called the Old Company) of the first part, John Cooper, liquidator of the Old Company, of the second part, and Edward Green, as trustee for this Company, of third part.

**EDINBURGH AND LEITH SAFE DEPOSIT COMPANY (LIMITED).**—Registered in Scotland, with a capital of £20,000 in £5 shares. In addition to the usual safe deposit business, the Company propose to carry on the business of gas, electrical and mechanical engineers, and all other businesses relating to lighting and heating.

**LANGNESS COPPER COMPANY (LIMITED).**—Registered with a capital of £35,000 in £1 shares, to acquire certain mining rights in the Isle of Man, and to carry on generally the business of miners.

**LONDON RUBBER AND PACKING COMPANY (LIMITED).**—Capital, £3,000 in £5 shares. Object: To acquire the business carried on by the London Rubber and Packing Company, dealing in india-rubber, gutta percha, leather, and electrical goods, &c., at 47, High Bridge, Newcastle-upon-Tyne; and to manufacture, construct and deal in all kinds of electrical articles, appliances and fittings, and leather, india-rubber and gutta percha goods of every description.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended March 27th amounted to £5,427.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The receipts of this Company for the week ended March 28th amounted to £702.

**CUBA SUBMARINE TELEGRAPH COMPANY.**—The estimated traffic receipts of this Company for the month of February were £4,000, as compared with £4,018 in the corresponding month of last year.

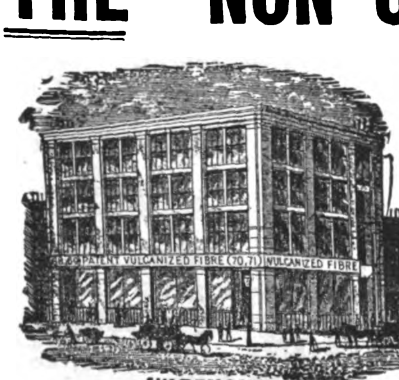
**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended March 27, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,431.

**SUBMARINE CABLES TRUST.**—It is notified that on and after the 15th inst. the coupon due in October last will be paid in full by Messrs. Glyn, Mills and Co., of Lombard-street, between the hours of 10 a.m. and 2 p.m. Certificate-holders are requested to present the coupons for October, 1890, only, and not those payable on April 15, 1891.

# THE NON-CONDUCTOR OF ELECTRICITY.

**VULCANISED FIBRE,**

PATENTED.



WAREHOUSE.

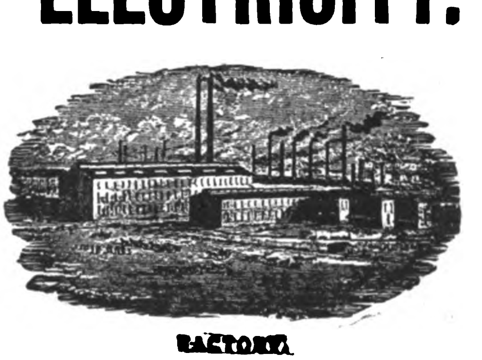
This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.



FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/8 per lb.

**MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.**

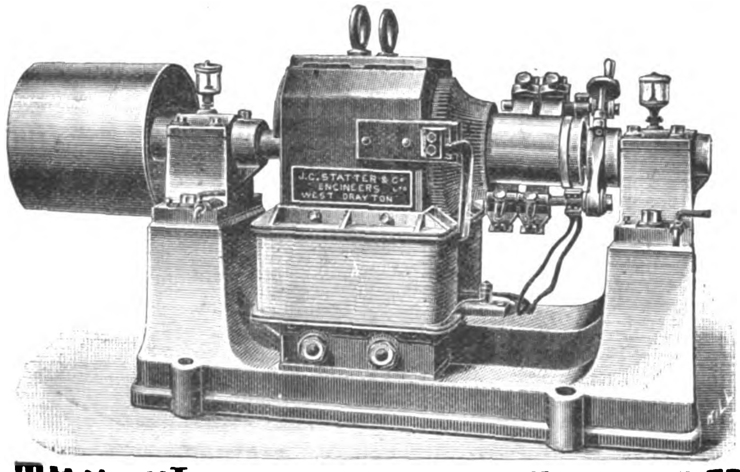
# IMPROVEMENTS IN DYNAMOS



## STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**
**MACHINES BUILT TO 500 KILOWATTS.**

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 673.—Vol. XXVI. FRIDAY, APRIL 10, 1891. Price Fourpence.

## NOTES.

With reference to our comments on the electric lighting of the British Museum in our last issue, we are glad to learn that there is ample power and plant to light the whole place, but only half is lighted on account of the expense of attendance. As it is, there are often more attendants and policemen than visitors. We were certainly under the impression that only sufficient plant had been provided for lighting half the galleries, and it was said, when the lighting was inaugurated, that there was no room for more. From the first evening there has been no attempt either to light the whole, or to enable the afternoon visitors to remain after dusk. If, instead of reopening the museum from eight till ten it were kept open continuously until two hours after dusk, we venture to think that a very considerable increase in the number of visitors would be found. It may be said that such a method would not meet the wants of a certain class, who can only get there between eight and ten in the evening. This may be so, but it has been proved that very unfortunately this class does not put in an appearance. The present arrangement is so very unusual that no argument can properly be drawn from the observed number of visitors.

Electrical engineers are justly proud of the modern dynamo as being one of the most efficient machines that has ever been produced, but they are none the less eager to introduce further improvements. Hitherto the electrical losses have been separated from the mechanical losses, and have been grouped into two classes, conductor losses and core losses. The former can be easily calculated from $C^2 R$, but the separation of the Foucault currents from hysteresis has been largely a matter of guess-work. In the present issue will be found two Papers, published simultaneously by request of the authors, and dealing with a very simple method of testing and analysing the core losses. We should be rather surprised if the curves turned out in practice to be straight lines, as assumed, and it is a pity that, after all, the mechanical friction enters so largely into the question. The method is so easy to carry out that we hope it will receive careful attention experimentally.

In a letter to the *Standard*, Mr. P. V. Luke, Director of the Construction Branch of the Indian Government Telegraph Department, suggests that as telegraphing without wires has been accomplished under certain circumstances, communication with our light-ships might be effected thus. He refers to the Paper by Mr. Melhuish (*Electrician*, Vol. XXIV., p. 597), and to Mr. Willoughby Smith's experiments at Eastbourne (*Electrician*, Vol. XXII., p. 56.) The idea certainly has some fascination about it, Mr. Preece succeeding in establishing communication across the Solent to the Isle of Wight, and telegraphed across the Severn without wires, merely using earthplates at a sufficient distance apart. But such methods are hardly practicable at present, and only serve to throw light on problems connected with cross-talk and the other disturbing influences.

The obvious way of communicating between a lightship or a lighthouse and the coast would be by flash signals, but a slight mist would effectually stop the beam of light, since mist is opaque to light. Why is it opaque? Partly because its particles are conductors of electricity, and partly because the frequency of the vibrations is high. The first reason cannot be avoided, and difficulties arise in attempting to get over the second. Hertz has shown how slower vibrations may be received and observed, but the wave length of such vibrations is at least a foot. Optical experiments with these radiations have to be carried out with huge prisms and reflectors, and even then the longest dimension of the apparatus being only a few wave lengths, all sorts of difficulties arise from diffraction and interference. These phenomena, though they puzzle microscopists, have not yet been investigated, for they only occur in ordinary optics when we use lenses and prisms of a few hundredths of a millimetre in diameter. But if we could reduce the frequency about 2,000 times, and produce vibrations of about two hundred thousand million per second, we should get waves about one millimetre long. These radiations would probably pierce not only a fog, but a brick wall. *When* we get such vibrations there will be many interesting uses for them. One, at all events, would be the possibility of communicating between lightships and the shore.

The inductive disturbances, which are so annoyingly common in telephony, are generally attributed to the electromotive forces induced in one circuit by the variation of current in the other; but it has been more than once suggested that the cross talk may be due to electrostatic and not electro-magnetic action. Mr. J. J. Carty has studied the phenomena from the latter point of view in a more thorough way than any other investigator. An account of his work will be found in *The Electrician* for December 6, 1889, and we print this week his further Paper read before the American Institute of Electrical Engineers. The experiments he describes are of great interest, and some of

Digitized by Google

them (notably that indicated in Fig. 9) are hard to explain, except on the theory he suggests. He seems, however, to have ignored the possibility of any disturbances being caused by electro-magnetic action. His wires are in general placed very close together—much closer than telephone wires are in practice—and though this no doubt increases the electrostatic action, it still more increases the mutual induction of the wires. His experiments, too, would have been more convincing if he had used metal sheets of suitable thickness, thus separating out the two effects, eliminating them in succession by screening.

THE subject of cross-talk is one of great importance and its explanation is still very obscure. If, Mr. CARTY's explanation is correct, it is remarkable that double metallic circuits yield such good results. The capacity of two wires is greatest when they are closely adjacent, as in a double circuit, and if cross talk is accounted for by the condenser action of wires placed at a considerable distance from each other, one would imagine that the condenser currents between the wires of a double metal circuit would be large enough to considerably distort the sounds transmitted, although, of course, no such injurious effect takes place. In connection with the electrostatic theory of cross-talk it is, however, worth noting that the capacity of two long thin wires is by no means negligible, even when their distance apart is very considerable. We calculate that the capacity of two parallel wires, whose distance apart is ten times their diameter, is 0·015 microfarads per mile. This may be increased to ten times this amount by bringing the wires near together till they are almost touching, but it cannot be very much diminished by separating them. In fact the capacity is more than one-quarter of this amount, even if the distance apart is 10,000 times the diameter; and as the alteration in distance makes such a small change in the capacity, it is probably unimportant that the wires should be straight and parallel, provided their distance from each other is considerable. These values seem too small to account for the disturbances except for sounds of very high frequency, but the fact that the capacity is not much diminished by increasing the distance of the wires is a point in favour of Mr. CARTY's experiments, and also tends to show that, if his explanation is correct, cross-talk may take place between telephonic circuits separated from each other by very great distances.

MR. PREECE, who has investigated this subject by numerous experiments carried out on a very large scale, has expressed a decided opinion that the origin of the disturbances is entirely electro-magnetic. His work, however, cannot be taken as deciding between the two theories. In fact, the possibility of detecting these disturbances at distances of several miles tends rather towards the conclusion that the electrostatic theory is the correct one; for, while electro-magnetic effects diminish inversely as the distance between the wires, the capacity effects are more nearly constant being inversely proportional to the logarithm of the distance. Mr. PREECE has calculated from some of his observations the smallest current which can be detected with the telephone, and in doing so has assumed that the disturbances are electro-magnetic. If this limiting current were calculated by some entirely different method, a comparison with Mr. PREECE's result would tend to show which of the theories is the correct one.

WE commented in a recent issue on some experiments by WIENER, who, by the skilful use of photography, succeeded in detecting the nodes and internodes in a wave of light rendered stationary by reflection from a metallic surface. These experiments have given rise to a very able controversy in the *Comptes Rendus* and the *Journal de Physique*. At first it was supposed that they completely confirmed FRESNEL's theory of light, according to which the direction of vibrations in a luminous ray is perpendicular to the plane of polarisation. It has, however, been pointed out by MM. POINCARÉ and POTIER that until something more is known as to the nature of photography, it is possible to interpret the experiments so as to conform either to FRESNEL's theory or to the rival theory of NEUMANN and MACCULLAGH, in which the luminous vibrations are supposed to occur in the plane of polarisation, and not perpendicular to it. In all kinds of waves, whether of sound, light, or electromagnetism, there are two kinds of disturbances taking place. In sound waves there are not only vibrational movements of the air, but also changes of pressure, and any undulatory disturbance is propagated in an elastic medium by means of both dilatations and rotational vibrations, the analogues of which in the electromagnetic theory are the displacement currents in the dielectric, and the magnetic changes. The energy of the wave is represented equally well by either kind of vibration, as the amplitudes are proportional; but the two disturbances do not increase and decrease together—in fact, one attains its greatest value when the other is least. The directions of these vibrations are perpendicular to each other, and it is impossible to determine the direction of either experimentally until it is known which kind of vibration affects the testing instrument. WIENER's experiments clearly demonstrate the interference effects caused by reflection, but do not afford a crucial test of the rival theories of FRESNEL and NEUMANN. They rather tend to show that these theories are complementary to one another. Each appears incomplete in itself, and the electro-magnetic theory reconciles them by binding them together.

A DECIDEDLY vigorous discussion sprang up in the House of Commons on Monday evening last, in connection with the vote of £1,900 for oil lamps used in the Houses of Parliament, the net result of which was a generally expressed opinion that if the annual oil bill could not be reduced it would be a good thing to extend the electric light throughout the building. Amongst the many instructive remarks made on this occasion was one by that champion of accuracy the senior member for Northampton, who was of opinion that the First Commissioner of Works would confer a public benefit if he would cause a record to be kept of the cost per hour of each electric lamp, many persons having found the present forms of the electric meter entirely incorrect. The indications of the average electric meter can certainly be relied upon to be true to within one or two per cent. Can as much be said for the statements of the average Member of Parliament?

Digitized by Google

**Aberdeen.**—The Town Council are about to advertise for a firm to undertake the electric lighting of the town.

**Royal Institution.**—The evening discourse on Friday next will be given by Prof. Rücker, and will be on "Magnetic Rocks."

**Basle.**—The canal for conveying the water required to drive the electrical plant for the Sissach Gelterkinden Electric Railway is now complete.

**Incandescent Lamp Litigation in France.**—The Société des Lampes Incandescentes Edison-Swan has commenced an action for infringement against the Société Khotinsky.

**African Cables.**—The Spanish Government is about to lay a cable from Bonny to Fernando Po. From the latter place a cable is to be laid by the German Government to Camerun.

**Institution of Civil Engineers.**—The annual dinner of this Institution was held on Wednesday evening in Merchant Taylors' Hall, Threadneedle-street. Upwards of 230 were present.

**Electric Lighting in Spain.**—The following towns in Spain have the electric light:—Valencia, 6,000 lamps; Gijon, 1,000; Albacete, 800; Cuenca, 700; Pampeluna, 550; Talavera, 400; Guadalajara, 70.

**St. Pancras Electrical Exhibition.**—This Exhibition, which has been open daily since March 14th, closed on April 1st. During the 14 days that the Exhibition was open over 14,000 people visited it.

**Brussels.**—It has been decided to construct a small circular electrical railway in the Bois de la Cambre. The scheme has been approved by Baron Jamblenne, who has worked out the technical details of the project.

**Physical Society.**—The Papers to be read before this Society next Friday are (1.) "On a Property of Magnetic Shunts," by Prof. Silvanus Thompson; (2.) "An Alternating Current Influence Machine," by Mr. Wimshurst.

**Recipe for a New Insulating Material.**—The *Revue Industrielle* gives the following:—Glove glue (*colle de gant*), 1,000 parts; resin oil, 100 parts; oxydised linseed oil, 500 parts; colophane, 150 parts; paraffin, 250 parts.

**Cannes.**—The water discharged from the Sianne Canal, at Cannes, France, is equivalent to 300 H.P. This power is about to be utilized for driving torbines, which will actuate dynamos for the supply of electric light and power in the town.

**National Telephone Electrical Society.** — On Wednesday, the 25th ult., Mr. C. A. Smith read a Paper before this Society on "Magneto and Dynamo Electric Generators." On Friday, the 3rd inst., Mr. W. A. Baxter, Chief Inspector, read a Paper on "The Bell Telephone."

**Electric Light for Coast Defence.**—Classes have been opened at the School of Military Engineering at Chatham for instructing officers and men of the Royal Artillery in the manipulation of the electric light and of electrical machinery. The first class has been taken from the Portsmouth garrison.

**The Ratio of the Centimetre to the Inch.**—The following very simple approximate ralation between centimetres and inches, viz., 33 to 13, was given in a recent letter to *Nature* by Dr. Oliver Lodge. This ratio should be useful for slide rule work. For ordinary arithmetical work we often use 4 to 1 + $1\frac{1}{2}$ per cent.

**Electric Launch Charging Stations on the Thames.**—We are informed that Messrs. Woodhouse and Rawson have arranged for the erection of a permanent charging station on the banks of the river at Chertsey, under the management of Mr. J. Taylor. The station is now in course of erection, and will be ready to undertake the charging of all sizes of electric launches by the beginning of the river season.

**Electric Funeral Trains.**—According to the *Western Electrician*, Pittsburg is soon to have electric funeral cars. The stockholders of the Suburban Rapid Transit Electric Railway Company decided at a recent meeting to place several cars at the disposal of funerals. There are seven cemeteries on the route traversed by the Company's system, and it is expected that the venture will be a great financial success.

**Gas and Electric Lighting in Rome.**—At the recent general meeting of the Società Anglo-Romana per l'Illuminazione di Roma col Gas e Altri Sistemi, it was declared that the total profits during 1890 amounted to £85,517. The electrical plant of this Company consists of four 600 H.P. dynamos and two 150 H.P. dynamos. The total number of lamps installed is equal to 33,000 eight c.p. lamps. There has been an increase equal to 12,000 eight c.p. lamps during the past year.

**The Naval Exhibition.**—A feature of this Exhibition will be a model of the Eddystone Lighthouse. The building will be in every way an exact reproduction of the new Eddystone Lighthouse itself. It is 167ft. 6in. in height; it is promised that the electric light on the top will be 5,000,000 c.p. This presumably refers to the illuminating power of a concentrated beam. But why not make the beam parallel? Then the candle-power would be infinitely great—on the photometer.

**Royal Society.**—The following Papers were read before the Royal Society yesterday: Sir William Thomson, P.R.S.: (1.) "On Electrostatic Screening by Gratings, Nets or Perforated Sheets of Conducting Material. (2.) "On Variational Electric and Magnetic Screening," Prof. Ayrton, F.R.S., and Dr. W. E. Sumpner, "The Measurement of the Power given by any Electric to any Circuit;" Prof. S. P. Thompson, "On Galvano-Hysteresis." Preliminary notice. Sir William Thomson's Papers will be found in another part of this issue.

**Brighton.**—At the meeting of the Town Council last week the Lighting Committee reported that they had received a letter from the Brighton and Hove Electric Lighting Company, proposing that the Corporation should treat for the purchase of the Company's undertaking. The committee recognised that the Company had some claim, and recommended a negotiation. This was deemed inexpedient by several members, and a negative amendment being submitted, a lengthened discussion ensued, but the report was ultimately adopted.

**Manchester.**—The Electric Lighting Sub-Committee of the Gas Committee of the Manchester Corporation have prepared a report with reference to electric lighting, to be presented at the next meeting of the Council. The Sub-Committee suggest that in the initial stages, with view to obviate mistakes as far as possible, the best professional and disinterested advice should be sought to draw up a complete scheme including the most efficient, modern, and economical appliances for the carrying out of the Corporation's Provisional Order.

**Rope Transmission.**—The two principal objections to the transmission of power by manilla rope have always been the inability of the rope to stand, for a long time, the effect of moisture, and the internal friction caused by passing over the sheaves. Both of these faults have, an American paper says, been greatly mitigated in the "Stevedore" transmission rope, which is laid up with tallow and plumbago with the twist of the rope, the tallow making it partially waterproof and the plumbago acting as a lubricant, and reducing the internal friction.

**The Copper Market.**—The deliveries of copper in England and France during March, although 1,500 tons less than in the corresponding month of 1890, exceeded the total supplies, the former being 9,962 tons and the latter 9,284. In the past twelve months the deliveries have exceeded the supplies by 33,585 tons. The stocks are now reduced to 58,353 tons, as compared with 91,938 tons a year ago, that amount being slightly under that of three years ago. The present price of copper at £53 per ton compares with £48. 15s. a year ago, and £39. 15s. two years ago.

**A Winter Thunderstorm.**—A somewhat remarkable storm occurred recently in the Cape Cod region. The area over which it was most severe comprised Cape Cod, the shores of Buzzard's Bay, Martha's Vineyard, and the eastern end of Long Island. A careful examination of the reported accidents by lightning in this district on the night of March 1st, shows that eight churches were struck, six houses, ten barns, one vessel at sea, one life-saving station, and one marine signal station. Strangely enough, there appears to have been no loss of human life, although five persons are reported to have been seriously injured. The storm occurred during a fall of snow.

**The Subway Question in Sheffield.**—The Works Sub-Committee of the Highways Committe of the Town Council recommend the early consideration of the subway question, in order that advantage may be taken of any opportunity offering for the construction of subways in the centre of the town. The Sub-committee believe that by accomodating the gas and water mains, together with telephone, telegraphic, and electric light wires, in connection with the sewers, great saving would result financially to the Corporation, whilst promoting the interests of all parties concerned.

**Electric Traction in Bremen.**—The Bremen Tramways Company has just decided to remove all its horse cars and to substitute electric cars. The Company has been induced to come to this decision on account of the good results obtained with the experimental line laid down last summer. It is intended to adopt the Thomson-Houston overhead wire system. The Imperial postal authorities objected to the use of the overhead conductor, owing to the interruption in the telephone service, but, notwithstanding this, the police authorities have already given their permission for the use of the system. The Senate is also prepared to give consent.

**Overhead Wires in Rochester, N.Y.**—The following statistics appeared in the report of the Brush Electric Light Company of Rochester, N.Y.:—

| | |
|---|---|
| Number of circuits | 29 |
| ,, miles overhead wires | 315 |
| ,, of arc lamps | 1,334 |
| ,, ,, motors | 549 |
| ,, ,, grounds during 1890 | 32 |
| ,, ,, times wires broken, 1890 | 3 |

It was only found necessary to shut down two circuits on account of grounds; the others were localised and repaired before the circuits were started.

**London-Paris Telephone Line.**—Experiments continue to be made in connection with this line. A few days ago London was placed in telephonic communication with Marseilles (a distance of more than 700 miles), and speaking was found to be possible, but far from good. The statement which has appeared in the daily papers to the effect that one can hear better at the London end than at the Paris end is, it is hardly necessary to say, without foundation. Any small disturbances to which the line is still liable are probably attributable to the method of running the wires on the French side, where a complete twist is effected every six posts instead of every four posts as with us, so that there is considerable want of symmetry.

**The Order of Railway Telegraphers.**—The Order of Railway Telegraphers is having a good deal of trouble of late, says the *Western Electrician*. The last difficulty promises to be serious. It is reported that the general manager of the Union Pacific has issued an order instructing the general superintendents to ask all the telegraph operators on their respective divisions to withdraw from the Order of Railway Telegraphers, and to discharge all who refuse. This order has been executed, and every operator on the entire system from the Missouri River to Portland, Ore., and from Denver to the Gulf, received a notice to withdraw from the Order or resign from the service of the Company. No reason was given for this demand, except that the Company did not wish the operators in its employment to belong to such an organisation.

**Cylinder Lubrication.**—It is well known that vegetable and animal oils are unsuitable for cylinder lubrication. In an article on the subject in the *Portfeuille Economique des Machines*, M. Recour states that when colza oil was used on the railway with which he was connected, it was necessary to burn out the deposit in the ports of the locomotive cylinders after the engine had run 18,000 miles. At the end of a year's service this deposit was from ·06in. to ·08in. thick on the piston faces, and from $\frac{1}{10}$in. to $\frac{1}{8}$in. thick on the covers and steam ports. In the exhaust ports the thickness of deposit was as much as ·27in. to ·35in. On analysis the deposits proved to consist of carbonaceous matter from the decomposition of the oil, and of the oxides of iron and copper due to the wear of the valve and cylinder surfaces. When tested in the laboratory at temperatures 212° Fahr. to 536° Fahr., it was found that colza oil first absorbed oxygen, then gave off hydrogen, and finally broke up into oleic and stearic acid with the separation of glycerine.

**Underground Telephone Wires in the City.**—At the last meeting of the City Commission of Sewers, a report was brought up from the Streets Committee on the application of the National Telephone Company to place a portion of their telephone cables beneath the public ways. The report recommended that permission should be given for the work, so far as the Company could arrange to do it, simultaneously with the electric lighting companies. A letter was read from the Brush Electrical Engineering Company pointing out the question of laying telephone cables in the same conduits with electric wires, was one which required the gravest consideration; and pending further investigations the Company hoped the Commission would defer a final decision on the subject. After some discussion, the matter was referred back to the Streets Committee to examine the report.

**Cable and Land Line Interruptions and Repairs.**—

| | Date of Interruption. | Date of repair. |
|---|---|---|
| | 1890. | 1891. |
| Jamaica Porto-Rico-St. Croix cable | Dec. 15 | March 2 |

**Proposed Lighting of Antwerp by Electricity.**—At the general meeting yesterday of the Antwerp Waterworks Company, the chairman, Mr. Charles Crew, referred to the negoitations which are pending for lighting the City of Antwerp by means of electricity. He stated that the town had been anxious for some time to have the city lighted by the electric light, but the Gas Company and their own Company had monopolies. They had both been approached by the parties interested, with whom conditional contracts had been entered into. It was proposed to obtain from this Company the hydraulic power which was required at the small local stations, the establishment of which was contemplated. The Gas Company, in consideration of an extension of their concession, had agreed to give up their monopoly so far as regarded the lighting of the city by electricity, and they themselves had agreed—while incurring no money risk or other responsibility—to their water being used for the purposes required for the payment of a royalty. There was a general desire at Antwerp for the electric light.

**Sir John Pender, K.C.M.G.**—During his recent visit to Constantinople, Sir John Pender was honoured with a private audience by the Sultan, by whom he was received with great cordiality. The Sultan expressed regret that, owing to ill-health, he had not been able to entertain Sir John as the head of the Submarine Telegraph System, but invited him to again visit Constantinople, when he would give a dinner in his honour. The Sultan further charged Sir John with kindly messages to many high personages in this country. At Athens Sir John entertained the King and Queen of Greece at lunch on board the Eastern Telegraph Company's cable steamer "Mirror." On his return journey, he visited Paris, and was decorated by the President of the French Republic with the Legion of Honour. Sir John's colleagues on the Board of the Eastern Telegraph Company have passed a resolution congratulating him on the honour bestowed upon him by the French Government, and thanking him on behalf of the shareholders for the valuable services he has rendered the Company by his visit to Egypt, Turkey, Greece, and Paris.

**City and South London Railway.**—At Lambeth Police Court, on Monday, the City and South London Railway Company were summoned by the London County Council for having, on or about March 6th, erected a certain structure beyond the general line of buildings at Stockwell without

Digitized by Google

the consent in writing of the Council. Mr. Burton appeared on behalf of the London County Council, and pointed out that the summons had reference to a zinc and wooden projection beyond the walls of the station, and beyond the proper building line. Mr. Hopkins observed that a similar case had been before him some time back. Mr. Burton said that was with regard to the line of frontage of stations and offices, and had been decided against the Company. The solicitor who appeared for the Company observed that this was a case exactly similar to that already heard, upon which a case had been granted for a superior Court. Mr. Hopkins agreed to adjourn the summons pending the decision of the superior Court. On Sunday last a regular service of trains was commenced between Stockwell and the City. Hitherto traffic has been carried on only on week days.

**Magnetic Phenomena in Central Russia.**—In a recent communication to the Académie des Sciences, General Alexis de Tillo calls attention to some remarkable local magnetic disturbances which occurred between the towns of Kharkov and Kourk. The area of disturbance is only about 22 miles from north to south by 15½ miles from east to west, and the following are the magnetic data for the principal centres of disturbance :—

| Village. | Declination. | Dip. | H. | Total intensity. |
|---|---|---|---|---|
| Nepchaevo | +48° west | +81 | 0·11 | 0·84 |
| Visloje | −33° east | +52 | 0·40 | 0·65 |
| Kisselevo | −38° east | +63 | 0·33 | 0·72 |
| Sobinino | +30° west | +60 | 0·38 | 0·75 |
| Petropaoloko | −20° east | +76 | 0·19 | 0·80 |

The greatest distance between the above-mentioned localities is not more than eight miles, and yet the declination varies by 86deg. and the dip by 29deg. The normal values for this district are :—Declination, 1° east ; dip + 64° ; H 0·21 ; total intensity, 0·48. So far as the geological constitution of the soil is known, it gives no clue to the cause of the disturbance.

**The Tudor Accumulator.**—The Tudor accumulator has attained considerable vogue in Belgium, especially in connection with central station work, as the following figures will show. The commune of Dolhain (Limburg) possesses a central lighting station which supplies current to 1,300 lamps, and it is provided with three batteries of 240 ampere-hour Tudor cells. The Compagnie Franco-Belge pour l'Eclairage Public par l'Electricité has four central stations in operation, and employs Tudor accumulators in all of them. The station in the Rue Montagne (Brussels), which has some 1,000 8 c.p. lamps and several arcs connected, possesses a battery of Tudor cells of 750 ampere-hours' capacity, and the station in the Passage du Nord (Brussels) is provided with two batteries of 756 ampere-hour cells. The Gand station has a battery of 590 ampere-hours' capacity; and, finally, the Ninove station has a 756 ampere-hour battery. The battery at the Passage du Nord was recently exposed to very severe test. The boilers at this station are below the level of the roadway, and during the recent thaw the boiler-house was flooded, and for four and twenty hours no steam could be generated. The batteries consequently had to bear the full brunt of the load, and according to the registering ammeter curve 1,780 ampere-hours were taken out of them, or 17·6 per cent. more than their normal capacity.

**Telegraph Extension under Difficulties.** — The *Pekin Gazette* contains a memorial from the Viceroy of Yunnan, reporting that the line of telegraph communication in Yunnan has been extended to Momein, on the borders of Burmah. The task of making the preliminary surveys was entrusted to a Chinese official, aided by a foreign artisan. The task of surveying the route and procuring the supply of poles occupied from March, 1888, to February 23, 1889. The construction of the line was commenced on the latter date and was completed on May 30th following. The distance from Yunnan Fu to Momein is 530 miles, and the route lies through a mountainous and densely-wooded country, where frequently no trace of habitation occurs for over 30 miles. The Mekong, the Salween, and the Shweilei rivers had all to be crossed in fever-stricken localities. The passage of the Salween, in particular, is attended with horror. Its waters are muddy and turbulent, and so deadly that the feet of men and hoofs of horses are said to rot and drop off from contact with them. The officers and men of the expedition crossed the river on rafts, and only reached the opposite bank after a very hard struggle. The season being summer, the malaria was at its worst, and no fewer than ten members of the party succumbed to its effects during the three days occupied in carrying the telegraph line across the river. The difficulties connected with the construction of this extension line have been far greater than any experienced in first introducing the telegraph system into Yunnan, and it is asked that the officers engaged on the work may receive rewards on the same scale as is accorded for the safe transmission of urgent messages from the field of battle.

**An Alternate-Current Electric Mining Plant.**—About a year ago the Gold King Milling and Mining Company, which owns a group of mines at Telluride (Col.), decided to instal an electric plant to work its machinery. The Gold King Mill is at an elevation of 11,000 feet above the sea, and 3,000 feet above the San Miguel Valley. Close by a branch of the San Miguel River falls 500 feet in a distance of less than a mile, and even at the season of lowest supply can furnish about 2,000 H.P. A contract was entered into with the Westinghouse Company to supply the necessary plant. A dam was erected, and from the headgate the water is conducted through an iron pipe 4,000 feet long to the power station. Here the stream is divided, and the water is delivered to two six-foot Pelton water-wheels. The ultimate capacity of 800 H.P. in the generators is provided for. The motor-station is two and a-half miles from the generators. The generator employed is a Westinghouse self-exciting incandescent alternator, motor and generator being alike, except in some minor details. It was determined to use an E.M.F. of 3,000 volts. The conductor is a No. 3 B. and S., bare copper wire, erected on poles. The loss in transmission is barely 5 per cent. The starting device employed is a two-wire 10 H.P. Tesla alternating motor. This is used simply and solely for bringing the large motor up to synchronism, when it is cut out until again required. The large motor is self-exciting, and takes care of itself easily enough after it is once brought up to speed. It is altogether probable, says the *Electrical World*, that other mines in the vicinity will shortly receive a similar equipment, as the region is one where fuel is none too easily obtained, and water power can be had almost for the asking.

**Institution of Electrical Engineers' Benevolent Fund.**—The Council of the Institution of Electrical Engineers believe that, although happily the necessity does not now exist, a time will inevitably arrive when a benevolent fund in connection with the Institution will be found most desirable for the assistance of necessitous members and their families, or the families of deceased members ; and they consider that the formation of such a fund should be commenced at once, while the Institution is yet comparatively young. The fund will be called the "Benevolent Fund of the Institution of Electrical Engineers," and it is proposed that it be managed and administered on lines similar to those which govern the Benevolent Fund of the Institution of Civil Engineers, which has been the means of effecting a vast amount of good, and one of the chief features of which is that the names of the recipients of any grants from the fund are not published. The members of last year's and this year's Council have among themselves already subscribed an amount of £224. 5s., and they trust that all members will assist in the establishment of the fund, not only by personally subscribing, but by using their influence to obtain subscriptions and donations from such of their friends as take an interest in the institution or in the profession which it represents. It is hoped that even the youngest members will give their support to the fund by a contribution, however small in amount. It is requested that all subscriptions or donations to the fund may be forwarded to the secretary of the Institution, and, in order to avoid confusion, that the ordinary subscriptions to the Institution be *not* included in the same remittance. A member of the Council will subscribe £52. 10s. if, before the end of the year, nine other members will each give a like sum

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 664.*)

§ 54. Compare two generating stations, one supplying through "closed," the other through "open" transformers. For each 10 H.P. converter on the circuits, the "closed" system will have to supply two amperes as load plus ·11 for exciting during the assumed six hours of heavy load, while during the daytime probably ·5 ampere for load plus the exciting current will be required, so that the ratio of heavy load to light load is about $\frac{\cdot 61}{2 \cdot 11} = \cdot 29$, and this is nearly enough the ratio of the plant in use. Under the same conditions the heaviest output of the "open transformer" station will be two amperes useful load plus ·9 ampere exciting current, and ·5 plus ·9 ampere on the light load, a ratio of $\frac{1 \cdot 4}{2 \cdot 9} = \cdot 48$, so that the closed system will run 29 per cent. of its plant during light load, as against 48 per cent. with open transformers. Recollect, that this does not mean 29 and 48 per cent. of the *power*—the open circuit transformers will be wasting less than half the power lost in the cores of their closed rivals. What it does mean is, that the current capacity of the alternators at light load must be 29 and 48 per cent. of heavy load for the closed and open systems respectively, so that the latter system will necessitate the running of large engines and dynamos during 16 or 20 hours a day at a fraction of their normal load, and therefore giving a very low all-round efficiency. In short, the coal wasted in running engines at a small load will cut down the saving effected in the open transformers, leaving only a balance, and that balance not by any means necessarily on the right side. This is a point on which there is really no evidence one way or another; no accurate analysis of alternate-current station running expenses having yet been published.

§ 55. It may be taken for granted that a station supplying through open transformers would be seriously hampered by the large idle current for exciting, just as many—perhaps all—closed transformer systems are now saddled with the inordinate waste of power in the cores. Station managers were once told that they need take no notice of the primary current on light load, it had a lag of ever so many degrees so it meant nothing at all practically as power; but at least one manager knew and had the courage to declare that the coal bill told a very different tale, that the product of volts and amperes hardly required multiplying by the cosine of the lag to make it tally with the coal consumption. We know definitely now what was only vaguely suspected a few years ago, we know what all the power went for: core hysteresis and eddy currents. We have learnt how to eliminate the latter by reducing the thickness of the core plates, their width is of insignificant importance. It would be rash to say that we can never hope to save the entire waste due to hysteresis, but it appears at present to be impossible to do so, except by throwing away the whole of the iron core. And when that is either wholly or partially done, a new difficulty and new loss arises in the shape of idle current. But, while it may be really impossible to produce changing induction in iron without hysteresis loss, it is certainly quite possible to produce large idle currents without using large alternators, so that there is still some hope of our ultimately being independent of hysteresis. The ground for that hope will be seen in a future article.

§ 56. By this time the sceptical reader is probably looking for some justification of the views of transformer phenomena advanced in these Papers. He wants to know what reasons can be given for preferring these vaunted practical notions to the old and complex analytical explanations of the phantom. Granted that the phantom has no relation to the real, have the transformers discussed here any resemblance to reality? Do those indicator diagrams represent facts? These are pertinent questions, and it is necessary to devote some space to their satisfaction. It should first of all be clearly understood that the analytical method must always fail to represent facts when iron forms the whole or any part of the magnetic medium in a transformer. Starting with the perfectly legitimate assumption of a sine E.M.F., analysis can only tell us what the value of the exciting current is when there is no hysteresis; for the attempt to find C necessitates the further assumption that B is expressible as a function of H, and therefore C, in order that terms involving rate of change of induction may be simplified into terms involving rate of change of current, by which means the necessary relation between E and C can be expressed. But It is known that the fundamental law of magnetisation of iron, nickel, and cobalt (the magnetic metals) is now, and is likely to remain for a long time to come, a dark mystery; thanks to Dr. Hopkinson and Prof. Ewing we are beginning to see a faint glimmer, but hardly more than enough to enable us to perceive the almost hopeless clumsiness of our modes of thought, when we are dealing with the ultimate construction of matter. For the present then it is mere waste of time—a darkening of counsel, to deal with an iron-cored transformer as though its coils had specifiable constant co-efficients of self and mutual induction.

§ 57. The diagram method involves no assumption as to the relation of B to C. Starting for example, with the assumption of a sine E.M.F. (an almost necessary assumption for analytical treatment, but not so for diagrams—only convenient), it is next assumed (but only for the moment) that the counter E, due to changing induction in the core, is also sinoidal; it follows that the induction itself must vary according to a sine law. The result of previous experiment on the magnetic properties of the iron core, enables the proper value for the existing current to be determined for each instant during the period. Now it is clear that if the primary coil had no resistance, the exciting current would require no electromotive force to maintain it, and the counter and impressed E.M.F.'s would be exactly equal and opposite at every instant. But the primary coil has a finite though small resistance, and this means that in addition to an impressed E.M.F. to balance the counter E.M.F., there must be just sufficient force to maintain the exciting current; an amount easily calculated by multiplying each instantaneous value of the current by the resistance of the primary coil. When all these values are added in their right order to the component E.M.F.'s balancing the counter E.M.F.'s, the result is a wave of total E.M.F., which, if applied at the primary terminals, would produce the exciting current and induction waves given by the diagram. This E.M.F. wave is not really a pure sine function; as has already been noticed, the C R part of the E is necessarily of the same shape as the current wave. Commercial transformers being made to carry the whole load current with a very small loss of volts over resistance, the value of C R for the exciting current, which in a closed transformer is a very small fraction of the full load current, becomes vanishingly small when compared with the counter E.M.F. wave. Consequently indicator diagrams represent very closely indeed the actual behaviour of real transformers.

§ 58. It must not be supposed for a moment that the construction of "no load" diagrams is impossible under some conditions—they may be useless, but they can be drawn for every condition. To take an extreme case, imagine No. 2 as a closed transformer had a primary coil of 2,240 turns as before, but instead of 1·4 per cent. drop at full load due to its resistance, let it have a drop of 20 per cent. This requires the resistance to be about 107 ohms, and since the maximum value of the exciting current is ·162 ampere, the maximum value of C R to maintain it is only 17·3 volts, so that even with an enormous full load drop, the shape of the impressed E.M.F. wave would hardly differ appreciably from that of the counter E.M.F. We do not assert that a given E.M.F. wave produces exactly specifiable current and induction waves, but given a counter E.M.F. wave (of any shape whatever) first the induction, then the exciting current, then C R, and finally the requisite E.M.F. wave may be found by drawing the diagram. It may be that the E.M.F. wave so found is one which no alternator produces, but it is absolutely certain that given a suitable alternator, the transformer would run according to the diagram. When the E.M.F. wave is very nearly the same shape as the counter

Digitized by Google

E.M.F. wave—a condition fulfilled with abundant accuracy by all commercial transformers—we may, if we please, begin by choosing a known wave form from some real alternator; then by drawing the counter E of the same form we can find the induction wave necessary to make such a counter wave. That is really the only difficult step in the progress from impressed **E** to exciting current. We have to find the integral of the counter E in order to plot **B**, and this is a tedious process unless E can be expressed by an integrable formula, for it is necessary to measure the area of the E curve from zero up to half a dozen or more equidistant epochs during a half period, and use the values of the areas as the ordinates of the induction wave. The writer hopes to deal with such non-analytical diagrams, as they may be called, in a future series of papers, where also the construction of diagrams for various loads on a transformer will be described. For the purpose of the present articles the "no load" diagrams give a sufficiently clear notion of the relation between exciting current induction and waste power.

§ **59.** We have now, we hope, dispelled any suspicion that the diagrams involve a fallacy. Just where analytical treatment breaks down, the method of diagrams gives us what is wanted; it appeals to experiment for the relation between **B** and **H**; and the only error introduced is vanishingly small in the case of all real transformers. But although the diagrams may bring us to a perfectly logical conclusion on the assumed basis of fact, how if some phenomena of vital importance

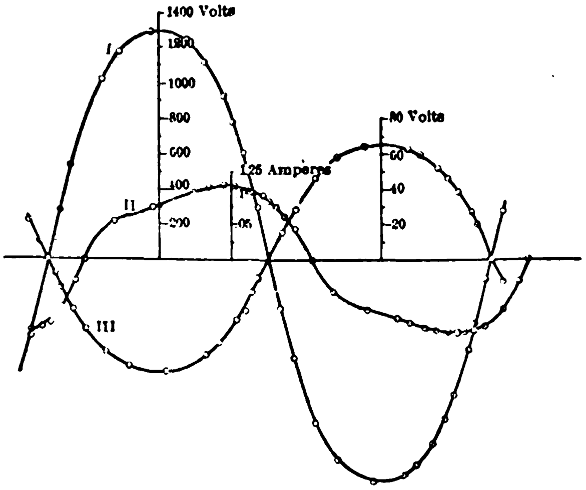

FIG. 17.—Humphrey and Powell's Curves of 40-light Transformer on Open Circuit. I., Primary volts. II., Primary current. III., Secondary volts.

have been neglected? What if the supposed viscous hysteresis is a fact? What if it is possible to carry iron through cyclic changes in induction without loss of energy; finally, suppose it is not necessary for the production of E.M.F. in the coils of a transformer that there should be any changing induction linked with them. These horrible suggestions are the result of certain recent experimental determinations of the losses in transformer cores made independently, and by different methods, by Mr. Mordey and Prof. Ayrton. It may as well be admitted at once, that if their results are confirmed, the diagram must be based on the new facts and those given in these Papers will require revision. The case for and against open magnetic circuits would not be materially affected if these new phenomena became recognised as substantial facts. Viscous hysteresis could only lead to a greater waste in the core than that assumed in these Papers, so that the arguments for the open circuit would be strengthened. The effect which seems to point to diminution of energy waste in the iron, only occurs as the load on the transformer is increased, so that there can be but little advantage here for a transformer running practically unloaded for 16 or 20 hours a day; what little gain there might be is only of slightly more importance to the closed than the open transformer.

§ **60.** Those who are inclined to accept the alleged phenomena alluded to in the last paragraph, will do well to remember that other experimenters besides those mentioned, have been working at the same problem and have arrived at totally different results. While we in England are trying to force L, M, $\frac{dc}{dt}$, and cos $\theta$ on an unwilling transformer, the American electricians are patiently and steadily adding to our knowledge of the real transformer by a direct appeal, not to Fourier's theorem, not to empirics, not to their imagination, but to Nature. The work done by Prof. Ryan and by various students at

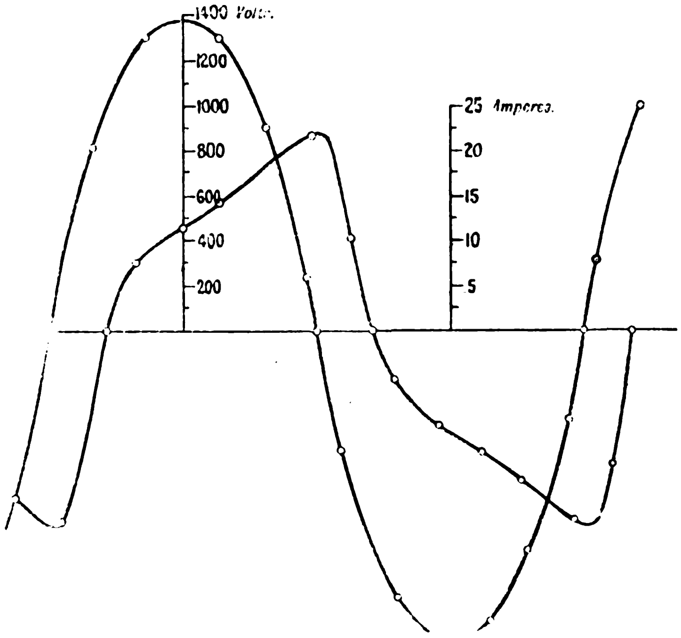

FIG. 18.—Humphrey and Powell's Curves of 10-light Transformer.

the Cornell University, answers in the clearest manner some of the vexed questions respecting hysteresis and eddy currents. Prof. Ryan's method consists, shortly, in running a real live transformer under all sorts of conditions, and ascertaining the shapes and relations of the primary and secondary E and C waves by means of a revolving contact, which enables him to obtain the simultaneous values of E and C at any desired epochs during a whole period. He thus obtains an indicator

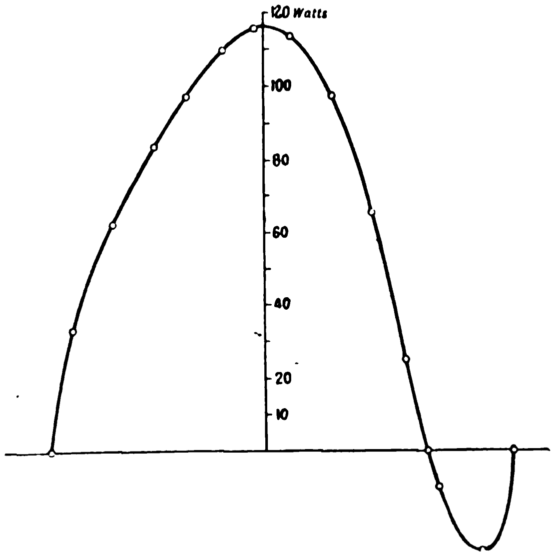

FIG. 19.—Humphrey and Powell's Curve of watts wasted on Open Circuit by 40-light Transformer.

diagram by observation, which stands in the same relation to the predicted diagrams given in these Papers, as an indicator card taken from an engine cylinder in actual work, does to a diagram which might be predicted from the laws of heat. Several diagrams taken by Ryan's method from closed transformers are given by Messrs. Humphrey and Powell, in a Paper read before the American Institution of Electrical Engineers, and published in the journal of that Institution, Vol. VII., No. 10. In Fig. 17 we reproduce the "no

Digitized by Google

load" diagram for a 40-light transformer. It will be noticed that the exciting current, although following roughly the course we have predicted, differs in having its sharper corners rounded off to a large extent, so much so that the maximum value does not occur at the epoch when $E = 0$, as of course it should do if eddy currents are small. Turning back to Fig. 10, it will be readily understood that any large increase in the Y component will tend to displace the maximum value of $X + Y$, and lead to a curve more closely resembling that found by Humphrey and Powell. Another diagram is given in Fig. 18, taken from a 10-light transformer in which the induction density was far too high. Notice the increased sharpness of the turning-points, and the sudden drop from maximum current to zero—precisely the results we should expect. The power wasted at no-load in the 40-lighter is shown in Fig. 19, which is taken from the same Paper. This curve includes $C^2R$ loss in addition to the core waste.

(*To be continued.*)

## ON ELECTROSTATIC SCREENING BY GRATINGS, NETS, OR PERFORATED SHEETS OF CONDUCTING MATERIAL.*

BY SIR WILLIAM THOMSON, D.C.L., P.R.S.

### 1. *Grating.*

§ 1. Maxwell, in his "Theory of a Grating of Parallel Wires" ('Electricity and Magnetism,' Arts. 203-205,† and Plate XIII.), gives a very valuable and interesting two-dimensional investigation of electrostatic screening, and a most instructive diagram of "Lines of Force near a Grating," which powerfully helps to understand and extend the theory, and to acquit it of an accusation wrongly made against it in the last two sentences of Art. 205. It is only on the supposition of the grate-bars being circular cylinders that the investigation is less than rigorous; and that supposition nowhere enters into the investigation; it merely appears in the word "radius," in the first line of the last sentence but one of Art. 204, and it is contradicted in lines 3 and 4, and by the rest of the sentence, and by the next sentence. (*See* § 6 below.)

§ 2. The conclusion, "$\alpha = -0{\cdot}11a$," in the last sentence of Art. 205, condemned as "evidently erroneous," is quite correct, and very interesting. It shows that a corrugated metal plate agreeing with the equipotential surface $c = \frac{1}{2}a$, exceeds in electrostatic capacity a plane metal surface through the poles of the diagram (Plate XIII.), with the surroundings described in Art. 204, and supplies the datum requisite for finding the exact amount of the excess. The reason for the greatness of the excess clearly is that the surface $c = \frac{1}{2}a$, which just touches the plane through the poles of the diagram midway between the poles, is everywhere nearer than this plane to the other plate of the condenser (*see* § 7 below).

§ 3. For $c = a/6$ we have, by (11) of Art. 205, $\alpha = 0$, and the corresponding equipotential, partially shown* in Maxwell's diagram, is a set of curves concave towards $z = -\infty$, and asymptotic to the lines $x = (i \pm \frac{1}{4})a$, $i$ denoting any integer. (See §§ 10 to 13 below.) For every value of $c$ less than $a/6$, the equipotential is a row of ovals; and the grating formed by constructing these ovals in metal has less electrostatic capacity in the circumstances described in Art. 205 than a plane through the poles or the ovals (this being no doubt what is meant by "a plane . . . in the same position" as the grating).

§ 4. For every value of $c$ exceeding $a/6$ the equipotential, instead of being the boundary of a grating, is a continuous corrugated surface, and its electrostatic capacity exceeds that of the plane through the poles.

§ 5. Begin now afresh, and let it be required to find the electric force in the air on either side of an infinite row of parallel bars at equal consecutive distances, $a$, each uniformly charged with electricity. Let $\rho a$ be the quantity per unit length on each bar, so that $\rho$ would be the surface density, if the same quantity were uniformly distributed over the plane of the bars. Taking O in one of the bars, O X perpendicular to the bars, and O Z perpendicular to their plane, we find (by Fourier's method) for the $z$-component of force at any point $(x, z)$ for which $z$ is positive,

$$Z = \frac{4\pi\rho}{a}\left(\tfrac{1}{2} + \epsilon^{-mz}\cos mz + \epsilon^{-mz}\cos 2mz + \&c.\right) \quad . \quad (1)$$

where

$$m = 2\pi/a \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

Summing this we find

$$Z = \frac{2\pi\rho}{a}\,\frac{\epsilon^{mz} - \epsilon^{-mz}}{\epsilon^{mz} - 2\cos mx + \epsilon^{-mz}} \quad . \quad . \quad . \quad (3).$$

This has equal positive and negative values for equal positive and negative values of $z$, and it therefore gives the value of the $z$-force, not only for positive, but also for negative, values of $z$. Taking now $-\int Z dz$, with constant assigned to make the integral zero for $z = \pm D$, we find

$$V = \rho a\left(\log\frac{1}{\epsilon^{mz} - 2\cos mx + \epsilon^{mz}} + mD\right) . \quad (4)$$

as the potential due to the grating, and two parallel planes at equal distances, D, on its two sides, each uniformly electrified with half the quantity of electricity of opposite sign to that on the grating.

§ 6. If we now construct in metal, C, any one complete equipotential surface, $V_0$, of this system, and electrify it with the same quantity of electricity as that which we gave originally to the infinite row of infinitely thin bars; and if we place metal planes, B, B', at the two places of zero-potential ($z = \pm D$), we have an insulated conductor, at potential $V_0$, between two planes, B, B', at zero potential, and at distance 2D asunder, on each of which the electric density is $\frac{1}{2}\rho$. For brevity I shall denote the insulated conductor by I.

Its electrostatic capacity per unit area of its medial plane (the plane of the original infinitely thin bars) is $\rho/V_0$.

§ 7. This conductor, I, is symmetrical on each side of its medial plane, and consists either of an infinite number of isolated parallel bars, each surrounding one of the original infinitely thin bars, or of a plate symmetrically corrugated on its two sides, with maximum and minimum thicknesses respectively at the places of the infinitely thin bars, and the lines midway between them. For the case of isolated bars, let $2c$ be the diameter of each, in the medial plane. Then, to find $V_0$, we must put $x = \pm c$ and $z = 0$, in (4). Thus we find

$$V_0 = 2\pi\rho\left(\frac{a}{2\pi}\log\frac{1}{4\sin^2\frac{\pi c}{a}} + D\right) \quad . \quad (5).$$

Hence the electrostatic capacity of I in the circumstances is

$$1\left\{2\pi\left(D + \frac{a}{2\pi}\log\frac{1}{4\sin^2\frac{\pi c}{a}}\right)\right\} . \quad . \quad . (6)$$

which is greater or less than $1 (2\pi D)$, the electrostatic capacity that it would have if reduced to its medial plane, according as $c >$ or $< \frac{1}{6}a$ (compare § 5 above). The conductor I, to be a grating, implies $\sin^2\frac{\pi c}{a} < 1$, and therefore requires that

$$V_0 > 2\pi\rho\left(\frac{a}{2\pi}\log 4\right) = 2\pi\rho\,(D - {\cdot}22a) \quad . \quad (7).$$

When $V_0$ exceeds this critical value, the conductor I is the continuous plate corrugated on each side, which was described in § 7. The critical value corresponds to an immediate case of a plate so deeply furrowed on each side as to be just cut through by its two surfaces crossing at right angles; and (7) shows that the electrostatic capacity of the conductor I so constituted is equal to that of a plane sheet of thickness,

$$2a\log[2^2]/(2\pi), \text{ or } {\cdot}44a \quad . \quad . \quad . \quad . \quad (8),$$

* Paper read before the Royal Society, April 9, 1891.

Digitized by Google

insulated midway between the two earth plates B, B′, at the same distance asunder as they had with I between them.

§ 8. By (4), (5), and (7), we have for the equation of the surface constituting the two sides of I in this critical case,

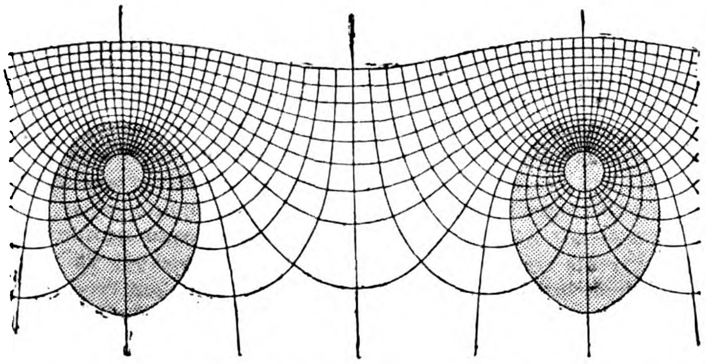
$$\epsilon^{-mz} - 2\cos mx + \epsilon^{-mz} = \log 4 \quad . \quad . \quad . \quad . \quad (9).$$

Taking double the positive value of $z$ which this gives when $x = 0$, we find

$$2a \log [(1+\surd 2)^2]/(2\pi), \text{ or } \cdot 562a \quad . \quad . \quad . \quad . \quad (10)$$

as the maximum thickness of I. This is $(1+\surd 2)/2$, or 1·28 times the amount shown in (8) for the thickness of plane-sided plate of equal electrostatic capacity; which is just such a relation as is expected before calculation!

§ 9. If $\phi(z, x)$ denote what V becomes when in place of $m$D we substitute $-mz$ in (4), we have the potential due to a uniform electrical force $\rho am$, or $2\pi\rho$, added to the $z$-component, of the force due to the grating with its given charge of $\rho a$ quantity per unit length of each bar; and it is the equipotentials and lines of force of this system that are represented in Maxwell's diagram of Plate XIII., reproduced here. In it the



resultant force for infinitely large positive values of $z$ is parallel to O Z, and of constant value $4\pi\rho$; and it is zero for infinitely large negative values of $z$. The approximation to these values is very close, at only so moderate a distance as $a$ on either side of the grating.

§ 10. Choosing, in the system of § 6, any one of the multiple-oval equipotentials around the infinitely thin bars, that indicated by the shading, for example, which I have added to Maxwell's diagram, let $c$ be the distance from the infinitely thin primary bar within it, at which it is cut by the plane of the primary bars. By putting in the expression for $\phi(z, x)$, $z = 0$, and $x = c$, we find

$$\phi(0, c) = \rho a \log \frac{1}{4\sin^2 \frac{\pi c}{a}} \quad . \quad . \quad . \quad (11)$$

as the potential at the surface of each of these chosen ovals. Construct now each of these ovals in metal, and let the supposed uniform force, $2\pi\rho$, be produced by uniform electrification of density $-\rho$, on a metal plane, B, at any great distance, $b$, on the positive side of the grating. We thus construct a grating of thick bars of oval-shaped cross section which, when electrified with the same quantity of electricity as that which we gave initially to the infinitely thin bars, and subjected to the influence of the equal quantity of negative electricity on B, has $\phi(z, x)$ for potential through external space from B ($z = b$), to infinite distance on the other side of the grating ($z = -\infty$), and has for potential through all the portions of space within the surfaces of the grate-bars the constant value expressed by (11). In this system the potential, for positive values of $z$ great in comparison with $a$, is, by (4) with $-mz$ instead of $-m$D,

$$\phi(z, x) \doteqdot -4\pi\rho z \quad . \quad . \quad . \quad . \quad (12).$$

The difference of potentials between B and the grating is, by (6) and (5),

$$\phi(0,c) - \phi(b,x) \doteqdot 4\pi\rho\left(b + \frac{a}{4\pi}\log\frac{1}{4\sin^2\frac{\pi c}{a}}\right) \quad . \quad . \quad (13).$$

Hence the electrostatic capacity of the mutually insulated system, B, and the grating of oval-shaped bars is equal to the capacity of a pair of parallel planes, B and a plane at a distance beyond the plane of the primitive infinitely thin bars equal to

$$\frac{a}{4\pi}\log\frac{1}{4\sin^2\frac{\pi c}{a}} \quad . \quad . \quad . \quad (14).$$

§ 11. If in (4) we put $-nz$ in place of $m$D, we have the potential of a system in which, besides the electricity of the primary bars there is distant electricity such as all in all to give at great enough distances on the two sides of the primitive bars uniform fields of $z$-force respectively equal to

$$\rho(m+n), \text{ for } z \doteqdot +\infty \text{ ; and } \rho(m-n), \text{ for } z \doteqdot -\infty \quad . \quad (15).$$

If, in (4) with $-nz$ instead of $+m$D, we put

$$\epsilon^{-V/\rho a} = C \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (16),$$

we find, as the equation of the equipotential surfaces,

$$-2\cos mx + \epsilon^{mz} + \epsilon^{-mz} = C\epsilon^{-nz} \quad . \quad . \quad . \quad (17).$$

By taking $n = 0$, or $n = m$, we fall back on the cases of §§ 5—8, and §§ 9, 10, respectively.

§ 12. To find an approximate equation for the equipotentials at distances around primitive bars small in comparison with $a$, the distance from bar to bar, let $x$ and $z$ be so small that we may neglect all powers of $mx$, $mz$, and $nz$, above the square, which implies that C is small of the same order as $(mx)^2$ and $(mz)^2$, (11) becomes

$$\left\{ \begin{array}{l} x^2 + \left(\dfrac{z + \frac{1}{2}nr^2}{1 + \frac{1}{4}n^2r^2}\right)^2 = r^2 \\ \text{where } r^2 \text{ denotes } m^{-2}\,C \end{array} \right\} \quad . \quad . \quad . \quad (18).$$

This shows that, to the degree of approximation in which we neglect cubes and higher powers of $mx$, $mz$, $nz$, the equipotential is a row of elliptic cylinders of eccentricity $\frac{1}{2}nr$, with the primitive bars for one set of their foci and their greater diametral planes perpendicular to the plane of the primitive bars. When $n = 0$, the equipotential is a row of circular cylinders having the primitive bars for their axes; and this is true to the higher approximation, in which we need only neglect powers above the cubes of $mx$ and $mz$, as we see by going back to equation (17), with $n = 0$.

§ 13. The conclusions of § 12 are useful for detailed investigation of the screening effect of plane gratings of circular or elliptic, straight parallel bars electrified with given quantities of electricity and placed with their planes perpendicular to the lines of force in a uniform field of force, and to corresponding problems in which potentials are given, as in Maxwell's §§ 203—205.

§ 14. Instead of a single row of parallel equidistant infinitely thin bars in one plane, let us take for primitives or foci, as we may call them, two or more such rows, parallel or not parallel, all in one plane or not in one plane. We may thus form an endless variety of force systems available for illustrating or helping to solve problems which may occur. Towards the several problems of electric screening we find important contributions by considering in two parallel planes rows of focal lines parallel to one another for one case and perpendicular to one another for another case. The consideration of three rows of focal lines in one plane, dividing it into equal and similar triangles alternately oriental in opposite directions, leads to a complete theory of electrostatic screening by a triangular lattice of metallic wire or ribbon. The fundamental potential formula for this system obtained by summation of expressions given each by an application of (4), to one of the three rows, is

$$V = \log \frac{1}{(\epsilon^{lz} - 2\cos lp + \epsilon^{-lz})^{\omega a}(\epsilon^{mz} - 2\cos mq + \epsilon^{-mz})^{\rho b}(\epsilon^{nz} - 2\cos nr + \epsilon^{-nz})^{\sigma c}} + 2\pi(\omega + \rho + \sigma)D \quad . \quad . \quad (19),$$

where $a$, $b$, $c$ denote the intervals between the successive lines of the three systems, $\omega a$, $\rho b$, $\sigma c$, the quantities of electricity per unit length of bar in the three systems; $p$, $q$, $r$, $z$, special

Digitized by Google

co-ordinates of the point for which (19) expresses the potential, viz., $z$, its distance from the plane of the focal bars, and $p$, $q$, $r$ its distances from three planes drawn perpendicular to this plane through a bar of each of the three systems; D the value of $z$ for a plane for which the potential is zero, and, lastly,

$$l = 2\pi/a,\ m = 2\pi/b,\ n = 2\pi/c \quad . \quad . \quad . \quad . \quad (20).$$

For the present, however, we may confine ourselves to the case of two rows of focal lines dividing a plane into squares and charged, both rows, with equal quantities, $\rho$, of electricity per unit length. The potential formula, a particular case of (19), is

$$V = \rho a \left[ \log \frac{1}{(\epsilon^{mz} - 2\cos m x + \epsilon^{-mz})(\epsilon^{mz} - 2\cos m y + \epsilon^{-mz})} + 2 m D \right] (21).$$

§ 15. The consideration of the equipotentials of this surface is very interesting. The equipotential lines in the plane of the focal bars given by the equation

$$16 \left( \sin \frac{\pi x}{a} \sin \frac{\pi y}{a} \right)^2 = \epsilon^{-V/\rho a} \quad . \quad . \quad . \quad (22)$$

are shown in the accompanying diagram of curves.

§ 16. Considerations quite analogous to those of §§ 6, 7, 8, and again the other considerations analogous to those of §§ 9—13, are, after the full explanations there given, easily completed, so as to formulate a full theory of electrostatic capacity and electrostatic screening for square nets of wire exposed to electric action giving uniform fields of force at distances on each or on one side of the plane of the net, considerable in comparison with $a$, the side of each square.

---

## ON VARIATIONAL ELECTRIC AND MAGNETIC SCREENING.*

BY SIR W. THOMSON, P.R.S.

§ 1. A screen of imperfectly conducting material is as thorough in its action, when time enough is allowed it, as is a similar screen of metal. But if it be tried against rapidly varying electrostatic force its action lags. On account of this lagging, it is easily seen that the screening effect against periodic variations of electrostatic force will be less and less the greater the frequency of the variation. This is readily illustrated by means of various forms of idiostatic electrometers. Thus, for example, a piece of paper supported on metal in metallic communication with the movable disc of an attracted disc electrometer, annuls the attraction (or renders it quite insensible) a few seconds of time after a difference of potential is established and kept constant between the attracted disc and the opposed metal plate, if the paper and the air surrounding it are in the ordinary hygrometric condition of our climates. But if the instrument is applied to measure a rapidly alternating difference of potential, with equal differences on the two sides of zero, it gives very little less than the same average force as that found when the paper is removed and all other circumstances kept the same. Probably, with ordinary clean white paper, in ordinary hygrometric conditions, a frequency of alternation of from 50 to 100 per second will more than suffice to render the screening influence of the paper insensible. And a much less frequency will suffice if the atmosphere surrounding the paper is artificially dried. Up to a frequency of millions per second, we may safely say that, the greater the frequency, the more perfect is the annulment of screening by the paper; and this statement holds also if the paper be thoroughly blackened on both sides with ink, although possibly in this condition a greater frequency than 50 to 100 per second might be required for practical annulment of the screening.

§ 2. Now, suppose, instead of attractive force between two bodies separated by the screen, as our test of electrification, that we have as test a faint spark, after the manner of Hertz. Let two well-insulated metal balls, A, B, be placed very nearly in contact, and two much larger balls, E, F, placed beside them, with the shortest distance between E, F, sufficient to prevent sparking, and with the lines joining the centres of the two pairs parallel. Let a rapidly alternating difference of potential be produced between E and F, varying, not abruptly, but according, we may suppose, to the simple harmonic law. Two sparks in every period will be observed between A and B. The interposition of a large paper screen between E, F, on one side, and A, B, on the other, in ordinary hygrometric conditions, will absolutely stop these sparks, if the frequency be less than, perhaps, four or five per second. With a frequency of 50 or more a clean white paper screen will make no perceptible difference. If the paper be thoroughly blackened with ink on both sides, a frequency of something more than 50 per second may be necessary, but some moderate frequency of a few hundreds per second will, no doubt, suffice to practically annul the effect of the interposition of the screen. With frequencies up to 1,000 million per second, as in some of Hertz's experiments, screens such as our blackened paper are still perfectly transparent; but if we raise the frequency to 500 million million, the influence to be transmitted is light, and the blackened paper becomes an almost perfect screen.

§ 3. Screening against a varying magnetic force follows an opposite law to screening against varying electrostatic force. For the present, I pass over the case of iron and other bodies possessing magnetic susceptibility, and consider only materials devoid of magnetic susceptibility, but possessing more or less of electric conductivity. However perfect the electric conductivity of the screen may be, it has no screening efficiency against a steady magnetic force. But if the magnetic force varies, currents are induced in the material of the screen which tend to diminish the magnetic force in the air on their remote side from the varying magnet. For simplicity, we shall suppose the variations to follow the simple harmonic law. The greater the electric conductivity of the material, the greater is the screening effect for the same frequency of alternation; and, the greater the frequency, the greater is the screening effect for the same material. If the screen be of copper, of specific resistance 1,640 sq. cm. per second (or electric diffusivity 130 sq. cm. per second), and with frequency 80 per second, what I have called the "mhoic effective thickness"* is 0·71 of a cm.; and the current intensity at depth $n \times 0{\cdot}71$ cm. from the surface of the screen next the exciting magnet is $\epsilon^{-n}$ of its value at the surface.

Thus (as $\epsilon^3 = 20{\cdot}09$) the current-intensity at depth 2·13cm. is one-twentieth of its surface value. Hence we may expect that a sufficiently large plate of copper of 2¼cm. thick or more will be a little less than perfect in its screening action against an alternating magnetic force of frequency 80 per second.

§ 4. Mr. Willoughby Smith's experiments on "Volta-electric induction," which he described in his inaugural address to the Society of Telegraph Engineers of November, 1883, afforded good illustrations of this kind of action with copper, zinc, tin, and lead screens, and with different degrees of frequency of alternation. His results with iron are also very interesting; they showed, as might be expected, comparatively little augmentation of screening effect with augmentation of frequency. This is just what is to be expected from the fact that a broad enough and long enough iron plate exercises a large magnetostatic screening influence; which, with a thick enough plate, will be so nearly complete that comparatively little is left for augmentation of the screening influence by alternations of greater and greater frequency.

§ 5. A copper shell closed around an alternating magnet produces a screening effect which on the principle of § 3 we may reckon to be little short of perfection if the thickness be 2¼cm. or more, and the frequency of alternation 80 per second.

§ 6. Suppose, now, the alternation of the magnetic force to be produced by the rotation of a magnet M about any axis. First, to find the effect of the rotation, imagine the magnet to be represented by ideal magnetic matter. Let (after the manner of Gauss in his treatment of the secular perturbations of the solar

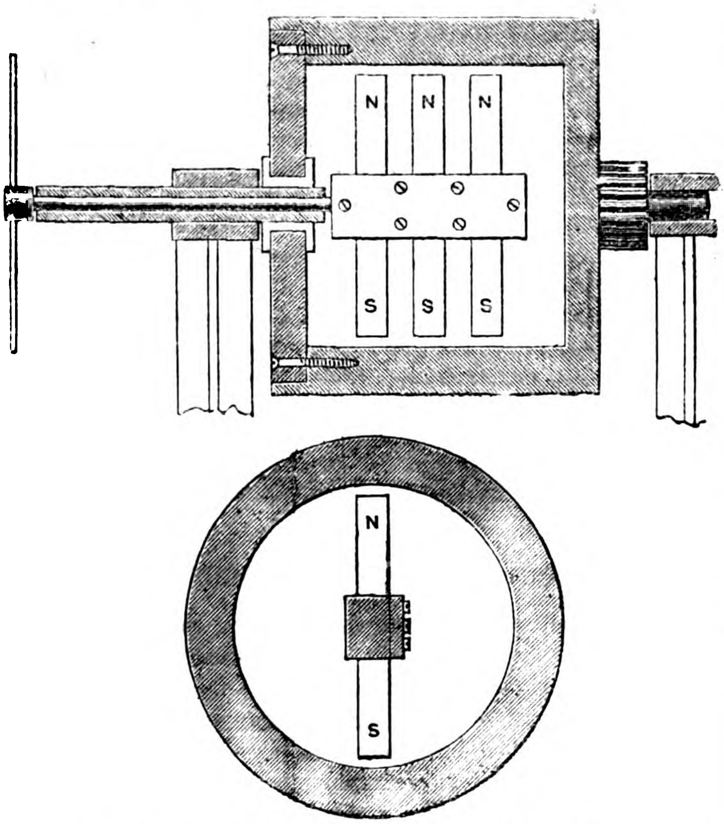
* Paper read before the Royal Society, April 9, 1891.

* "Collected Papers," Vol. III., Art. cii. § 35.

Digitized by Google

system) the ideal magnetic matter be uniformly distributed over the circles described by its different points. For brevity call I the ideal magnet symmetrical round the axis, which is thus constituted. The magnetic force throughout the space around the rotating magnet will be the same as that due to I, compounded with an alternating force of which the component at any point in the direction of any fixed line varies from zero in the two opposite directions in each period of the rotation. If the copper shell is thick enough, and the angular velocity of the rotation great enough, the alternating component is almost annulled for external space, and only the steady force due to I is allowed to act in the space outside the copper shell.

§ 7. Consider now, in the space outside the copper shell, a point P rotating with the magnet M. It will experience a force simply equal to that due to M when there is no rotation, and when M and P rotate together, P will experience a force gradually altering as the speed of rotation increases, until, when the speed becomes sufficiently great, it becomes sensibly the same as the force due to the symmetrical magnet I. Now superimpose upon the whole system of the magnet, and the point P, and the copper shell, a rotation equal and opposite to that of M and P. The statement just made with reference to the magnetic force at P remains unaltered, and we have now a fixed magnet M and a point P at rest, with reference to it, while the copper shell rotates round the axis around which we first supposed M to rotate.



§ 8. A little piece of apparatus, constructed to illustrate the result experimentally, is submitted to the Royal Society and shown in action. In the copper shell is a cylindric drum, 1·25cm. thick, closed at its two ends with circular discs 1cm. thick. The magnet is supported on the inner end of a stiff wire passing through the centre of a perforated fixed shaft which passes through a hole in one end of the drum, and serves as one of the bearings; the other bearing is a rotating pivot fixed to the outside of the other end of the drum. The accompanying sections, drawn to a scale of three-fourths full size, explain the arrangement sufficiently. A magnetic needle outside, deflected by the fixed magnet when the drum is at rest, shows a great diminution of the deflection when the drum is set to rotate. If the (compound triple) magnet inside be reversed by aid of the central wire and cross-head shown in the diagram, the magnetometer outside is greatly affected when the copper shell is at rest; it is scarcely affected perceptibly when the copper shell is rotating rapidly.

§ 8. When the copper shell is a figure of revolution, the magnetic force at any point of the space outside or inside is steady, whatever be the speed of rotation; but if the shell be not a figure of revolution, the steady force in the external space observable when the shell is at rest becomes the resultant of the force due to a fixed magnet intermediate between M and I compounded with an alternating force with amplitude of alternation increasing to a maximum, and ultimately diminishing to zero, as the angular velocity is increased without limit.

§ 9. If M be symmetrical, with reference to its northern and southern polarity, on the two sides of a plane through the axis of rotation, I becomes a null magnet, the ideal magnetic matter in every circle of which it is constituted being annulled by equal quantities of positive and negative magnetic matter being laid on it. Thus, when the rotation is sufficiently rapid, the magnetic force is annulled throughout the space external to the shell. The transition from the steady force of M to the final annulment of force, when the copper shell is symmetrical round its axis of rotation, is, through a steadily diminishing force, without alternations. When the shell is not symmetrical round its axis of rotation, the transition to zero is accompanied with alternations as described in § 8.

§ 10. When M is not symmetrical on the two sides of a plane through the axis of rotation, I is not null; and the condition approximated to through external space with increasing speed of rotation is the force due to I, which is an ideal magnet symmetrical round the axis of rotation. Suppose now a second shell enclosing the first to be caused to rotate about an axis precisely through and precisely perpendicular to the axis of rotation of the first shell. The magnetic force at I is by this second shell perfectly annulled through all the space external to it when the rotation is sufficiently rapid. Thus we arrive at the remarkable result that two closed conducting shells, rotating round axes exactly perpendicular to one another through one point, annul for all external space the magnetic force of any magnet whatever held fixed within the inner shell, when the rotation is sufficiently rapid.

§ 11. Instead of the outer shell, an infinite plane disc of metal might be substituted with the same result; and a disc large enough to produce very nearly the same screening effect as if it were infinitely large is easily arranged for; and an experimental illustration of the result may be shown, by a slight addition to the apparatus before the Royal Society, but there would be no special interest in this illustration. What would really be interesting would be a simple experimental illustration of screening against magnetic force by a rotating disc with a fixed magnet held close to it on one side. A bar magnet held with its magnetic axis bisected perpendicularly by the axis of rotation would have its magnetic force almost perfectly annulled by sufficiently rapid rotation at points in the air as near as may be to it, on the other side of the disc, if the diameter of the disc exceeds considerably the length of the magnet.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

CONTENTS OF THE CURRENT NUMBER.

NOTES ... 685
The Magnetic Circuit of Transformers: Closed versus Open. By S. Evershed. Continued. Illustrated ... 690
On Electrostatic Screening by Gratings, Nets, or Perforated Sheets of Conducting Material. By Sir William Thomson, D.C.L., P.R.S. Illustrated ... 692
On Variational Electric and Magnetic Screening. By Sir W. Thomson, P.R.S. Illustrated ... 694
Meetings of Scientific Societies 695
OUR ISOLATED LIGHTHOUSES ... 696
The Electric Current and its Laws.—VI. By John T. Sprague. Illus. Continued. 697
The Separation of Foucault and Hysteresis Losses. By Gisbert Kapp. Illustrated ... 699
Graphic Method for Analysing Losses in Armature Cores, &c. By R. H. Housman. Illustrated ... 700
The Propagation of Hertzian Electrical Oscillations in Air. By MM. E. Sarasin and L. de la Rive ... 701
Notes on the Design of Multipolar Dynamos. By W. B. Esson. Illustrated ... 702
Inductive Disturbances in Telephone Circuits. By J. J. Carty. Illustrated ... 705
The Short Gearless Tramway Motor. Illustrated ... 708
The Cost of the Generation and Distribution of Electrical Energy. By R. E. B. Crompton, M.Inst. C.E ... 708
American Notes ... 709
CORRESPONDENCE—
Sparking Distances—Robert Shand ... 709
Trade Notes and Notices ... 710
PATENT RECORD ... 711
COMPANIES' MEETINGS, &c.—
Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited) ... 711
Poole and White (Limited) ... 712

STEEL-PLATE PORTRAITS

*Of W. H. Preece, F.R.S.; Michael Faraday; Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S., and Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers), have been issued as Supplements to* "THE ELECTRICIAN." *A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar of Brown Ornamental Frames, price, post free, 4s. 6d.*

## OUR ISOLATED LIGHTHOUSES.

We are glad to notice that the appalling shipping disasters which have occurred in distant waters during the past winter have not entirely diverted attention from the more numerous, if less tragic, incidents of the same kind around our own shores. The *Standard*, which has always been forward in pointing out the defects of our coast communication, is again opening its columns to the discussion of this important subject; and we gladly hasten to render what assistance we can to recommend it to the consideration of our professional readers. Last autumn we pointed out that the chief problem to be solved in connection with one aspect of the question was the devising of a practical coupling for cable attachment to the floating lightship. The experiments off Harwich were not entirely successful—or, at all events, failed to an extent which afforded the Trinity House Brethren an excuse for declining to subsidise an extension of the trials. Had that highly useful body been in possession of adequate funds we doubt not that its verdict would have been less critical. But the functions entrusted to Trinity House are of such vital moment that any diversion of its resources to be spent on a new departure would be, perhaps, quite unwarrantable. In other words, we cannot blame the Brethren for not expending money with which they are charged for a definite purpose, upon a quite novel object

outside their strict sphere of operations. That this sphere ought not to be so limited is now self-evident; but as it cannot be enlarged without a substantial increase of funds, the Board naturally confines its attention chiefly to maintaining Lightships and Lighthouses in an efficient condition to serve their original purpose.

But two things more were needed long after these kindly beacons and pathfinders were established—namely, appliances for rescuing those who had gone astray in spite of such provision, and the means of communicating intelligence as to where the rescuing service was needed. Philanthropy has done its part nobly in providing the former; science can now provide the latter. The discovery of the electric telegraph, and, perhaps, still more, the invention of the telephone, have placed at our disposal a prompt and sure connecting link between the danger signals and the relief stations. It requires only that funds shall be forthcoming to make the protecting system complete, and render our shores, if not exempt from shipwrecks, free from the terrible consequences which so often and so needlessly attend them. To some remarks addressed to him on the subject, the Secretary of the Board of Trade is recently reported to have said that he hoped the source from which the money was to come would be indicated by anybody who called upon him to carry out such a scheme. In no other country in the world probably would such a reply have been made. It is reserved for the Ministers of the wealthiest of all nations to put on the airs of the poorest. The fact can be explained only by the charitable assumption that no British Minister can himself initiate an expenditure, but must wait until he receives his orders from the polling booths. Unfortunately, if this is the case, there is a poor look-out for the distressed mariner, for he has no vote. It has been sorrowfully remarked by one of the ablest of living political writers, that while we allow ourselves to be governed by "factory hands," the bravest, the most stalwart, and most loyal of our countrymen are disfranchised. Probably, for this reason, the National Lifeboat Institution is not national at all, but depends largely for its sustenance on occasional legacies and other benefactions, and on the superfluous coppers of visitors to the seaside watering places.

If we were told that the scheme is impracticable, or that it would not serve the purpose intended, the delay in establishing an electrical cordon of communication so long under discussion would be, at all events, arguable. But nobody is bold enough to make either of these assertions except with the manifest object of deprecating the cost. At all events, there can be no question as to the feasibility of attaching and maintaining cable communication with lighthouses—or towers, as they are sometimes more correctly called. Yet it has been left to a private corporation to do all that has hitherto been done in that direction; and even LLOYDS find the enterprise too costly, simply because—so it is alleged—the Post Office rental is too heavy. Granting that it is the business of LLOYDS to supply such a want, and that they alone have an interest in doing so, the Post Office, being employed as a firm of contractors to carry out the work, is not only right in demanding a fair remuneration, but it would be clearly not justified in imposing royalties. But the mere statement of the facts reveals the disgraceful condition into which the whole case has drifted. Nothing but red tape fanaticism can excuse the greatest maritime nation doing nothing—as a nation—to render its shores free from shipping disasters, beyond what is strictly demanded on commercial principles. Lightships and Lighthouses do all that is possible to direct our mercantile marine, but nothing to save the lives of the crews or passengers —is this a matter for private philanthropy?

The motion, of which notice has been given in the House of Commons, by Sir EDWARD BIRKBECK, would, if carried, put this really national question on its proper footing. That telephonic or telegraphic communication should be provided "between the coastguard stations and signal stations on the coasts of the United Kingdom" is desirable, will not be disputed; but that it should be—in the terms of the motion—"provided by the Government" is a proposition which we should like to see fairly discussed and settled in the House. The House of Commons has only to say the word and the thing will be done. Neither the Trinity House nor the Post Office, we are fully assured, will raise the least objection. We have already stated the case of the first-mentioned body. As regards the Post Office, Mr. F. E. BAINES, one of its most competent authorities, has long ago formulated a scheme, by means of which every outlying station, either of coastguardsmen, lifeboat men, or light signalmen, could be put in connection with the main lines of service amply provided by his department. Of course, such a system as that would be serviceable also during a time of war. We have so frequently dwelt upon the necessity of connecting our look-out stations at sea with the naval and military stations on land, that there is no need to enlarge upon it now. It is, perhaps, not so urgent on this ground as on the other; but we rather incline to the belief that when the work is done, if it ever is done, it will be through the instrumentality of the naval and military authorities. The matter has been discussed at considerable length between the Admiralty and the Treasury. As part of the expenditure upon home defences, connecting lines all round the coast would be an insignificant item, as a work of humanity it utterly fails to move the Treasury. It is to be hoped then that, *lucus a non lucendo*, the Minister for War may be induced to give his support to this work of peace.

## THE ELECTRIC CURRENT AND ITS LAWS.—VI.

BY JOHN T. SPRAGUE.

(*Continued from p. 672.*)

§ 50. We have to express the material equivalents in terms of the "gramme," because all our other related measures of the C.G.S. and practical systems are based upon that as the unit of mass and consequently of energy; but we have no real knowledge about the actual "mass" of equivalents; for all we know these are related to quadrillionths of a gramme. Still it is these ultimate units of matter which are the physical basis of "lines of force," and in the case of current, it is by these units of zinc, each taking its place in turn to be dissolved by the acid, that the amperage is generated, and the energy of its voltance transmitted into and along the line of amperage.

This is no assumption or hypothesis; it is simple fact. This is what differentiates linear, dual electric energy from radiant energy, such as heat. The idea that the energy leaves its natural line of action, as a function of amperage, to become radiant as external undulations to be controlled by the current from which it has escaped, *is* pure assumption, adopted for the mere convenience of theorising, in opposition to the principle stated § 42. The theorists are seeking to found their system upon the more complicated phenomena of alternating currents and variable periods, instead of starting from simple facts and their working in nature, and then following the principle so found into more complicated conditions. I have shown that the energy is developed only within a line of force, and I will follow its actions in that line, leaving others to explain why it should leave it in order to come back again.

I prefer another term to "line of force," viz.: "polar or polarisable chain." The central idea of a line is unity acted on externally by an impressed force; the "chain" represents a unity built up of individuals, of links each exerting its own powers.

Digitized by Google

§ 51. I have shown (§ 48) that current is simply the evidence of the material changes going on, and is identical with chemical equivalence; and the known relation of magnetism to current shows that this also is a function of the equivalence of matter and its structure out of units. Current may be readily conceived as a motion of the units, the links of the polar chain, under stress of the voltance energy. A little examination will show that whatever other motions may occur in the chain, there must be (within the electrolyte, starting from the zinc surface, the real seat of the voltance), a semi-rotation of each molecule; the molecule being a pair of equivalent ions, united by their polar forces, and broken up by the superior impressed force due to voltance. If we conceive a new formed molecule of zinc sulphate Zn ($Zn\,SO_4$), it must obviously turn over and become Zn ($SO_4$ Zn) in order to prepare for the next action on the zinc. So we can trace the actions; the superior polar force of voltance breaking up the molecules and reforming them within the polar chain, till a point is reached at the negative plate, where a final disruption must occur, and some ion be released, equivalent to the zinc, whose entrance into the polar order furnished the energy which worked the disturbance.

$$Zn\ SO_4\ Zn\ SO_4\ H_2\ SO_4\ Cu$$

This shows copper released, as in the Daniell; cut off the last molecule, and it shows hydrogen released as in the Smee cell.

§ 52. Precisely the same actions occur in a decomposition cell or voltameter, except that these have re-voltance, energy to be absorbed from the chain instead of voltance, or energy sent into the chain.

I may here refer to, only to dismiss, a theory which presents much fascination to the mathematical mind, and is advocated by many eminent men: viz., the existence in the electrolyte of free uncombined ions of both sorts, each kind charged with + or − electricity. Can anyone really imagine a number of such free charged bodies mingling together and not uniting? We may overlook for the moment the fundamental fact that no such separate charges of electricity have any existence in nature; that a + charge is always definitely related a − charge, and that they are no more separable than N and S magnetic poles.

But the notion is absolutely inconsistent with the established laws of thermo-chemistry; any such free ions would unite and give up their energy as a known value of heat: once combined they can be "dissociated" only by being supplied with the necessary voltance. Whence is this to come in the ordinary conditions? It is supplied by the voltage which disappears at the electrodes, where the real dissociation occurs, and where the ions are found experimentally; but even then, *not as free ions*, but, except possibly for the moment of nascence, as ions united into molecules. *Free* ions are found nowhere except, as Mr. Evershed says of free ether, inside the text books and hypothetical papers. As an instance of how everything can be pressed into the service of a hypothesis, I may refer to the note on "Magnetic Rotation," p. 532. Here we have a difference shown by electrolytes, which give a rotation much higher than that due to the sum of the action of the constituents. That this may show some definite relation of structure to electrolysis is likely enough. But it is actually asserted that "any exceptional value is due to the occurrence of electrolytic dissociation." I may be very dense, but it really seems to me that the free substances ought to give merely the *sum* of their separate actions, not an excess. I can conceive an excess due to some particular structure resulting from combination.

§ 53. To return to our proper muttons, the "stress" of energy in the polar chain depends on the voltance of the reaction, and here we have at once the evidence that it is *in the chain* and not outside. The chemical action which turns chemical affinity into electric voltage is in the chain, at the junction of the zinc with the liquid, where the voltance of the zinc is transformed. Insert one cell after another in the chain, that is in series, and you add its voltage to the circuit; nor does it make any difference what part of the chain you insert them in. Insert them out of the chain, that is in parallel, and you no longer add to the voltage at all; you merely set up fresh polar chains.

We know this; it is no assumption. We know that if the action occurs out of the chain, we do not obtain voltage or electric energy, but waste zinc and waste energy as heat which radiates away. We actually do have both facts in our batteries: what is called "local action" is just zinc going to waste, because out of the polar chain. Why does this energy never find its way to that "waste pipe," the conductors How is it that it altogether escapes the control which prevent? the loss of any energy once put into the circuit, until it has done its work?

§ 54. We may now trace briefly how the same principles operate in other "sources." Take the thermo-pile: what is it but just a polar chain, with points at which the molecular structure changes? viz., the junction of metals with the different capacities for heat. A differential heating induces a differential molecular motion which transmits a part of the energy which has entered the chain, as that motion which we call electric current.

Take the dynamo. We are told that the voltage depends on the number of lines of force cut, and the idea is good enough for mere purposes of calculation. But why should cutting a line of force do anything but break it? Substitute the idea of forcing a polarisable chain into the line of force, so that its links are compelled to form part of the line, just as a regiment entering a formation would have to, and we have something intelligible. The molecules of the wire, in equilibrium under the constant forces affecting them, have suddenly to rearrange themselves in a polar order, which means a motion which is an electric current, because the arrangement is continuously changing. The conditions are identical with those of battery cells, of thermo-piles, of conductors; in all size, that is sectional area affects amperage capacity, or the number of polar chains which can be formed; in all the number in series, the successive inlets of energy on the one chain, means voltage, because it means voltance, the density of the energy which is put into the one chain.

§ 55. We may now follow the transformed "electric energy" into the circuit, considering for reasons given (§ 42), the circuit of simplest conditions, viz., of constant current, which, as is well known, are wholly unconcerned with either inductance or magnetance, these being purely phenomena of, because causes of, the variable period.

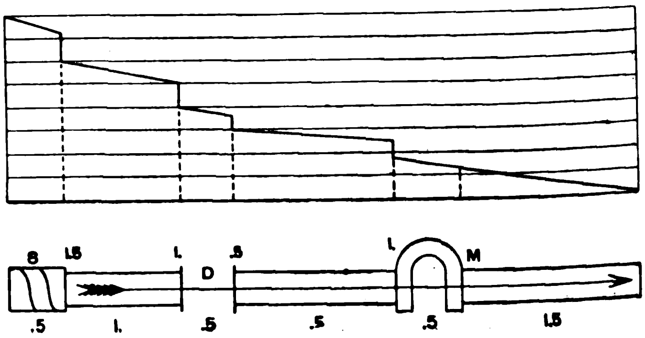

Fig. 5.

We find that the whole energy of the source is accounted for by several outlets: (1), various re-voltances or E.M.F.'s; (2), the true resistance of the circuit $C^2$ R; (3), work done through the agency of the circuit. Let Fig. 5 represent all these in the form of what is called "fall of potential," measurable in voltage lost, which means energy expended, and, therefore, eliminates the expression $C^2R$.

We may look at the matter in another way: if we put the case as a current of one ampere, then fall of potential is $-e$ in volts, and ohmage R, equivalent in value, so that the sum of these equals the gross voltage of the source.

The circuit is represented by the arrow traversing the source S, a voltameter D, and an electro-magnet M, doing work equivalent to a counter E.M.F. of one volt. These re-voltances are stated in figures above the line, while the ohmage of the several parts of the circuit are stated below the line. By some

Digitized by Google

oversight, there is ·5 too much introduced, but this is a detail of no consequence to the principle.

It will be seen that re-voltances appear as dead drops. They reduce the gross voltage, which is the vertical line at the beginning of the slope of potential, because they correspond to energy which is absorbed, and taken out of the circuit; while that absorbed in overcoming the resistance, appears as heat distributed over the whole circuit in the ratio of the ohmage of its several parts, and is shown in corresponding slopes.

§ 56. Let us look at the re-voltances first. Zinc forming zinc sulphate gives a gross voltage of 2·248 according to the old values of the ampere, &c., and it is needless to recalculate for the sake of a matter of 2 or 3 per cent.; this is subject to two reduction (*a*) the reaction of the material of which the – plate of the cell is composed; and (*b*) the voltance of the substance set free at the – plate.

The actual values are of no moment, so I have assumed whole figures; gross voltage 8, subject to re-voltage in the source itself = 1·5, leaving a net voltage = 6·5, furnished by the source. We next enter the voltameter, giving off at one electrode hydrogen with re-voltance = 1, and at the other oxygen with re-voltance = ·5. The known and calculated E.M.F. of what is called the decomposition of water is close on volts 1·5, and I have assumed that this is divided in the ratio of the relative volumes. Then the work of the electro-magnet is assumed to equal one volt of counter E.M.F.; this really means a unit of voltance per unit current, which is tantamount to power reckoned in watts or to any equivalent mode of reckoning energy.

In like manner, the resistance of the circuit, the energy consumed in the mechanical work of transmitting current, which, like other mechanical frictions, appears as heat, absorbs the remaining energy of the source, and tells us why the rate of current is controlled by the resistance of the circuit. Re-voltages are independent of current rate (not re-voltance which is governed by material quantity as well as the density of energy); until they are overcome no current is generated at all, or in Ohm's formula $E - e$ must be a positive value. Then, current must be proportioned to the energy available to force it through the circuit, and we have $\frac{E - e}{R} = C$

§ 57. Why need we go out of the conducting circuit to find a vehicle for energy? In what way, except in the special molecular motion which we call electric current, does the case of electric transmission of energy differ from any other case of transmission of energy?

Does anyone in his senses argue that when a mechanical motor transmits energy by means of shafting or belts, the energy is really transmitted by some imaginary medium, and that the shaft and the belt are mere waste pipes to get rid of some hypothetically superfluous energy which chokes the medium? If some mathematician were to administer that notion to a mechanical engineer, what sort of reception would he get? Yet the cases differ in no respect. Just as the motor puts a stress on the belt, just as the number of rotations of the motor controls the rotations of every wheel in the circuit, so does the electric source put a stress on its circuit, and its molecular reactions control the molecular reactions throughout its circuit. But we must calmly accept an equally baseless imagination on pain of being told we are half-educated electricians, and heretics.

§ 58. "Ah! but what about the variable period?" I hear some of the opposite party say. Well, my friend, what about the variable period? Just go and introduce the element of "frequency" and alternation to some mechanical motor (provided the owner will permit you), and then you shall see what you shall see. Just keep on starting and stopping a steam engine on full duty. Is there any single phenomenon of the variable period that you will not find a mechanical equivalent for? Stresses in any quantity; lost energy as much as you please. Only develop high "frequency" enough, and you will be glad to find any "medium" which will convey away the superfluous energy of the owner of the engine. I will now proceed to show this by examining the conditions of the hydraulic circuit, which is a nearly perfect analogue of the electric circuit.

*(To be concluded.)*

## THE SEPARATION OF FOUCAULT AND HYSTERESIS LOSSES.

BY GISBERT KAPP.

The total loss of power taking place in the armature of a continuous current dynamo beyond the unavoidable loss due to copper resistance, is made up of the following:—

(*a.*) Loss through mechanical friction.

(*b.*) Loss through hysteresis in the armature core.

(*c.*) Loss through Foucault currents, either in the armature core or in all the conductors, or in the conductors under commutation only, if the setting of the brushes is faulty.

A further loss of power is due to air resistance, but this is so insignificant that it may be neglected.

It need hardly be pointed out that any simple method by which we can separately determine these losses is of practical value, and I propose to describe such a method in the hope that some reader of *The Electrician* may find a way to further develop it, so as to become applicable to alternators and transformers, a class of apparatus in which the exact determination of Foucault and hysteresis losses is of even greater importance than it is in continuous current dynamos.

The method is based upon the supposition that the torque required to overcome hysteresis and mechanical friction is independent of the speed, and that, therefore, the work lost through these two causes (if the field strength remains constant) is simply proportional to the speed. Since both mechanical friction and hysteresis are assumed to follow the same law, it is clear that a method based on such an assumption cannot be used to separate these two losses, but can only give their sum. The loss by friction can, however, be determined with a fair degree of accuracy from the dimensions of the bearings, weights, magnetic attraction, speed, the lubrications, &c., and thus we can, at least approximately, get the hysteresis alone, provided we can separate the Foucault losses. It should also be remembered that the purely mechanical loss by friction is generally very small as compared with the other two losses, and an error in the estimate of the friction has only a small effect on the correct determination of the hysteresis loss, and no effect whatever on the determination of Foucault losses.

For the same excitation the Foucault losses must obviously increase as the square of the speed. We have, therefore, the following equation for the total number of watts wasted in the armature, other than by copper resistance:—

$$W = n\,H + n^2\,F.$$

*n* being the speed in revolutions per minute, and H and F coefficient which depend upon the excitation, but do not vary with the speed. The coefficient H refers to the loss due to hysteresis and friction, and the coefficient F refers to the loss due to Foucault currents.

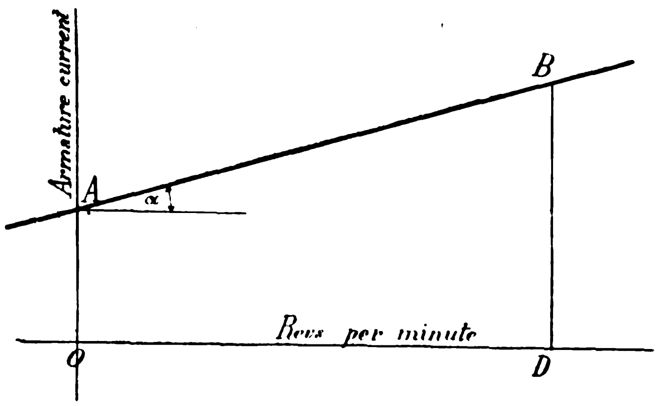
Mr. W. Mordey was probably the first to make use of this equation in order to determine and separate the various losses which occur in the armature. His method is as follows:—He drives the armatures by means of a belt from an electromotor, and notes either the electrical power supplied to the motor, or by means of a transmission dynamometer the mechanical power given to the armature with its field inert, and also with its field excited to various degrees. Provided the transmission dynamometer is correctly calibrated, or the efficiency of the motor is accurately known for these various conditions, and the loss of power in the belt is also known, this method can be used to separate not only Foucault losses from losses due to hysteresis and friction, but also the initial friction loss when the armature is revolving in a non-excited field from the hysteresis and friction loss when the armature is revolving in an excited field. Keeping the excitation constant, Mr. Mordey varies the power supplied to the armature under test, and thus gets a series of values for W and *n*, which are plotted in a curve. Selecting any two points on this curve (not too near each other) it is easy by a trial and error method, or by the solution of a quadratic equation to determine the

Digitized by Google

values of H and F, which will satisfy this curve throughout its range, and having found these values, the above equation enables us at once to separately determine the losses.

There are, however, some objections to this method. In the first place, it pre-supposes the possession of a reliable transmission dynamometer or an exact knowledge of the efficiency of the motor and of the loss of power in the belt, both points on which legitimate doubts may be entertained. In the second place, and this is the more serious objection, the necessity of using a second machine as a motor and rigging up a belt transmission, involves an amount of labour and expense which one would be glad to avoid. In the new method no second machine is required, but it has the disadvantage of being only applicable to armatures which have already received their winding; whereas Mr. Mordey's method can be used to investigate an armature core before it is wound. The method about to be described is also based on the above formula, but the power W is supplied to the armature under test electrically instead of mechanically; in other words, the dynamo to be tested is run light as a motor, and note is taken of the speed and armature current whilst the excitation is kept constant. At least one reading of the pressure at the brushes (preferably at the highest speed and armature current) must also be taken, but more such readings may be taken as a check. Since the dynamo is running light, the armature reaction on the field will be small enough to allow us to neglect it, or, in other words, we are justified in assuming that the field strength remains constant for all speeds. It should, however, be remembered that this is only an approximation, and that the Foucault currents, if they are very strong, will produce a distortion of the field, quite apart from the very small distortion produced by the armature current proper. In fairly good machines such a result need, of course, not be expected.

Assuming, then, a constant field of $z$ (English) lines, and denoting by $\tau$ the number of external armature conductors in



a two-pole machine, we have the E.M.F. at the brushes given by

$$e = z\,\tau\, n\, 10^{-6}$$

if we neglect the very small E.M.F. lost in armature resistance. The power supplied by the current $c$ is

$$W = e\,c,$$

or

$$c\,z\,\tau\,n\,10^{-6} = n\,H + n^2 F,$$

from which it follows that

$$c\,z\,\tau\,10^{-6} = H + n\,F.$$

Since $z$ and $\tau$ are constant, the current is equal to the sum of a constant, $\frac{H}{z\,\tau\,10^{-6}}$ and another factor, which varies directly with the speed. The curve representing the current as a function of the speed must, therefore, be a straight line, as shown in the annexed diagram. The height O A at which this line intersects the vertical axis is a measure of the current required to overcome the torque of friction and hysteresis, and the inclination of the line is a measure of the influence of Foucault currents, or in symbols

$$\tan \alpha = \frac{F}{z\,\tau\,10^{-6}}.$$

Let $c_0 = $ O A be the initial current, then we find directly from the diagram the value of the coefficient $H = c_0\, z\, \tau\, 10^{-6}$, and inserting this in the formula given above, the value of

$$F = \frac{W - n H}{n^2},$$

where $n$ and $w$ are observed values. It should be noted that in practice it is not even necessary to know the winding and field strength. All we need do is to observe the current and speed, in order to determine the position of the straight line A B, and take an accurate reading of the pressure $e$ and current $c = $ D B observed at a particular speed O D. The ratio $c_0/c$ at once gives the ratio of loss due to hysteresis and friction to the total loss which includes the Foucault losses, and since we know the total loss ($w = c\,e$) its two component parts can be found by a simple rule of three, and a subtraction. If the current curve A B is not a straight line, it is a sign that the Foucault currents are strong enough to produce a distortion of the field.

## GRAPHIC METHOD FOR ANALYSING LOSSES IN ARMATURE CORES, &c.

BY R. H. HOUSMAN.

It has long been known that the losses in the armature core of a continuous-current dynamo may be accurately measured by running it as a motor without load, and noting the

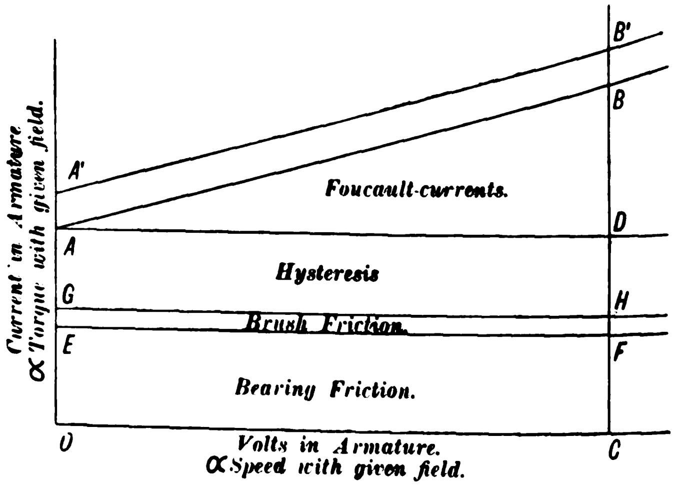


FIG. 1.—Electrical Diagram.

power absorbed. It was also shown by Mr. Mordey some little time ago that by plotting the losses, so measured, at different speeds, those which are proportional to the square of the speed (Foucault currents) may be separated from those which are directly proportional to the speed (hysteresis), by a mathematical process; but this process debars the method from general use.

It is, however, possible, by a simple graphical construction, to separate the different losses without any recourse to mathematics at all. The method is as follows:—Measure the current required to run the armature as a motor light with different volts on the armature, the magnets being separately excited so as to keep the field constant. On plotting the results as a curve, as in A B, Fig. 1, it will be found that the curve is a perfectly straight line, cutting the axis of current at some distance from the origin.

Now, taking any point B on the curve, and drawing B C parallel to A O, it is evident that the total loss is represented by the product O C × C B.

Next draw A D parallel to O C; this divides the area representing the total loss into two parts, one of which, O D, is proportional to O C, and the other, A D × D B, is proportional to the square of O C, since B D is proportional to A D which = O C. The first of these areas represents the waste of energy per

Digitized by Google

second due to hysteresis and friction combined, while the second gives the loss due to Foucault currents. It must be noticed that it is the product of the co-ordinates of any point on A B which represents the waste, and not the area of the figure A O C B. In this respect the diagram resembles the characteristic of a dynamo rather than the diagram of a steam engine.

Friction of bearings and brushes must be determined separately by coupling direct to a similar motor, and observing the increase of current required to drive with the fields unexcited. This will be constant at all speeds.

From this experiment draw O E equal to the current observed as required for friction alone, then E F being drawn parallel to O C the rectangle O F represents loss by bearing friction. By a similar experiment the loss by brush friction may be determined, and G H drawn, so that E H represents the loss from this cause. The remaining rectangle G D will then show the loss due to hysteresis. It will be readily understood that only the losses represented by G H × H B (Foucault currents + hysteresis) appear as heat in the armature.

A second set of experiments may be made with a different strength of field, and plotted in a curve A′ B′, which is in general parallel to A B, showing that Foucault currents are constant for given volts. A′ B′ will be above or below A B, according as the change of field intensity has increased or diminished, the sum of the losses due to hysteresis and friction, these two varying inversely, though not in simple inverse ratio.

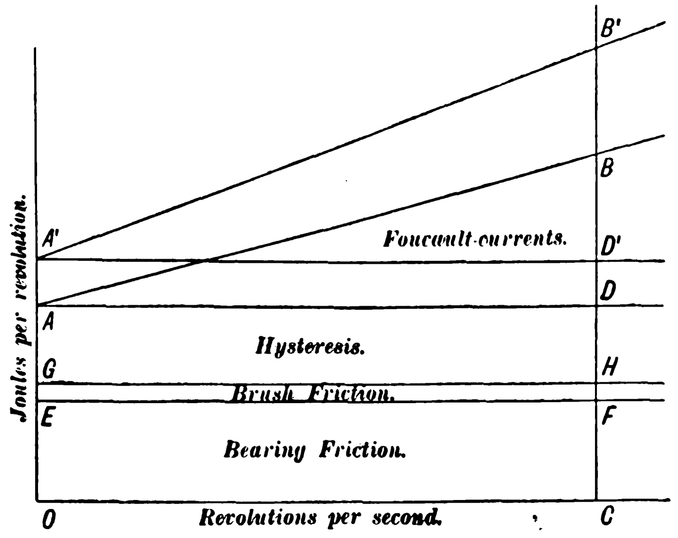

FIG. 2.—Mechanical Diagram.

At a certain intensity the total losses for given volts will be a minimum ; this in practice seems generally to occur between 15,000 and 16,000 lines per sq. cm. in the iron of the armature, but the exact figure depends on whether friction is large or small. In machines with little friction, the best intensity may be much lower. There is a curious point about the Foucault currents at high intensities (18,000 or 20,000) ; they show a decided tendency to *increase*, the slope of the curve A B becoming much steeper. This is probably due to the increased stray field in the shaft and flanges at the ends of the armature, which being solid metal may have large currents in them when the field through them reaches 200 to 300 lines per sq. cm.

In Fig. 1. all the quantities have been measured electrically, hence it may be called the electrical curve to distinguish it from another diagram which may be derived from it, in which the quantities are measured in mechanical units. The electrical diagram has the disadvantage that, for each intensity of field, a separate friction line has to be drawn, which makes it difficult to distinguish how much of the whole loss is electrical and how much frictional, when there is more than one curve drawn on the same diagram. This difficulty is obviated by plotting revs. per sec. instead of volts along the horizontal axis, and work per revolution in Joules instead of current along the vertical axis. It will be noticed that the product of these two is expressed in watts (or work per second), as before, but it only requires an alteration of scale to make the co-ordinates revolutions per minute and foot-pounds per revolution respectively, in which case the product ÷ 33,000 gives horse power.

In this diagram the same friction line holds good for all intensities, and the frictional and electrical losses are separated by the line G H (Fig. 2). It will also be seen that the quantities G A and G A′ represent the losses by hysteresis, in Joules per cycle, at the two intensities, for which A B and A′ B′ are drawn respectively. The loss per cubic centimetre from this cause is always found to be much greater than that generally given.

## THE PROPAGATION OF HERTZIAN ELECTRICAL OSCILLATIONS IN AIR.*

BY MM. E. SARASIN AND L. DE LA RIVE.

We have already had the honour of presenting to the Academy the first results obtained by us on repeating the beautiful experiments of Hertz on rapid electrical oscillations†. We confined ourselves on that occasion to the case of electrical oscillations transmitted along a conducting wire. Since then we have repeated another of Hertz's experiments, which consists in following the propagation of the electric induction across air in the absence of any metallic conductor. The primary exciter is placed in front of a large plane metallic sheet arranged parallel to it. The electric waves which emanate from it are propagated across the air, and impinge on the sheet of metal, which acts as a mirror, the reflected waves forming, with the direct waves, a stationary system, the first node of which is at the mirror itself. In order to study this system of concamerations which is established in front of the mirror, a circular resonator is moved about in two different principal positions, (1) constantly parallel to the mirror and to the primary, *i.e.*, in the plane of the wave, (2) displaced into the plane drawn nominally to the mirror through the axis of the primary, *i.e.*, plane of vibration. In both cases the results are absolutely concordant so far as concerns the equidistant positions of maximum and minimum E.M.F.'s. In addition to these two methods of proceeding, Hertz employed a third, which consisted in causing interference between waves arriving at the same resonator from the same exciter, either directly across the air or along a conducting wire. From these experiments Hertz concluded by the great wave length, that the rate of propagation across air in the absence of any conducting wire, was almost twice that observed along a wire, the two speeds being in the ratio of about 7:4. This disagrees with Maxwell's theory which makes the two speeds equal.

In view of its great theoretical importance we have applied ourselves specially to the verification of this particular point. Having proved by our previous experiments in connection with oscillations propagated along wires that the oscillatory period of a given circular resonator is constant, whatever the primary exciter by which it is energised, the same exciter permitting us to observe as many wave lengths as we possess different sized circles, we set to work to compare the length of a wave given by the same circular resonator when the impulse was propagated along wires, with that given when the impulse was propagated in air without wires. As reflecting surface we employed a large screen of sheet lead 2·8m. high and 3m. broad, kept plane and vertical by its own weight. The primary exciters and the large Ruhmkorff coils were the same that we employed in our previous investigations. The exciter was placed in front of the mirror, with its axis horizontal and its spark gap on the normal to the centre of the metal screen. Its distance from this was varied between 4m. and 10m. The circular resonator was fixed on a carriage sliding along a large wooden optical bench, already described. We widely varied the conditions of the experiment, and repeated the observations a great number of times, and we

summarise in the table above the results which we obtained with ten different circles.* We give in this table the mean of the results obtained with each circle, and in order to abbreviate we have not separated out the measurements made with primary exciters of different dimensions, which did not exhibit any systematic difference. In these last investigations in air as in our previous ones with wires, we have, in fact, proved that *a circular resonator always gives the same wave length*, even when the dimensions of the primary exciter is varied within certain limits.(†) We have, therefore, again observed what we have termed *multiple resonance*. In the case of large wave lengths (circles of 1 metre and ·75 metre in diameter), which are very rapidly carried a long distance from the mirror and approach the direct action of the primary, one can only verify with any degree of precision one internode and node besides the node at the mirror itself. With smaller circles, for which the size of the mirror is more suitable, one can easily determine three internodes and nodes, including that at the mirror. The equidistance of the internodes and nodes is, as one can see, fairly satisfactory.‡

The most important result of our investigation arises from the comparison of the figures in the last three lines of the table. These show that the wave length obtained is in every instance sensibly equal in the case of propagation, through air and along wires, the quarter of either wave length being nearly equal to twice the diameter of the corresponding circle. From this it follows that *the rate of propagation of Hertzian electrical oscillations, through air, is very sensibly the same as that of those transmitted along a conducting wire.*§

## NOTES ON THE DESIGN OF MULTIPOLAR DYNAMOS.||

BY W. B. ESSON.

Though comparisons have frequently been made of the capabilities of machines having two poles and those having a greater number, I am not aware that the design of multipolar dynamos has yet received systematic treatment in any communication, or that a very satisfactory basis for comparison of the two types has up to the present been suggested. A perusal of the notes scattered about in technical journals, proceedings of societies, and text-books shows that the ideas on this subject are of the vaguest character, their expression having a most uncertain tone, and generally manifesting some erroneous notion. It is with a view of clearing the ground a little, and inducing some expression of correct ideas from members present, that these notes are brought before the Institution.

1. *Prevention of Sparking in Machines generally.*

In the Paper which I submitted for your consideration 12 months ago, attention was directed to certain empirical formulæ relating to the armature loads for direct-current machines. From the data furnished by a large number of examples, some of which were given in the Paper, an expression for the load which could be safely carried by armatures without causing sparking was obtained; this expression, though admittedly of an arbitrary character, having been proved by my own experience, and that of my colleagues, to have been of some service. In that Paper the term "ampere-turns" was employed to denote the product of the number of conductors on the exterior of the armature and the current carried by each, and I am afraid this may have led to some confusion; at least, so it appears from the discussion. In order that there shall be no misunderstanding in the present case, I shall call this product, quite irrespectively of the number of poles, the *volume* of current carried. The volume is, therefore, the total current flowing parallel to the armature shaft, independently of direction and whatever the number of poles, and it is obtained by multiplying the conductors on the exterior of the armature by the current flowing in each; or, considering the exterior winding as a copper cylinder, it is the total current flowing in it parallel to the axis.

In his Paper on "Armature Reactions," read here last year, Mr. Swinburne had worked out the limiting load from a theoretical point of view, and those who were present will remember that to obtain the results given in his Paper, the author assumed that the brushes were placed almost close to the polar tips. So far as the practical consideration of the subject goes, it matters little, I think, whether this is strictly accurate or not; because, while moving the brushes back from the tips increases the ampere-turns producing the cross field, the magnetic resistance of the cross circuit is at the same time increased, due to the interposition of an increased air-gap. For the moment, however, it will be assumed that the brushes are somewhere near the pole-tips—in their vicinity, let us say—and that the only conductors concerned in producing the cross field are those covered by the pole-pieces. This is sufficiently near the truth for our purpose. Under these circumstances the magnetising force in ampere-turns producing a cross field is, of course, $\frac{v\,\phi}{360}$, where $v$ is the volume, and $\phi$ the angle embraced by each pole-piece in degrees. Call $l$ the length of the air-gap, measured from the surface of the armature core to the polar surface, and I the induction per square centimetre which would be produced in the gap due to the field magnets alone. When a current flows in the armature the field is weakened at the pole-tips nearer the brushes, and strengthened at those farther from them. Imagine that the armature is loaded so that the forward induction under the nearer pole-tips is just balanced by the cross induction, and we have $\frac{v\,\phi}{360} = 2\,l \times \cdot 8\,\mathrm{I}$, assuming that the components of the cross circuit, other than the air-gap, have no resistance. According to this equation, with a value $v = \frac{576\,l\,\mathrm{I}}{\phi}$,* the forward and cross induction at the pole-tips would be equal, the field would be *nil* at the brushes, and, the machine being unstable, any increase of current would at once cause great sparking.

The above expression gives what might be called the theoretical load limit, on the assumption that no field is required for reversing

* The sensitiveness of the micrometer screw is a very important element in this branch of research, especially with small circles which only give very feeble sparks. We employed finally a screw giving $\frac{1}{150}$th of a millimetre.

(†) The intensity of the spark being weaker in this experiment than in the case of wires, and diminishing, moreover, much more rapidly as one goes further from the primary, observations are always less clearly defined than with wires. In order, therefore, to work under good conditions it is necessary to give the primary dimensions appropriate to the resonator. The limits between which one can conveniently observe the phenomenon of multiple resonance are less wide than with wires, but they can easily be made to vary by 100 per cent. or even more.

‡ Hertz places the first node at a certain distance behind the mirror. This disturbance of the extremity does not seem to be deducible from our experiments. As is to be seen from the table, the first quarter of a wave length does not show any sensible systematic difference compared with the rest.

§ We have already made this statement in a preliminary communication on this subject, made to the Société de physique et d'Histoire Naturelle de Genève, at its meeting of May 1, 1890 ("Archives des Sciences Physiques et Naturelles," Vol. XXIII., p. 557), but we have entirely reinvestigated the matter, varying the conditions of the experiment in a number of ways, and it is this work which we summarise here. Lecker, of Vienna, for his part has found by an entirely new method that the rate of propagation of the electrical oscillation along a wire is that of light.

|| Paper read before the Institution of Electrical Engineers, April 9, 1891.

* I have pointed out to Mr. Swinburne that the equations $\mathrm{A} = \frac{10\,b\,g\,\mathrm{B}_a}{\theta^2\,r}$ and $\mathrm{A}_2 = \frac{10\,\mathrm{B}_a\,r\,\mathrm{R}\,l}{v^2}$, which he gave last year on page 266 of his reply, ought to be $\mathrm{A} = \frac{5\,b\,g\,\mathrm{B}_a}{\theta^2\,r}$ and $\mathrm{A}_2 = \frac{20\,\mathrm{B}_a\,r\,\mathrm{R}\,l}{v^2}$ respectively. In looking over his Paper and reply, Mr. Swinburne finds other slips, which he will probably correct as discussion on the present Paper proceeds.—W. B. E.

the current in the sections as they pass the brushes, but it need scarcely be pointed out that in practice the volume is always much under what would be given by the formula. In the nature of things, one expects in the dynamos of different makers a considerable variation in the relation which the actual load bears to the limit above indicated, and such differences undoubtedly exist; but while one finds, on examining a large number of machines, several under, in few cases are there any having for $v$ a greater value than half that given by the equation. This large margin must be considered in the light of a safety factor, for it would be folly to build machines the commutators of which would be liable to ruin by an occasional increase of current over the normal. No one expects machines to stand, in continuous working, a current of 50 per cent. over their normal output, for the rise in temperature would then be excessive; but, from the sparking point of view, this increase in a well-designed machine ought to make but little difference to it. Generally, the relation existing between the volume, gap dimensions, and induction in the best machines is expressed approximately by the equation,

$$v = \frac{288\, l\, I}{\phi} \quad . \ . \ . \ . \ . \ . \ . \ . \quad (1)$$

which gives, I consider, a very good rule for use in practical work. According to this, the working volume has about half the value expressing the absolute limit, this relation indicating the margin of safe working dictated by practice and experience. The formula expresses, in fact, an empirical relation which has a certain degree of flexibility. But with such a large margin it will be readily perceived that the strict accuracy of our assumption about the position of the brushes is of trifling importance, as is also our assuming that the whole of the magnetising force of the cross field is spent in the air-gap.

It is easy to translate the above expression into the form I previously used for cylinder armatures. Call $r$ the radical depth of the armature core, $w$ the width of the pole-piece, and $I_2$ the induction in the core. The induction I in the gap is $\frac{2\, r\, I_2}{w}$; and substituting for I its value, we have

$$v = \frac{576\, r\, I_2\, l}{w\, \phi} \quad . \ . \ . \ . \ . \ . \quad (2)$$

Taking the induction in the armature core at from 17,000 to 18,000 C.G.S. per square centimetre, and inserting an average value of $\phi$, we get for bi-polar Gramme-wound machines the expression,

$$v = \frac{r\, l\, 85{,}000}{w} \quad . \ . \ . \ . \ . \ . \ . \ . \quad (3)$$

which I had used for some time, and which was given in my last year's Paper. This is only a rough approximation, for, as Mr. Swinburne has pointed out, to be quite accurate the angle should appear in the denominator as in (1) and (2). The simplest form the expression can take is given in (1). This contains nothing but the length of the air-gap, the induction in it, and the angle of the pole-piece. It will be observed that it takes no notice of the diameter of the armature or of the number of poles. So far as the sparking limit is concerned, it gives a rule which may be employed in designing machines of any size and with any number of poles.

### 2. *The Relation of* v *to the Diameter of the Armature.*

But besides taking care that the armature load does not approach the sparking limit, we must provide ample surface for getting rid of the heat generated in the conductors. The first thing to be settled in designing a new machine is what this amount of heat shall be; or, in other words, we must fix the ratio which the energy appearing at the terminals shall bear to the total electrical energy produced. Having settled this, sufficient radiating surface must be allowed to prevent too great a rise in temperature—a point to which due consideration has already been given.

The principal factors which determine the relation of the volume to the diameter of the armature are efficiency and temperature. It will be seen that the equation (1) gives no direct information respecting the diameter for a given volume, and as long as I, $l$ and $\phi$ remain unchanged, the tendency to sparking would be the same whatever the diameter. But it is not so with the heat generated or the temperature rise, for assuming $v$ and $l$ to be related as shown, the smaller the diameter, the greater would be the temperature. To carry a given volume we must have, consistent with the waste of power permissible, a certain section of copper; and this copper should be disposed so that a cooling surface is provided sufficient to keep the rise in temperature within the specified limit, while the gap, being of sufficient length to prevent sparking, should have only the dimensions necessary for accommodating the conductors and allowing of proper clearance.

Through the kindness of members of the Institution and others, who have liberally supplied me with figures, I have been able to ascertain the nature of the relation between the diameter and volume existing in all the best known machines, from the smallest to the largest sizes. The figures refer to both cylinder and drum-wound armatures, and include machines with two, four, six, and eight poles. Though I am not at liberty to publish the data in full, the general results are given. There is not so much agreement between the dynamos of different makers in respect to this relation as might have been expected, and for $v$ we have all kinds of values, ranging from 200 to 1,000 times the diameter of the armature in centimetres. If full advantage of the length of the air-gap were taken, and the thickest possible conductor used in each case, the diameter, to give a uniform temperature for all sizes, would be about proportional to the square root of the volume; but there are several reasons why this proportion should not obtain in practice. With this relation the ratio of the stray to the useful field would increase with the diameter, thus entailing an extravagant expenditure of energy in producing the requisite gap induction. Again, while the total field through the armature would increase simply as the diameter, the volume carried would increase as the *square* of the diameter, this being at variance with the well-established rule that the total field through the armature increases rather than diminishes relatively to the volume as the size is increased. It will be understood, of course, that precisely the same result is arrived at whether we consider the volume fixed and endeavour to find the best diameter, or consider the diameter fixed and seek for the best volume. It is simply a question of obtaining the most economical construction, having regard to cost of materials, efficiency, prevention of sparking, and temperature limit, though the figures at my disposal show estimates of the relative values of these several factors to be by no means uniform.

Though the relation lacks definiteness to some extent, I find in the data of a large number of machines indications sufficiently pronounced to justify us in regarding the volume carried by the armatures of two-pole dynamos as proportional to the diameter for all sizes. In designing cylinder machines the value of $v$ may be taken as 400 times the diameter of the armature in centimetres, while for drum armatures the volume is obtained by multiplying the diameter by 600.* The cylinder armature has for a given volume a larger diameter, because of the influence of the interior wires. These being heaped inside to one and a-half or twice the depth of the exterior winding, also being longer, a larger diameter is required for a given volume, both from efficiency and temperature considerations. Necessarily, the relations here given are not of a hard-and-fast character, and may be varied considerably. But whatever the proportion adopted, it is absolutely essential that the sparking limit already considered be not too closely approached.

In machines having four and six poles the same average relation between the volume and diameter holds in practice for both cylinders and drums. In the calculations which follow these figures will therefore be adopted.

### 3. *Output of Direct-Current Armatures.*

If we call N the total number of lines of force entering the armature from all the poles, however many, and $n$ the number of revolutions per second, the average E.M.F. generated in each conductor is, of course, $N\, n\, 10^{-8}$. If C be the total current flowing, each conductor will carry with the sections coupled in the ordinary way $\frac{C}{p}$ amperes, $p$ being the number of poles. The electrical work due to each conductor, is $\frac{C}{p} \times \frac{N\, n}{10^8}$; and the total work, $\frac{w\, C}{p} \times \frac{N n}{10^8}$, where $w$ is the number of conductors, counted all round the exterior of the armature. The quantity $\frac{w\, C}{p}$ is what we have called the *volume*, and we get for the total electrical output in watts the expression,

$$W = N\, n\, v\, 10^{-8} \quad . \ . \ . \ . \ . \ . \quad (4)$$

which is quite independent of the manner of coupling up the armature sections. It will be evident, I think, that with the same relation existing between $v$ and $d$ for two, four, and six poles, the output of an armature of given diameter and length, running at the same speed, is quite independent of the number of poles. It matters not whether N be furnished by two poles only, or by four poles of half the angular width, provided its value remains unaltered.

The volume, then, may be expressed in terms of the diameter. The quantity N may be expressed in terms of the diameter × length of the armature. Taking an induction of 5,000 C.G.S. units per square centimetre in the air-gap—a very usual figure—and assuming that the fraction of the armature circumference covered by the pole-pieces = 2·25 $d$, we get, calling L the length of the armature in centimetres, 11,250 $d$ L as the total number of lines of force entering the core. Call this, in round numbers, 12,000 $d$ L. Substituting for N and $v$ their values, the output becomes for cylinder armatures

$$W = \cdot 048\, d^2\, L\, n \quad . \ . \ . \ . \ . \ . \quad (5)$$

* In my last Paper the number given was 570. This I now amend as above.—W. B. E.

Digitized by Google

and for drum armatures

$$W = \cdot 072\, d^2 L n \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

This applies to all direct-current machines, whether bi-polar or multi-polar; though it will be understood, of course, that the induction in the gap may be greater or less than what has been assumed. In that case the coefficients ·048 and ·072 would be altered, without changing, however, the form of the expression.

4. *Output of Alternating-Current Armatures.*

The armature loads for alternators, though producing a cross magnetisation, as in direct-current machines, raise no considerations, of course, as regards sparking. But on account of the greater proximity of the poles, and the greater stray field resulting, it is desirable to make the layer of copper on the armature core as thin, and the air-gaps as short as possible. As a consequence, probably, of the increased ratio of stray to useful field, the induction is less in the gaps of alternating than in those of direct-current machines. Here it will be assumed that the virtual induction is 4,000 C.G.S. units per square centimetre, meaning that this represents the induction to which the resultant E.M.F. is due. The impressed E.M.F. is greater than the resultant, and the induction due to the field magnets alone is greater than 4,000; but what I am dealing with is the field resulting from the inter-action of the magnet and armature fields; it is the field to which the resultant E.M.F. = C R is due, this and the current being coincident in phase. Usually the poles cover a fraction of the circumference = 1·5 *d*, the value of N for alternators being then 6,000 *d* L. About half the circumference being covered with wire, under usual conditions of temperature and efficiency we have for *v* a mean value of 400, which gives for the product of mean resultant E.M.F. and mean current = ·024 $d^2$ L *n*. In some cases, as in the Westinghouse machine, the conductors cover considerably more than half the circumference, and *v* is therefore greater. But here, on account of the differential effect produced on the separate wires of the same section, the added turns have nothing like a proportionally increased value, and the expression will give approximately the value of the product of mean resultant E.M.F. and mean current, even in these machines. Assuming that the E.M.F. is a sine function of the time, to get the watts we must multiply by $\frac{\pi^2}{8}$, which gives us, therefore, as the output of the alternator,

$$W = \cdot 0296\, d^2 L n \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

or rather over 40 per cent. of the work done by a drum-wound direct-current machine having an armature of the same external dimensions. Some comparisons have been made of the output of direct and alternating machines of the same weight, but these, in the nature of things, must be misleading. The two types are quite unlike in their proportions, as Figs. 1 and 2 show, and no one would think of making them the same. Fig. 1 represents the magnetic system of a four-pole direct, and Fig. 2 that of a 12-pole alternating machine of the same output; and while it will be observed that the iron parts—core and yoke-rings—are much heavier in the former, it will be noticed that the copper in the magnet coils is much heavier in the latter. In fact, though the iron in the alternator is only 55 per cent. of that in the direct-current machine, the copper required is no less than 250 per cent. It is difficult, then, to understand what useful purpose is served by comparisons such as I have alluded to.

FIG. 1.

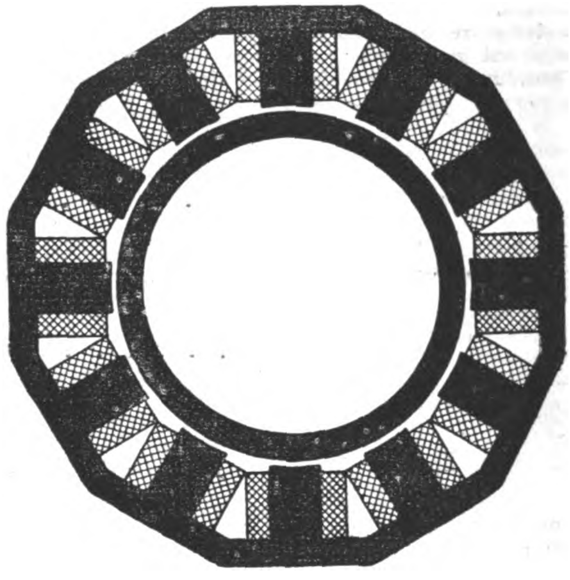

FIG. 2.

5. *Relation of Air-gap to Diameter of Armature and Number of Poles in Direct-Current Machines.*

Having established the proportionality of the volume and diameter, it is easy to find the relation which must exist between the diameter and length of air-gap for any particular angle of embrace in order that sparking may not occur. I need not take up time ringing changes on the several equations, as to obtain the relation now referred to, all that has to be done is to substitute for *v* in (1) its value in terms of the diameter accordingly as the winding is of the cylinder or drum type, and find the connection between *l* and *d*. Preserving the same safety factor throughout, it will be found that two-pole dynamos with a mean gap induction of 5,000 C.G.S. units per square centimetre, and pole-pieces embracing an angle of 130deg., must have—the volume being related to the diameter as described—a gap of not less than ·036 *d* if cylinder-wound, or ·054 *d* if drum-wound. As will have been observed, the air-gap may diminish as the induction is increased or as the volume is reduced.

But, as is also seen from the equation, the gap required for any particular volume is proportional to the angle of embrace, and if we substitute for two poles a greater number of correspondingly less angular width, working with an increased diameter and volume without a proportionally increased gap is made possible. This is where the advantage of the four, six, or even eight-pole machine comes in. Keeping to two poles, increasing the diameter requires either a proportional increase in the gap, whether the space is required for the conductors and clearance or not, or an increased induction, or a diminished polar angle, or a combination of these. In either case, the magnetising force spent in the gap is increased; and, other things remaining the same, obviously it would be of some advantage to adopt a construction which, while producing no greater tendency to sparking, would admit of the air-gap being reduced until its length was just sufficient to accommodate the conductors and allow of the necessary clearance. The work done by an armature of given external dimensions we have seen to be quite independent of the number of poles, and the choice of this number can only be a question, therefore, of structural and working economy.

6. *Dimensions of the Armature.*

It has been observed that the output of an armature is proportional to $d^2$ L; and the induction being the same, the weight of the core for a given number of poles must be proportional to the output, the radial depth increasing directly as the diameter, so that a proportionally increased field may be carried. The number of poles being fixed, the weight of the core for a given output may be taken, therefore, as approximately constant, whatever the ratio of L to *d*.

As the number of poles is increased, the induction remaining the same, the radial depth of the core is diminished in proportion, and, within the limits of practice, we may make the further assumption that the weight is inversely as the number of poles. The money value of a reduction in the weight of material due to increasing the poles can easily be arrived at.

Digitized by Google

The power wasted in hysteresis is proportional to the weight of iron magnetised, and to the number of reversals per second. The weight being inversely, and the reversals directly, as the number of poles, the power wasted is for a given output the same; furthermore, as the output is proportional to the speed, we may say that for a given induction the loss in hysteresis is about proportional to the output only, without reference to speed of rotation, weight of core, or number of poles. If it be more important to reduce the loss by hysteresis than to reduce the weight of material, it can, of course, be done. It is a point for the designer to consider.

So much for the core; let us now consider the copper part. Taking Gramme-wound armatures having an interior opening equal to ·66, or two-thirds of the core diameter, it is found—the output, speed, and temperature being predetermined—that the ratio of L to $d$ may vary through a considerable range without making any great difference in the weight of copper or efficiency. For instance, the most efficient relation being $L=\frac{d}{3}$, it may be varied on the one hand till $L=d$, or on the other till $L=\frac{d}{6}$, without increasing the copper by more than about 10 per cent. Of course the watts wasted in the armature are correspondingly increased, but within the limits of the large variation mentioned the reduction in the electrical efficiency of the machine is under one-half per cent. In two-pole machines L varies from ·5 to 1·5 $d$, the normal relation being about $L=d$. As has been seen, the gap has to be increased in proportion to the diameter, unless a greater number of poles be employed; and the disadvantage of an increased magnetising force would, in machines with only two poles, counterbalance the slight advantage of getting the armature dimensions nearer the best proportion. When the poles are increased, however, the gap may remain fixed, and if the radial depth of the core be correspondingly diminished, the proportions for least copper and highest efficiency are altered: thus in a four-pole Gramme we can work from $L=\frac{d}{3}$ up to $L=\frac{d}{12}$ without a greater variation than 10 per cent. in the weight of copper. Observe, this is a question differing altogether from the one which was considered in my former Paper. In that case the length and radial depth of the armature over the winding were fixed, the problem then being to find the best relation of copper to iron. Here both radial depth and length of core alter, also the peripheral velocity, though the revolutions per minute remain the same. Why the velocity is allowed to alter will be immediately apparent; I only show at the moment that the dimensions of the armature may have their relations altered considerably without making any considerable difference to the weight of copper or efficiency.

To drum-wound armatures precisely the same reasoning applies. Here, speed and temperature being fixed as before, the best proportion for two-pole machines is about $L=3{\cdot}3\,d$; but because of the distance between the bearings which such a relation would necessitate being inconveniently great, we rarely find $L=2\,d$ exceeded. The latter requires about 5 per cent. more copper than the former; while for the usual proportion, $L=1{\cdot}5\,d$, 12½ per cent. more is required than for $L=3{\cdot}3\,d$. The variation which can be made without overstepping the limits of economy has a smaller range in drum than in cylinder machines, owing to the greater relative importance of the end wires, because of their greater length. If the length of the core is reduced below $L=1{\cdot}5\,d$, the copper in machines with two poles increases rapidly; but if the number of poles be increased, the length of the end wires being shortened nearly in proportion, the core length may be reduced to a fraction of the diameter without sacrifice of copper or efficiency. In a four-pole machine, for instance, the same copper is used with $L={\cdot}5\,d$ as in a two-pole one with $L=2\,d$; while for six poles, without increasing the copper, the relation may be as small as $L={\cdot}25\,d$. The effect of adding poles when the diameter is relatively great is not so noticeable in Gramme-wound machines, as the end wires are less important.

All the above facts go to prove that if there is anything to be gained, as regards the production of the field, by increasing the diameter of the armature and the number of poles, there is nothing, considering the armature by itself, to be lost by it. It may, in fact, be rather an advantage, because the weight of the iron core is reduced. It is true the peripheral velocity is increased; but this does not matter in the least, provided a certain limit is not exceeded. Opinions differ as to what the limit should be, some machines working at 50 feet per second, others at 100, and a few as high as 125. But there is no reason whatever why any properly constructed armature should not run at a periphery speed of 100 feet per second; and provided this velocity is not exceeded, any advantage which may be obtained by a relatively large armature and increased number of poles should be secured.

*(To be continued.)*

## INDUCTIVE DISTURBANCES IN TELEPHONE CIRCUITS.*

BY J. J. CARTY.

It was not known until 1838 that the earth might be used instead of a return wire in the circuit of a telegraph line. This fact was discovered by Steinheil, while making experiments to determine whether the track of a railroad could be used to complete the circuit instead of a return wire. Steinheil's discovery has been considered as one of the most important in the art of telegraphy, and since his time it has been the almost universal practice to use the earth as a return in telegraph circuits. When, however, the earth return is used with the telephone, it is found that owing to the extreme sensitiveness of that instrument, many foreign currents, which would produce but little effect on telegraph instruments, become a source of serious trouble. For this reason, in telephony it is often necessary to use a complete metallic circuit. Thus it has come to pass that a return to the original practice of employing metallic circuits, as in the case of the crudest telegraph instruments, is now regarded as a most important improvement in connection with that most highly developed of telegraph instruments, the telephone. To obtain complete freedom from inductive

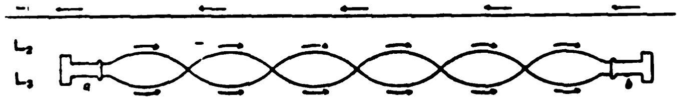

FIG. 1.

disturbances in the telephone, it is necessary not only to use a metallic circuit, but to place the two wires composing the circuit in a special relation to the source of disturbance. One of the methods of so arranging the wires is shown in Fig. 1. In this case the two sides of the circuit $L_2$ and $L_3$ are twisted spirally about each other, so that their average distance from the dirturbing wire $L_1$ shall be the same. With such a plan, the telephones $a$ and $b$ are not affected by induction from the wire $L_1$. This fact has usually been explained by assuming that a current, commencing to flow in $L_1$, tends to induce two currents in the opposite direction to itself, one in the wire $L_2$ and the other in the wire $L_3$; that both currents are of the same strength because the average distance of $L_2$ and $L_3$ from the disturbing wire $L_1$ is the same; and that the telephones $a$ and $b$ are silent because they are acted upon by two equal and opposite forces. The above theory seems at first sight to be correct, and indicates the line of explanation adopted in many works treating of the subject.†

I have made a number of experiments which seem to prove that in the case described, the inductive action, instead of tending to produce a simple current in each side of the metallic circuit, actually does produce a number of different currents in each wire and in both

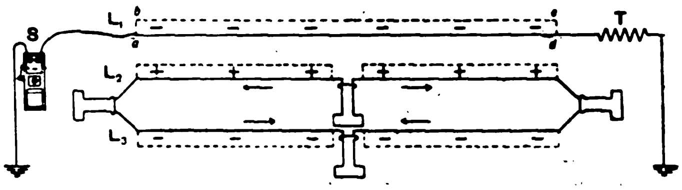

FIG. 2.

directions. In Fig. 2, $L_2$ and $L_3$ are two well insulated copper wires, 500ft. long and 3ft. apart. These wires are joined together at each end through an ordinary telephone. $L_1$ is a well-insulated wire similar to the other two, and placed within one-half an inch of $L_2$. At one end of $L_1$ is placed a Blake transmitter T, and at the other end is placed a subscriber's bell, S; $L_1$ being grounded at both ends as shown. When the transmitter T is operated, either by speaking into it, or by vibrating a powerful tuning fork in front of it, disturbances are produced at the end telephones.

If telephones are inserted at the centre of $L_2$ and $L_3$ it is found that at these points no sound is heard, while the noise of the end telephones continues as before. This constitutes a simple case of inductive disturbance, and can only be explained by assuming that the wire $L_1$ acts electrostatically upon the circuit composed of $L_2$ and $L_3$, or in other words, that we are dealing with a system of condensers in series, of which $L_1$ constitutes one plate, the earth another and the wires $L_2$ and $L_3$, two intermediate plates, which are

* Paper read before the American Institute of Electrical Engineers, March 17, 1891.

Digitized by Google

joined together through the end telephones. Let us assume that at a given instant the height of potential along the wire $L_1$ is represented by the lines *a b* and *c d*, and the charge upon $L_1$ by the rectangle *a b c d*. The presence of this charge, which we will say is of the minus sign, is accompanied by an equal but plus charge on $L_2$. This produces a minus charge on the wire $L_3$, which in turn acts upon the earth. Now we will assume that the potential of $L_1$ reduced to zero. This causes a restoration of the equilibrium in the circuit composed of $L_2$ and $L_3$, which is accompanied by a set of currents as represented by the arrows. The plus charge on $L_2$, flowing through the end telephones, neutralises the minus charge on $L_3$, thus leaving a neutral point at the centre of each of the wires $L_2$ and $L_3$.

In this and the succeeding experiments the induced charges are represented by rectangles. This is not a strictly accurate method, but as an error in this respect only affects the result quantitatively, and cannot alter the conclusions, I have adopted it on account of the simplicity of treatment which it permits. The potential along the wire $L_1$ at a given instant is represented as being constant, as it is found that owing to the high impedance in the instrument S, there is practically no fall of potential in the wire itself. Furthermore, it was found in the experiments about to be described that

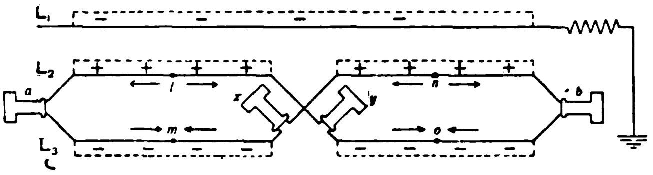

Fig. 3.

the results were the same, whether the disturbing wire was open or connected to earth through the bell S. There would be a fall of potential along the wire $L_1$ if it were of such a length as often found in practice, and the distribution of the charge would be modified accordingly. But as this fact would only affect the location of the neutral points, the question of the fall of potential will not be taken into consideration, and the disturbing wire will be shown open at one end.

Fig. 3 shows the same circuits as used in the previous experiment, except that the wires $L_2$ and $L_3$ are caused to change places at their centres, but are continued in the same plane, as in Fig. 2. This is what is called a "transposition." The telephones at the ends and in the middle are retained as before. Under these conditions, when the transmitter is operated, a diminished sound is heard at *a* and *b*; and *x* and *y*, instead of being silent as in the first case, now emit a sound of the same intensity as *a* and *b*. When telephones are placed at the quarters *l*, *m*, *n*, *o*, the sounds at *a b* and *x y* continue as before, but nothing is heard at *l*, *m*, *n*, *o*. The effect of this one transposition has been to reduce the disturbance at the end telephones *a* and *b*, and to cause a shifting of the neutral points from the centres to the quarters, and an increase of their number from two to four.

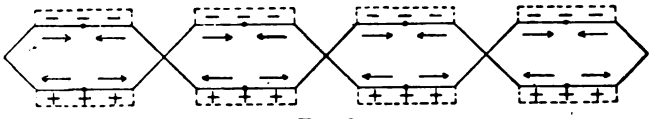

Fig. 4.

An examination of the induced charge shows how these results have been brought about. It will be seen by reference to Fig. 3, that there is on the first half of $L_2$ a positive charge, and on the second half a negative charge, and on the first half $L_3$ a negative charge, and on the second half, a positive charge. When the positive charge on $L_2$ discharges, half of it goes through the telephone *a*, and half through the telephone *y*. The positive charge on $L_3$ escapes in a similar manner, half going through telephone *x*, and half through telephone *b*. This produces four currents, two starting from point *l* and two starting from the point *n*. One of currents from *l* meets a current at *o* coming from the point *n*, and one of the currents starting at the point *n* meets a current at *m*, which started from *l*. The currents flowing through the end telephones in this case are not so strong as when no transposition is employed, because they are due to an induced charge which is represented by an area half as great. It is found that as the number of transpositions is increased, the number of neutral points is also increased, and that the area representing the charge which escapes through the end telephones is reduced. To obtain silence, therefore, it is necessary to increase the frequency of transpositions until the discharge through the end telephones is so small as not to produce sounds therein. Fig. 4 shows a circuit containing three transpositions, one at the centre and one half-way between the centre and each end. In this case, if we could neglect the resistance of the telephones, the current going through the ends would be reduced to one-fourth of its original proportions, and eight neutral points would be produced, one in each wire at the centre of each transposition.

In practice the impedance of the telephones must be taken into consideration, so that if in Fig. 3 the middle telephones *x* and *y* were omitted, the neutral points would be found to move towards the ends, and the currents flowing through the end telephones would be correspondingly reduced.

According to this theory of transpositions, if the instruments and distances between wires on a given circuit remain constant, for a given period of alternations in the disturbing wire, the number of transpositions necessary to obtain silence will depend on the E.M.F. of the disturbing wire, and the specific inductive capacity of the dielectric. An increase in the value of either of these factors will, if silence is to be maintained, require additional transpositions, their number depending upon the value of the change which is made.

Where the disturbing wire is placed at an equal distance from both sides of a metallic circuit, no noise is produced in telephones located in that circuit, and a balance once being obtained, it is

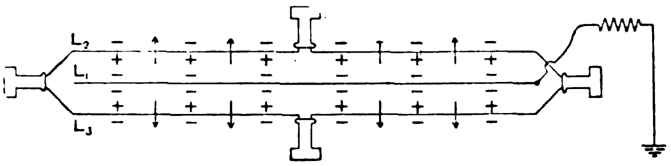

Fig. 5.

independent of both the E.M.F. of the disturbing wire and the specific inductive capacity of the dielectric. Fig. 5 shows such an arrangement of circuits—$L_2$ and $L_3$ are the two wires composing the metallic circuit placed the same distance apart as before, and the disturbing wire is at an equal distance from both. When the disturbing wire is in operation, no sound is heard at the end telephones, or at telephones located at the centres. This may be accounted for by assuming that at a given instant a negative charge is on the disturbing wire, which produces a positive charge on the inside of $L_2$ and $L_3$ and a negative charge on the outside of those wires; and that when the charge is removed from the disturbing wire, a set of currents is set up in the wires $L_2$ and $L_3$ in a direction at right angles to their axes, as shown by the arrows. In this case the flow is lateral, and no current passes through the end telephones or through telephones located at the centres. It will thus be seen that this method of arranging wires differs essentially in its action from the plan of using transpositions. Unfortunately, however, its practical application is limited to two circuits.

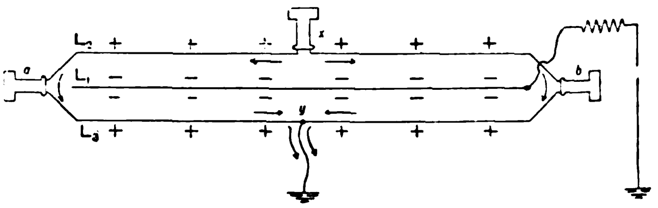

Fig. 6.

Where the disturbing wire occupies the position shown in Fig. 5, the flow in the conductors is lateral only when the wires $L_2$ and $L_3$ are insulated from the earth. If a ground be attached to the centre of $L_3$, as shown in Fig. 6, the flow of current becomes longitudinal, and the telephones *a* and *b* are found to be affected by loud disturbances, while the telephone *x*, at the centre of $L_2$, is found to be silent. This is because the disturbing wire, which we will say is negatively charged, induces a positive charge upon $L_2$ and $L_3$ and a negative charge upon the earth. The discharge in this case is effected by two currents starting from *x*, which thus becomes a neutral point, and passing through the end telephones to the ground as shown by the arrows. If the ground be removed from the point *y* toward the telephone *a*, the neutral point will be found to move toward telephone *b*, and if the ground be put at the centre of resistance of the telephone *a*, the neutral point will be found to be at the centre of the telephone *b*. This is well illustrated in Fig. 7, where *a* and *b* are telephones of special construction, admitting of the attachment of grounding-keys $K_1$ and $K_2$ at their respective centres. In this instance, when the disturbing wire is in operation and both keys open, no sound is heard at any of the telephones, the flow of current being lateral. If the key $K_1$ be closed, sound is immediately heard at telephones *x* and *y* located at the centres of $L_2$ and $L_3$, but the telephones

Digitized by Google

*a* and *b* are still silent. This is because the charge and discharge take place along the conductors $L_2$ and $L_3$ to and from the earth at $K_1$, thus passing through *x* and *y*, *a* being silent because the currents go through it differentially, and *b* is silent because it is located at a neutral point. To prove that current flows through telephone *a*, another telephone may be inserted in the ground branch at $K_1$, and it will be found to be loudly affected. If both keys $K_1$ and $K_2$ are closed, silence is again obtained in the four telephones *a*, *b*, *x*, *y*. In this case the charge and discharge from the wires $L_2$ and $L_3$ divide at the centre and flow back and forth at both ends, *x* and *y* being silent because they are at neutral points, and *a* and *b* are not affected by the currents which flow through them because of the differential action referred to.

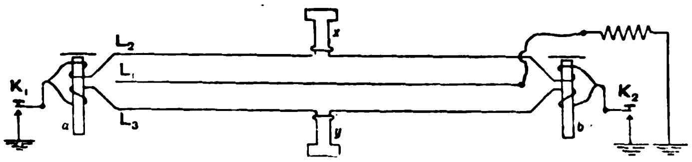

FIG. 7.

Two systems have now been described, one in which the induced current is lateral, and the other in which it is longitudinal. I think it follows from the foregoing experiments, that where wires are twisted about each other as shown in Fig. 1, both of these actions are combined. At the left hand of Fig. 8, a cross-section of the three wires $L_1$, $L_2$, and $L_3$ [Fig. 1] is shown. In this position the wires occupy a place with reference to each other exactly as in Fig. 2, and the tendency of the disturbing wire is to cause a longitudinal flow in $L_2$ and $L_3$. If repeated cross-sections of these wires are made, a point will be reached at which the three wires are disposed as shown at the right hand of Fig. 8, where it is seen that the disturbing wire $L_1$ is at an equal distance from $L_2$ and $L_3$, and the tendency is to produce a lateral flow. The actual currents produced must be the resultant of these two actions.

FIG. 8.

Fig. 9 shows a plan quite different in principle from anything heretofore employed. It is of interest not so much on account of any practical application which it may have at present, but because it is a very striking proof of the electrostatic nature of inductive crosstalk between telephone circuits. $L_1$, $L_2$, and $L_3$ are the same wires as used in the previous cases, $L_1$ being half an inch from $L_2$, with the addition of an extra wire $L_4$ placed half an inch from $L_3$ and joined by a conductor *w* with the disturbing wire $L_1$. $L_2$ and $L_3$ are three feet apart. When in this condition the transmitter is operated, no disturbance whatever is heard in the end telephones; if the wire *w* be disconnected, the usual noise is heard, but is found to disappear as often as $L_1$ and $L_4$ are joined together. This action is explained by the fact that $L_4$ is at the same potential as $L_1$, on account of being joined to it by the wire *w*, and acts with

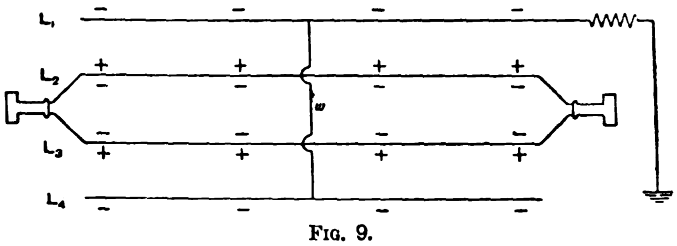

FIG. 9.

the same force on $L_3$ that $L_1$ does on $L_2$. The flow in this case is lateral, as indicated by the arrows; and the telephones are silent.

Neutral points may be produced in a circuit by the use of shunts. Fig. 10 shows the usual arrangement of circuits with the telephones *a* and *b* at the ends, and another telephone *x*, of equal impedance, branched between the two wires at the centre. In this case four neutral points are found, two in each wire. The currents produced by the discharge are indicated by the arrows. Thus by the addition of one shunt, the disturbing currents in the end telephones have been reduced one-half. If similar shunts were placed at the quarters, the currents at the end telephones would be still further reduced to one-quarter of their original strength. This plan is not a practical one, because of its shunting effect on the telephone current, but is of value as showing one of the actions which occur when instruments are bridged into metallic circuits. It is interesting to note that in Fig. 10 the telephone *x* is affected by a current twice as great as that which flows through either of the end telephones.

Before closing I shall describe one more experiment. In Fig. 11, $L_1$ is the disturbing wire and $L_2$ is a grounded telephone circuit placed one-half an inch from $L_1$. At the centre of $L_2$ there is an ordinary telephone repeating-coil or transformer C, containing two windings *e* and *f* of copper wire, each having a resistance of 160 ohms. One end of each winding is grounded, and the other end is connected to the line as shown. Assuming that the impedance of each telephone is equal to that of each coil of the transformer, a neutral point will be found at the centre of each half of $L_2$,

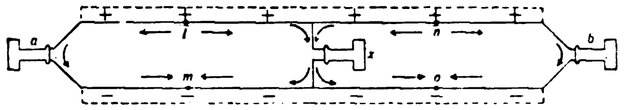

FIG. 10.

and the disturbing currents flowing through the end telephones will be only half as strong as though the transformer were omitted. If now the connections of the transformer be reversed so that the discharges from the two sections of the line pass through it in opposite directions, no magnetism will be produced in the core *k*, and consequently the transformer coils offer an easier path to the discharge. This causes the neutral points to move toward the end telephones, and consequently reduces the disturbance still further. I have not had an opportunity of trying this experiment with a transformer whose coils contained a low copper resistance and a high inductance; but, according to theory, we might expect that such a transformer having its coils connected

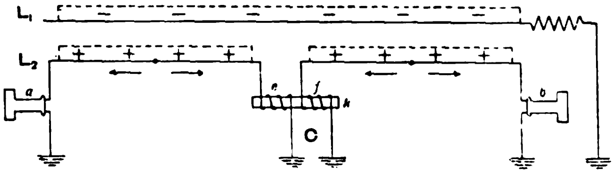

FIG. 11.

differentially, should free a grounded line of considerable length from cross talk and other electrostatic disturbances. The number of such coils which can be worked in a given line is, of course, limited, but with properly designed apparatus a large number of them might be used. This arrangement is also interesting when considered with reference to electro-magnetic induction, and brings to mind a question as to whether we may not at some future time abandon the use of metallic circuits and again make use of Steinheil's discovery.

### SUPPLEMENTARY NOTE, COMMUNICATED BY MR. T. D. LOCKWOOD.

If Mr. Carty continues to hold the views of two years back, I understand him to believe that electrostatic in contradistinction to electro-magnetic induction is chargeable with the major amount of discredit as an agency in disturbances on telephone lines. From long experience and observation, it appears to me that the several agencies in causing disturbing phenomena in telephone circuits which manifest themselves in the telephone receiver preponderate largely in accordance with the conditions of the circuit; that the environment (to use the language of social science) of a telephone circuit has a good deal to do with its behaviour. Thus a line which has considerable leakage uniformly distributed throughout its length will suffer very little from electrostatic induction either manifested as a disturbance, or as a retarding agency. If we exhaustively examine the literature of the subject we shall find that the idea that electrostatic phenomena are concerned in disturbances of telephone and telegraph circuits, is by no means new. Mr. Culley presented a Paper once upon this subject, before the Society of Telegraph Engineers, which Paper, together with a most instructive discussion, is published in the journal of that Society, and Mr. Preece and myself from time to time have also repeatedly referred to it.

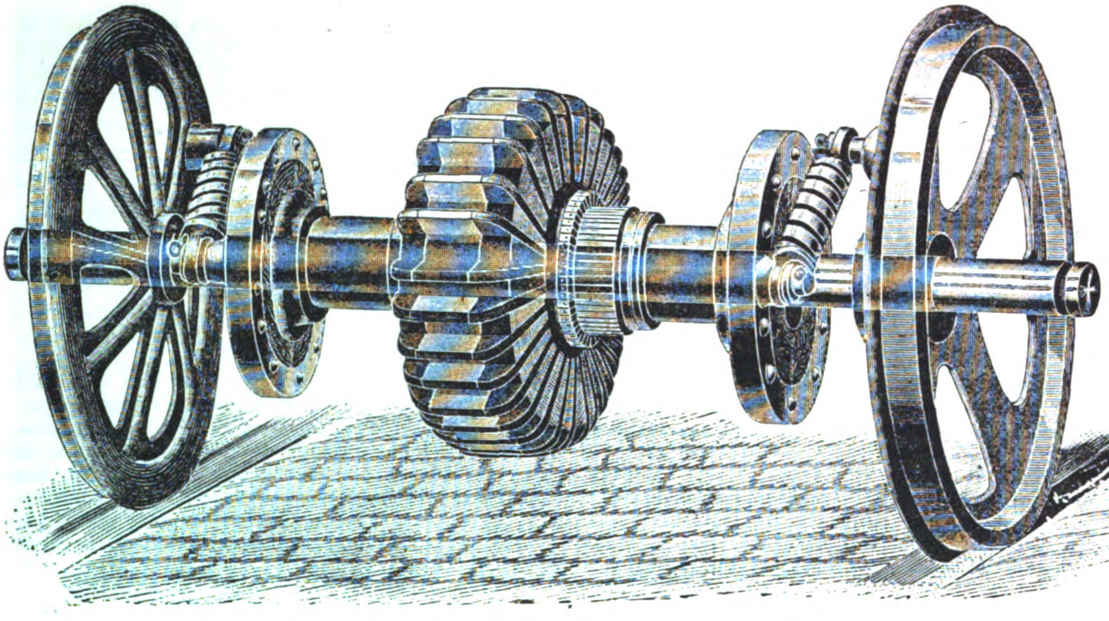
I think, while he is undoubtedly right in attributing a large share of inductive disturbance in telephone lines, that he does not give sufficient weight to the equally undoubted fact, that electro-magnetic induction is also an important factor; and that, as I have already pointed out, the conditions of any individual circuit largely govern its action. An interposed plate for an envelope of metal between the disturbed and disturbing circuits will, if sufficiently thick, and if united to earth, screen so much of the induction as is electrostatic in its origin; but it will not screen electro-magnetic induction; and thus whenever it is worth while, the sources of inductive disturbances can be analysed. And while the inductively neutral metallic circuit—the circuit with two wires closely

Digitized by Google

adjacent and twisted together—is indeed a specific against electro-magnetic inductive disturbance, it also tends to increase the retarding effect of electrostatic induction exercised between the two wires of the circuit. In conclusion, I wish to suggest that inasmuch as the telephone only notes electrical changes, we cannot accurately say that sounds can be produced in it by electrostatic charge. It is the fact that it is the motion caused in the act of forming and dissipating charge that produces the disturbing sound. But a charge in the act of formation or dissipation is practically a current; and as a current in the act of change, it necessarily varies also the magnetic field constituted by the circuit within which it is circulating; and as a further consequence therefore sets up in an adjacent and disturbed circuit electro-magnetic induction currents. Thus the disturbing action is a compound one; operating first by the successive inductive charges and discharges induced in the disturbed circuit, by the changes occurring in the disturbing circuit; and secondly, by electro-magnetically induced currents developed in the disturbed circuit by changes in the magnetic field constituted by the disturbing circuit.

## THE SHORT GEARLESS TRAMWAY MOTOR.*

In the accompanying figure is represented the latest type of railway motor constructed by the Short Electric Railway Company, of Cleveland, O. All gearing has been eliminated from this motor. It is placed directly upon the car axle and makes 100 to 150 revolutions per minute. Referring to the accompanying illustration, it shows a pair of wheels with their axle running through the hollow armature shaft of the gearless motor. This hollow shaft is made of steel, and is about six inches in diameter on the outside, with an opening inside of nearly five inches, so that there is a clearance between the axle of the car and the inside of this hollow shaft of an inch air-space all round. In the centre of this shaft the armature and the commutator are fastened, and on each end of the armature shaft is keyed two heavy crank discs made with an iron hub and rim, and a wooden web. This thoroughly insulates the armature shaft from the rim of the crank wheel. This crank wheel rim, as will be seen, has upon one side a crank pin. The car wheel has a crank pin also, and between the two is stretched a heavy coil spring, capable of pulling with a very slight elongation 2,500 or 3,000 pounds. The power of the motor in turning the wheel is transmitted through these springs, and the wheel is readily turned in the direction in which the armature tends to rotate. Just inside of the crank discs are the bearings of the hollow armature shaft in the motor frame. The motor frame is made of two peculiarly-shaped castings of steel, with arms projecting forward and backward. These arms rest on rubber cushions placed on channel bars which go from side to side of the motor frame. In this way the armature is held up in the frame and away from the axle, and the entire weight of the motor is supported by these spring cushions and by the car boxes outside of the wheels at the points where the car body is supported. None of the weight of the motor falls on the axle inside of the wheels. The spring cushions upon which the motor frame rests are limited in their movements to a fixed distance so that the inside of the armature shaft cannot come down upon the axle. By these means the motor is carried entirely on springs. Our contemporary does not describe the magnets. We presume they are of the ordinary Short pattern.



Short Gearless Tramway Motor.

## THE COST OF THE GENERATION AND DISTRIBUTION OF ELECTRICAL ENERGY.*

BY MR. R. E. B. CROMPTON, M.INST. C.E.

Machinery for the supply and distribution of electrical energy came under two heads, namely, the generating-plant, comprising boilers, steam dynamos and switching-apparatus, and the distributing-plant, consisting of a network of conductors, supplemented in some cases by accumulators, and in other cases by transforming-apparatus to change energy from high-pressure to low-pressure.

*Part I.—Cost of Generation.*—With the high efficiency of 96 per cent. which was now attainable in dynamos, the cost of the electrical energy ought only to be a small fraction in excess of that of a corresponding amount of mechanical energy. The wide difference between the calculated amount and the figures attained in practice were considered. The three items of cost, namely, material, labour, and up-keep, were influenced chiefly by the "load-factor," the design and arrangement of the plant, and the local cost of material and labour.

The author had given the name of load-factor to the relation which the actual output of any given plant bore to what would be its output if it were worked continuously at the full load. In order to compare the relative economy of fuel, water, or other material used in generating electrical energy, he had fixed on a consumption of 25lb. of water and 2½lb. of Welsh coal per unit generated as a standard which might be reached in the future, although nothing approaching those figures had yet been attained in practice.

He then proceeded to describe the electrical supply stations from which the data for the Paper had been obtained, namely, the Kensington and Knightsbridge Electric Lighting Company, and the St. James's and Pall Mall Electric Lighting Company. The load-factor of these stations varied from the exceedingly low figure of 2·5 for the Kensington station in the month of August to 41·5 on one occasion, which was the best load-factor of the St. James's and Pall Mall Company's station, and showed how these varying load-factors affected the cost of productions. It was pointed out that a limited use of storage-plant could reduce the consumption of fuel, &c., and shown by a diagram that the proportion of accumulators should be about 20 per cent., or 1-5th of the whole generating plant. The author recommended a return to the older type of internally-fired boilers; the chief cause of the small evaporation, in low load-factor stations, was the loss of heat incurred in getting

* Abstract of a Paper read before the Institution of Civil Engineers, April 7, 1891.

Digitized by Google

up steam in several boilers for only short periods every evening. Several types of boilers which had been found to have special advantages were described, one important consideration being that in electric light stations the space from front to back was frequently limited, so that a boiler which could be built up to a height of from 14 to 16 feet offered several advantages.

*Distribution.*—The cost of distributing electrical energy was made up of that of the up-keep of the distributing-plant and of the percentage of the energy which was lost by the fall of pressure in the conductors. It followed that the merit of competing systems was inversely as the cost of generating the units so wasted divided by the up-keep of the conductors. For instance, if in distributing 20,000 units to a given distance, system A wasted 1,000 units in a given time, the cost of up-keep for the same time being £10, whereas system B wasted 3,000 units at a cost of up-keep of £3, B was slightly better than A, because $\frac{3000}{10} : \frac{1000}{3} :: 300$ to 333. It was difficult to apply the method of comparison to the systems now in use as the cost of up-keep was not yet known with sufficient accuracy. The author's opinion was that whenever underground mains consisted of continuously insulated cables, the sum required for up-keep would be not less than 4 per cent. of the original cost, and was not likely to exceed 7 per cent. When, however, the underground mains took the form of bare copper conductors with glass or porcelain insulators the cost of up-keep might be as low as from 1 to 2 per cent. In this connection the distribution system of the Kensington and Knightsbridge Company was described, and reference was made to the systems of supply for St. James's and Pall Mall, Westminster, Notting Hill, and for the St. Pancras Vestry, also that in use at Birmingham.

The Author had found difficulty in obtaining accurate accounts of the cost of distribution by the alternating-transformer system, but all the published accounts had shown that the total net cost per unit was greatly in excess of that of the low-pressure system. The Author had under his charge a plant of generating and distributing machinery on the alternating-transformer system for the public lighting of Chelmsford, a small private demand existing in addition. In this case the machinery was worked for long periods at a high load-factor, so that the cost of generating was exceptionally low, and as the load in the transformers was perfectly regular it had been possible to so proportion them as to be worked continuously at their maximum efficiency. A table showed the load-factors for this station for the months of August and December, 1890, and a 24 hours' load-diagram, taken on the 20th of January, 1891, was exhibited. The annual load-factor was found to be 31·0, and the pounds of coal per unit generated, 8·88; the pounds of coal per unit delivered, 10.70, hence the efficiency reached 83 per cent. But this was an extremely favourable example, and an alternating-transformer installation in a medium-sized private house in the Kensington district, tested by Professor Ayrton, was found to have a mean annual efficiency of only 53 per cent. The remedy for this defect in the alternating system consisted in what had been called "banking" the transformers. This meant that a district to be supplied with electricity should be laid with a low-pressure net-work, in all respects similar to that provided for the direct low-pressure system; but in place of the feeders, and at the point where the feeder-mains were connected to the network, a fireproof and incombustible chamber should be formed under the surface of the roadway. In this a number of transformers of graduated sizes were arranged, with the high-pressure mains connected to them, so that the transformers might be switched into action automatically as required, that was to say, during the hours of light load the smallest only would be in action, the others being automatically added as the demand increased.

Summarising his experience, the Author endeavoured to show:—(1.) The actual cost of generating and distributing electrical energy on the scale at which it was now produced, and with the machinery that was already installed. (2.) The direction in which improvements might be introduced to secure greater economy. (3.) The important effect of a variable load-factor, which might be almost entirely eliminated from the cost-sheets of those who desired to employ electrical energy continuously. (4.) That the losses on distribution in low-pressure supply were already so low that further improvement could not be expected. (5.) That the existing systems of alternating supply would have to be greatly modified if they were to be used in residential neighbourhoods having low load-factors.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *March* 30, 1891.

**The Overhead Trolley System in New York.**—It is again rumoured that an attempt will be made to introduce the trolley system on the Broadway and Third Avenue lines in this city, instead of the proposed cable. The advocates of electric traction have been decidedly encouraged by the action of the authorities regarding the proposed electric road in the upper part of New York City. Permission has been granted for the erection of the necessary overhead structure, and work will probably begin in the coming spring. Of course, to propose the use of overhead wires on Broadway means flying in the face of a certain section of public opinion, one, however, that is, for the most part, anything but intelligent in its opposition, and is only led on by newspaper excitement. No serious opposition is likely to come from the municipal government.

**Edison Slow-Speed Motor.**—The Edison Company announce the appearance of a new slow-speed motor. Mr. Edison has been for several weeks at the works in Schenectady, perfecting its details, and it is likely that something of a surprise is in store for us. Among other new machines a very neat little alternating current fan motor will be shortly placed upon the market. It is designed by Mr. William Stanley, jun. Mr. Stanley is also at work on a similar design of larger dimensions.

**Rapid Alternations in Transformer Work.**—Another active worker in the alternating field, Mr. Nikola Tesla, is continuing his very interesting experiments on extremely rapid alternations, and seems to be gradually evolving not only a vast amount of information, but some things that promise practical results from these extraordinary conditions. He has certainly done a great service if his work has convinced electricians of the desirability of increasing the frequency in alternating systems. Already the American practice employs nearly double the frequency common in Europe, and the figure is likely to be raised rather than lowered. The senseless opposition to alternating currents seems to have somewhat subsided now, and there is opportunity for more work in that line than ever before. The Thomson-Houston Company, too, is busily engaged in extending its alternating work.

**Storage Battery Traction in New York.**—Storage battery traction in New York seems to have come to grief. The cars that have been running on the Fourth Avenue line have practically suspended operations, and nothing is being done with them, or with the system. Financial troubles are reported to be at the bottom of the difficulty. Attempts have recently been made to utilise the alkaline storage battery. At least two inventors, Messrs. Entz and Slattery, have been working actively in that direction, although neither of them has seen fit to make public any results of interest. The alkaline battery did not meet with so signal a success in France that one feels much encouraged to expect any extraordinary results here.

## CORRESPONDENCE.

### SPARKING DISTANCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your issue of the 27th ult. contains an extract of a Paper, published in the *Electrical World*, of New York, describing some experiments on the striking distance of alternating electromotive forces, which were carried out at the laboratory of Prof. Elihu Thomson; and in your note concerning the same you refer to the importance (as pointed out by De la Rue) attaching to the form of the discharge points, as affecting the length of the sparks produced, also the need of more information regarding the form of the points used in the experiments described, &c.

In the published description of the experiments, it was stated that "the points were as sharp as the means at command rendered it possible to make them." I may add here that they were conical in shape, having a diameter at base = ·075in., and a height from base to point = ·5in. They were first shaped in

Digitized by Google

the lathe, and, while still kept slowly rotating, rubbed vertically on a fine whetstone until the sides of the cones were perfectly straight and smooth, and the points sharp. The points thus formed were sharper than ordinary needle-points, and, to keep them so, to prevent deformation when bringing them together, a little cushion of soft lead was slipped between them, the thickness of which was, of course, considered when computing the distance separating the points.

With what is said regarding the importance attaching to the shape of the points, I entirely agree; the curves shown clearly indicate the importance of this consideration. You do well in emphasising its importance, however, because the various statements which one finds on the subject indicate that its importance is not sufficiently recognised; thus, the writer of an excellent Paper recently published in one of our technical Journals states, quite briefly, that "to produce a spark one inch in length required a potential of about 100,000 volts." This may undoubtedly be true when particular forms of discharge surfaces are employed; if very sharp points are used probably less than one-fifth of the potential stated would suffice. When points become blunted—become more or less hemispherical in shape—the spark becomes shorter, and a curve showing maximum values of the ratios less irregular than is the case with very sharp points, when blunt points are used. Curves showing maximum and minimum resultsapproximate each other closely; with very sharp points, however, the discharges are erratic.

One result obtained while making the experiments described (discharge between point and sphere at about 700 volts) subsequent attempts failed to reproduce. It would certainly appear in this case that an unusual combination of favourable conditions conspired to precipitate the discharge. The object of the experiments, however, was to find the maximum striking distance; consequently, the greatest spark lengths observed are those shown in the curves. I would here point out that when data of this kind is wanted for application under working conditions, the thing which it is generally required to be known is not the average spark length, but the greatest spark length which the electromotive force used may be expected, under the most favourable conditions, to produce.

Concerning disruptive discharges, Mr. J. E. H. Gordon aptly quotes Prof. Clerk Maxwell, who has compared such experiments to the splitting of a piece of wood by a wedge. The possibility is stated of determining the average force necessary to split the wood, also the impossibility of saying how closely the force required in any particular experiment will approximate that average. If we think of the wedge as represented by the axe of the wood-chopper, it becomes obvious how much the force of the blows necessary to split the wood depends upon the more or less perfect condition of the axe's edge. Everyone who is at all familiar with the experiment of splitting thick glass plates with Ruhmkorff coil discharges, and the precautions which are to be taken to concentrate the potential to what is virtually a point on each side of the dielectric layer, will readily understand that the analogy of the wedge is by no means a far-fetched comparison.

The subject of disruptive discharge is so seldom discussed without some allusion (generally speculative in its nature) being made to the discharges occurring in the great laboratory of nature, that the writer is tempted to be orthodox, and in order to attest the same, will here introduce an idea which he has heard expressed by Prof. Elihu Thomson, to the effect that the phenomenal values of potential which have sometimes been spoken of as producing lightning discharges may be more fanciful than real. May not a potential only sufficient to break down a first layer of the dielectric, act as a sort of electric wedge capable of opening a path for itself, as it were, through many hundreds of feet? Suppose, for example, a highly electrified cloud to be passing in the atmosphere over some prominent object situated on the earth's surface, and that the attractions of the electricities of the earth and of the oppositely charged cloud cause a depression of a part of the latter's surface, at a point situated over such prominence, we have then a set of conditions analogous to those obtaining in the experiment before referred to, of splitting the glass plates. If now, some rain-drops fall, may not they assist in making up the wedge, which, entering the dielectric, begins to make the path for the discharge to pass? It has been observed that during a storm the most brilliant discharges are usually seen amidst the densist rain, and that frequently an unusual flurry of rain-drops immediately succeeds the discharge, as though the charge remained upon the cloud until the falling drops brought it within striking distance, when it flashed to earth, the rain-drops, which had first assisted it, arriving later. If the charged rain-drops do assist the clouds' discharge, and such an assumption does not seem unreasonable, it becomes quite thinkable that a true discharge between earth and clouds may be effected by a potential, moderate indeed compared with the millions of volts often spoken of as necessary to effect a discharge.—Yours, &c. ROBERT SHAND.

Lynn, Mass., March 23, 1891.

## TRADE NOTES AND NOTICES.

### "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division of this Directory will be found extensive and reliable. *Orders should be forwarded at once.*

PLANT FOR SALE.—Messrs. Wheatley Kirk, Price and Goulty announce in our advertisement columns that they have for sale four horizontal high-pressure engines, each 35 horse-power nominal, two coupled together as a pair, and two single, with three steel Lancashire boilers, each 24ft. by 7ft. 2in. diameter; these are all of Marshall, Sons and Co.'s make, and are in excellent condition. There are also four Babcock-Wilcox boilers, each of 164 horse-power nominal, and four Siemens alternating dynamos, each for an output of 2,500 volts and 33 amperes. Particulars as to prices, orders to view, &c., may be obtained of Messrs. Wheatley Kirk, Price and Goulty, 52, Queen Victoria-street, London, E.C., who have also for sale valuable plant and machinery at 4, Station-buildings, Acton-street, Kingsland, London, N.

AN ALUMINIUM ELECTRIC COMPANY.—A private Company has been formed for the manufacture of aluminium, and promises to supply this metal at 2s. per lb. The Company, whose offices are at 11, Great Sutton-street, Clerkenwell, also promises an aluminium storage battery.

ATLAS ELECTRICAL MANUFACTURING AND SUPPLY COMPANY (LIMITED).—We are glad to learn that the fire which occurred at this Company's works on Friday last will not in any way prevent the Company from executing orders sent on to them immediately, as they have made arrangements in order to prevent unnecessary delay.

CHANGE OF ADDRESS.—Mr. Magnus Volk informs us that he has removed from Manor Cottage, Halliford, Shepperton, Middlesex, to Volks' Electric Laboratory, 17, Eglantine-road, Wandsworth, S.W.

THE LUMMER-BRODHUN PHOTOMETER.—This instrument, illustrated in our last issue, was first described in "Zeitschrift für Instrumentenkunde." Messrs. O. Berend & Co., of 61, Fore-street, E.C., inform us that it is made by Hartmann & Braun, and is supplied by them.

MESSRS. PRIESTMAN BROS.—We have received from this firm illustrated particulars of the latest type of their well-known oil engine, together with prices and general dimensions. The particulars are accompanied with extracts from certificates of experts, and a number of very flattering testimonials from users of the engine. Amongst others who have adopted the engine are included the English, Victorian, New Zealand, Egyptian, and Norwegian Governments, the Trinity House, the Northern and the Irish Light House Boards.

# COMPANIES' MEETINGS & REPORTS.

## Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited).

Extraordinary general meetings of the holders of Priority shares and of Founders' shares were held at the Cannon-street Hotel on the 6th inst., under the presidency of Sir John H. Morris.

The SECRETARY (Mr. J. SHURMER) read the notice convening the meeting, which intimated that the following resolution would be submitted thereto. Resolved :—

*That the Articles of Association be altered in manner following :—*

(a) *Article 109 shall be cancelled.*

(b) *In place thereof the following Article shall be substituted, namely—"(109).—All dividends shall be payable out of profits only ; but such dividends may be declared and paid either in cash or by the distribution of specific assets taken at their par value, and in particular of shares, debentures, or other securities of any other company, or partly in one way and partly in the other."*

(c) *Article 110 shall be altered by inserting after the words "until they have received a return" the words following, namely, "(either in cash or in shares, debentures, or other securities taken at their par value.)"*

The CHAIRMAN stated that the meeting had been called for the purpose of carrying out the wishes of the shareholders as unanimously expressed at the general meeting of the Company last January. The Board were then urged to take measures for distributing securities held by the Company, but it was pointed out that this could not be done under the existing Articles of Association, when it was resolved unanimously by the shareholders who were present on that occasion that the Directors should take the necessary measures for having the Articles altered, so as to enable the securities to be distributed. He dwelt upon this point because objection had been taken to the action of the Directors, who had been accused of rather "rushing" the matter on the shareholders. Whatever action had been taken, however, had emanated from the shareholders, whose wishes it was the only object of the Board to carry out. Acting on the shareholders' wish, the opinion of counsel had been taken, which was to the effect that a distribution of securities could be made after certain specific alterations in the Articles of Association, and these alterations were embodied in the resolutions now before the meeting, as read by the secretary. It struck him as quite possible that they might agree to alter Clause 109, and yet not agree to alter 110, or they might propose that Article 110 should be altered in some other way than that proposed in the resolution. If this were the wish of the shareholders it must emanate from themselves. He then proposed the cancelling of Article 109.

Mr. JOHN MACFARLAN seconded the motion.

Sir THOMAS H. FARRER, Bart., stated that as he had not attended the last meeting he had had some difficulty in understanding precisely what the object of the alterations was. What occurred to him when he saw the proposal in the first instance was that it was very questionable for a body of shareholders, consisting of two different sets with somewhat diverse interests, at this early period of the history of the Company to alter what was a fundamental relation between the two sets of shareholders when the Company was started. He happened to hold Priority Shares and Founders' Shares in such a proportion that he believed it made absolutely no difference to him whether an advantage was given to the Priority or to the Founders' Shares, and therefore he could treat the matter impartially. As he understood the matter, the suggested distribution would, if it were at present carried into effect, alter in some degree the relation which, by the deed of settlement, existed between the two classes of shares—an alteration which, in itself, unless there were very good reasons for it, he regarded as a considerable evil. As far as he could understand it, if the distribution was such as had been proposed, the Priority shareholders would at once receive. in the form of shares and debentures, some thing which might, or might not, as events turned out, be more than they would have received if the present state of things continued. At the present moment, undoubtedly, they would receive less, because the shares which would be contributed were at a discount, and, as he understood some of them were Vendors' Shares, and on that account could not be sold and turned into money for a considerable period after the arrangement was made. They would, therefore, be postponing their right, and further, they would be giving to the founders something which the latter had as yet no right to. They would be consenting to the distribution amongst the founders of a certain proportion of the assets of the Company to which the owners of Founders' Shares were not entitled until another £5 in cash had been given to the Priority shareholders. He could not but believe that the Company was quite certain to realise a further £5 in cash upon the Priority Shares, the holders of which he advised not to insist, therefore, upon an immediate distribution. Moreover, he did not think it desirable in the present state of the Company that these shares and debentures should be hawked about in the market. From all he could gather there was every probability that the difficulties which had existed would be overcome, and nothing but harm could be done, meanwhile, by putting into the hands of shareholders, who really knew very little about the business, shares, many of which could not be sold at present, and which, if sold, would be disposed of at a great disadvantage. He had, therefore, come to the meeting determined to oppose anything like an immediate distribution, but if the shareholders agreed to it, he saw no reason why the Board should not, in the future, after the Priority Shares had received the additional £5 per share in cash, to which they were entitled, distribute shares in lieu of distributing cash.

Digitized by Google

He had come, therefore, to the meeting prepared to vote for the abolition of Article 109, and for the alteration which was proposed in Article 110, but he also came prepared with an amendment to Article 110, which would have the effect of preserving to the Priority shareholders their right to the £5 in cash. Having intimated the wording which he desired, he concluded by moving an amendment to this effect.

Prof. LAMBERT expressed his readiness to second the amendment, which he thought was a compromise that would meet both the desire of the Board and the question of justice.

The CHAIRMAN repeated that the desire of the Directors was to do everything in the interests of the shareholders, and he thought he might inform them that the amendment which had been proposed had been in reality suggested by himself.

The proposed alterations in Article 109 were then agreed to; and the alteration in Article 110 was also approved, modified as suggested by the amendment. Clause 110 will, therefore, read as follows:—"The Priority Shares shall be entitled to all profits until they have received a return in cash equal to the amount paid on the shares, and in addition 100 per cent. premium, also in cash, before the Founders' Shares receive any return, and, in addition, the Priority Shares shall receive one-fourth of all the surplus profits, the remainder being then divided among the holders of the Founders' Shares."

Mr. F. L. RAWSON observed that his own idea was that it was the duty of the Directors to distribute the shares as rapidly as possible. It might be necessary to call further meetings, because although they themselves knew what they wanted and what they meant, yet the alteration which had been made in Clause 110, when legally interpreted, might not carry out the intention. One of the chief objections to the distribution of the securities was the fear that they would be still further lowering the price of the shares; but an effectual way out of this difficulty would be the formation of a Trust Company, as had been done in the case of the Globe Telegraph and the Dynamite Trust Company.

The resolutions were afterwards submitted, as already agreed to, to separate meeting of holders of the Founders' Shares and to an aggregate meeting of the holders of both Priority and Founders' Shares.

## Poole and White (Limited).

This Company held their first annual general meeting privately at the offices of the Company, 58, Bread-street, Cheapside, on April 7th; Mr. Tryon, the Chairman of the Company, presiding.

The CHAIRMAN informed the shareholders present that the great success which had attended the Company's operations during the past year would necessitate the taking of much larger works than at present, and that for this purpose it was proposed to issue further capital.

We are informed that the meeting unanimously adopted the report, and before the close it was announced that the greater part of the further capital required was already subscribed.

## Oriental Telephone Company (Limited).

The following is the report of the Directors for the year ending 31st December last, to be presented at the eleventh ordinary general meeting of the Company to be held at the Cannon-street Hotel, E.C., on Wednesday, the 15th inst., at 1 o'clock.

The Revenue Account shows a balance to credit of £8,835. 8s. 11d., which, together with £1,237. 2s. 8d. brought forward from 1889, shows an amount of £10,072. 11s. 7d. available for disposal, which the Directors recommend should be dealt with as follows:—To add £2,500 to the Reserve Fund; to write off £832. 19s. 7d. in reduction of Capital Expenditure; and to pay a dividend of 2½ per cent. free of Income Tax on the total paid-up capital of the Company, which will absorb £4,488. 12s. 3d., leaving £2,250. 19s. 9d. to be carried forward.

The Shareholders will notice that an alteration has been made in the mode of appropriating the profits. They will have gathered from former reports of that the Directors have been endeavouring to come to some arrangement with the holders of Vendors' Shares for a re-adjustment of Capital Account. A conference was held last autumn with one of the largest holders, and at his suggestion the services of an Actuary were called in, in order that a disinterested opinion might be obtained of the relative values of the two classes of shares. The Actuary having raised a question as to the correct interpretation of the Agreements with the Vendors relating to the payment of dividends, the point was submitted to Counsel, and in pursuance of the advice received, it has been deemed necessary to declare the dividend rateably on the paid-up Capital of the Company, Vendors' Shares included, and to carry the dividends declared upon the Vendors' Shares to a separate account, from which it will be distributed to the holders of the Ordinary Shares until their claims, according to the Agreements with the Vendors, have been discharged. By this arrangement the deficiency to which those agreements relate has to be made up exclusively out of the dividends upon the Vendors' shares, without any obligation on the part of the holders of Ordinary shares to bring the dividends on these shares into account for the purpose of making up such deficiency. The distribution now recommended on the total paid-up capital of the Company is equal to £3. 12s. 2d. per cent. on each Ordinary share issued prior to February 4, 1886, as compared with £3 per cent. last year.

The Indian Companies during the past year show an improvement, the Bengal Telephone Company having paid 5 per cent. against 4½ per cent the previous year, and the Bombay Company 4 per cent. as against 3 per cent. The increase would have been larger but for the action of the Indian Government, to which the Directors have called attention in previous reports. The Telephone Company of Egypt has declared a dividend of 6 per cent. for the past year on its Preferred shares, carrying forward £1,508. 5s. 5d. All the foregoing dividends on the shares held by this Company have been brought as usual into the accounts appended.

The branches worked directly by the Company nearly all exhibit an improvement on previous returns, which is partly due to the rise in silver.

In order to provide the Telephone Company of Egypt with further working capital for extensions in that country, your Directors have taken £1,500 of its 6 per cent. Debentures.

The accounts of the China and Japan Telephone Company have not yet been closed, but they point to a small surplus after paying Debenture Interest.

By a recent Act of Parliament, Companies are enabled, at a moderate expense, to amend their Memoranda of Association. The Directors, whilst they will always bear primarily in mind the original objects of this Company, have come to the conclusion that it is desirable that the powers of its Memorandum of Association should be extended so as to authorise the supply of electric apparatus and material, and the application of electric power generally.

The resolution below will therefore be submitted to the meeting:—

*"That the Company's Memorandum of Association be altered as follows:—By adding at the end of paragraph (b) of clause 3 the words 'or generation, employment or utilisation of electricity or magnetism.' By inserting after the said paragraph (b) the following additional paragraph (b 1.)—'To carry on any business or manufacture relating to the generation, employment or utilisation of electricity or magnetism or the apparatus connected therewith.'"*

Should the above resolution be passed by the requisite majority, it will be submitted for confirmation as a special resolution to an extraordinary general meeting which will be subsequently convened.

PATENT

SILICIUM BRONZE AND SILICIUM COPPER WIRE.

The best for overhead Telephone and Telegraph Lines,

AND ALL ELECTRICAL PURPOSES.

Hard Drawn High Conductivity Copper Wire.

ROLLED AND DRAWN PHOSPHOR BRONZE.

PHOSPHOR BRONZE — VULCAN — PHOSPHOR — DURO METAL

PHOSPHOR BRONZE BEARINGS, BUSHES, AND OTHER PARTS OF ELECTRICAL MACHINERY

*SOLE PROPRIETORS of the British, Indian and Colonial Patents,*

THE PHOSPHOR BRONZE COMPANY (Limited),

*87, Sumner Street, Southwark, London, S.E.*

WIRE AND SHEET MILLS: BAGOT STREET, BIRMINGHAM.

The retiring Directors at the present meeting are the Right Hon. G. A. F. Cavendish Bentinck, M.P., and Mr. B. St. John Ackers, both of whom being eligible offer themselves for re-election. The Auditors of the Company, Messrs. Deloitte, Dever, Griffiths and Co., also retire, and offer themselves for re-election.

## New York Belting and Packing Company (Limited).

The first ordinary general meeting of this Company was held on Tuesday last, at the Cannon-street Hotel, under the presidency of Samuel Pope, Esq., Q.C.

The CHAIRMAN said: As a quorum of members is not present I can only, previous to adjourning this meeting in accordance with the law, say a few words in a general conversational way. Our general manager is in America, and has been there for the last two months, and if it had been possible to postpone this meeting for two or three days longer we should have done so, because we expected his arrival home in the course of the present week. As, however, our four months expire to-morrow, we were obliged to hold our statutory meeting to-day. In a week's time we shall probably be able to furnish the report of our manager in America. Meanwhile, speaking generally, the general manager reports to us that he has found everything in order, that the books have been admirably kept, that as far as he can judge there has been no over-valuation of assets, that we are in possession of one of the finest industrial concerns in the United States, and under an instruction from us he made a special inquiry with respect to some disquieting rumours which reached us as to a bad debt by the old company which might come to the disturbance of the new. I am happy to say that he writes us that there is no reason for any ground of apprehension that the bad debt which has been rumoured is one that will affect the new company in the least, but that the whole responsibility of it has been taken and secured by the old company before the business was transferred. I may also say that we expect that Mr. Belmont, the banker, of New York, who is largely interested with us, will take a seat on the Board, and give us the advantage of his great financial experience on the other side. We shall get more information, of course, when the manager arrives here, as he will then give us a detailed report.

The CHAIRMAN then notified that the regular meeting stood adjourned to 2.30 on Tuesday next.

The Secretary (Mr. JOHN C. WYLDE) then read the notice convening the meeting, and after a few remarks from the Chairman, the meeting adjourned.

## NEW COMPANIES REGISTERED.

**FROUDE-HURRELL TORPEDO COMPANY (LIMITED).**—Registered with a capital of £10,000 in £10 shares. Among the objects are the manufacturing establishing, and working apparatus for the distribution and utilisation of electric and other power, and the constructing, establishing, purchasing hiring, and dealing in railways, vessels, telegraphic and telephonic wires, &c. The registered office is 2, South-square, Gray's Inn, W.C.

**NEW COMPANIES REGISTERED DURING MARCH.**—Among the new companies registered during March dealing with electricity or engineering were the following:—

| | Capital. |
|---|---|
| Alexander Mathieson and Sons (Limited), in £10 shares | £120,000 |
| Dermatine Company (Limited), in £5 shares | 55,000 |
| Edinburgh and Leith Safe Deposit Company (Limited), in £5 shares | 20,000 |
| Froude Hurrell Torpedo Company (Limited), in £10 shares | 10,000 |
| Jarrow Forge and Engineering Company (Limited), in £10 shares | 80,000 |
| John Priest and Son (Limited), in £10 shares | 30,000 |
| Liverpool and District Pulsion Telephone Company (Limited), in £1 shares | 6,100 |
| London Rubber and Packing Company (Limited), in £5 shares | 3,000 |
| Langness Copper Company (Limited), in £1 shares | 35,000 |
| Weybridge Electric Supply Company (Limited), in £5 shares | 15,000 |

**WEYBRIDGE ELECTRIC SUPPLY COMPANY (LIMITED).**—Registered by Henry F. Kite, 11, Queen Victoria-street, E.C., with a capital of £15,000 in £5 shares. Object: To carry into effect an agreement made March 20th between the Laing, Wharton, and Down Syndicate (Limited), of the one part, and Percy Mossop, of Thames-street, Weybridge, on behalf of the Company of the other part, for the acquisition of the Electric Lighting Depôt, Weybridge, and to develop and extend the same. Registered without articles of association.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the week ended April 3rd amounted to £5,136.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The traffic receipts of this Company for the week ended April 5th amounted to £901.

**DIRECT SPANISH TELEGRAPH COMPANY.**—The traffic receipts of this Company for the month of March, 1891, amounted to £1,930, as against £2,382 in the corresponding period of last year, or a decrease of £452.

**EASTERN TELEGRAPH COMPANY (LIMITED).**—The traffic receipts of this Company for the month of March, 1891, amounted to £58,447, as against £58,471 in the corresponding period of 1890, or a decrease of £24.

**EASTERN EXTENSION TELEGRAPH COMPANY.**—This Company notify that the accounts to the 31st December last show, subject to audit, a balance of profit of £106,257 after payment of three interim dividends. The directors propose to distribute on the 22nd April the usual dividend of 2s. 6d. per share, making a total dividend of 5 per cent. for the year 1890. It is also proposed to pay a bonus of 4s. per share, or 2 per cent., making a total distribution of 7 per cent. for the past year. The balance of £25,007 has been carried to the reserve fund, which now stands at £495,239. The general meeting of the shareholders takes place on the 22nd instant. We refer our readers to our advertisement columns for full particulars of the recent drawing of 320 Debentures of £100 each. These Debentures will be paid off at par on the 1st July next. The receipts of this Company for March, 1891, amounted to £44,716, as against £41,133 in the corresponding period of last year, showing an increase of £5,583.

**ELMORE'S AUSTRO-HUNGARIAN PATENT COPPER DEPOSITING COMPANY (LIMITED).**—It is announced that the title of this Company will in future be Elmore's German and Austro-Hungarian Metal Company (Limited), and that the offices of the Company have been removed to 64, Cannon-street, E.C.

**FOREIGN ELECTRIC DATE AND TIME STAMP COMPANY (LIMITED).**—The statutory general meeting was held on Tuesday at the offices, 90, Queen-street, London, E.C. The meeting was simply held to conform with the Act, no business being transacted.

**GLOBE TELEGRAPH AND TRUST COMPANY.**—The directors of this Company have declared an interim dividend of 2s. 6d. per share.

**GREAT NORTHERN TELEGRAPH COMPANY.**—The traffic returns of this Company are as follows:—Receipts in March, 1891, £22,800; 1st January to 31st March, 1891, £64,400; corresponding months, 1890, £60,200; corresponding months, 1889, £63,000.

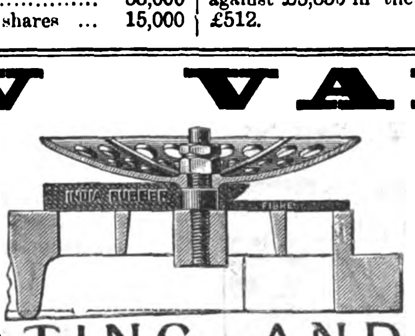
**ST. JAMES' AND PALL MALL ELECTRIC LIGHT COMPANY (LIMITED).**—The allotment letters for the 10,000 £5 Preference shares recently offered by this Company have been posted.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended April 3, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,165.

**WEST INDIA AND PANAMA TELEGRAPH COMPANY.**—The receipts of this Company for the half-month ended March 31st, were £3,338, as against £3,850 in the corresponding period of last year, or a decrease of £512.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1886.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

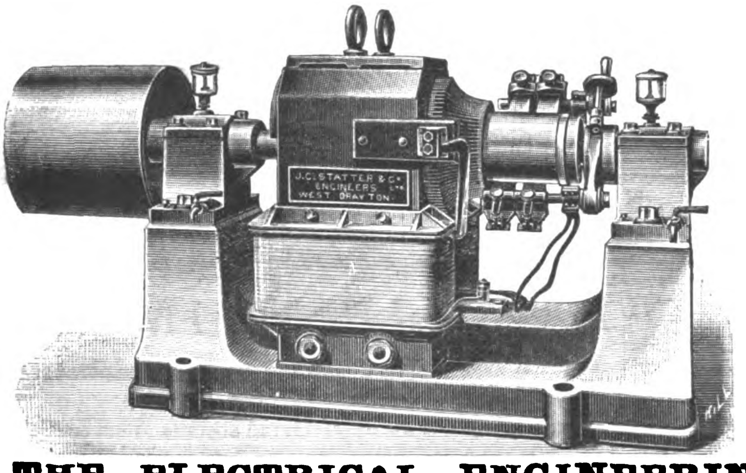
IMPROVEMENTS IN DYNAMOS



STATTER-BRUNTON DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

STOCK SIZES UP TO 77 KILOWATTS.
MACHINES BUILT TO 500 KILOWATTS.

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 674.—Vol. XXVI. FRIDAY, APRIL 17, 1891. Price Fourpence.

## NOTES.

If the theory of cycles in the history of human affairs be a true one, we are now between two periods of inventive activity, and are rising on a wave of litigation. Two cases of interest were tried this week, one has been adjourned and the other ordered to stand over, while to-day, unless his opponents are allowed to continue their policy of pleading for delays and extension of time, Mr. Lane Fox will succeed in getting a hearing for his action.

The case of Savory and Moore *v.* The London Electric Supply Corporation is one which might have established a serious precedent by attaching the stigma of "nuisance" to a transformer sub-station. In the hands of unscrupulous experts, or of ignorant and prejudiced witnesses, the judge might have been persuaded that the presence of 10,000 volts and a number of transformers and switches was so "highly dangerous" that the building containing them was comparable to a nitro-glycerine factory. It appears that a good case was made for the safety of the fireproof room containing the transformers, but the intentions of the Supply Company as to the use to which the upper part of the building would be put, were not disclosed.

Advocates of transformer sub-stations are fond of saying that it is easy enough to rent a cellar "somewhere," and it is well that Mr. Justice Kekewich has been satisfied that proper fireproof construction is all that is needed to eliminate any possible danger or damage to neighbouring property. It is not surprising that Messrs. Savory and Moore, who have been seriously inconvenienced by noise and vibration when the machinery was running, and who were placed in a very awkward position during the recent fire, should vigorously oppose the construction of a sub-station. The public ought to learn that a transformer *may* burn out, but it does not burst into flames when such an accident happens. Switches and fuses ought not to contain any inflammable material, and no combustible substance other than the insulation of the cables need be found in the station. Insulation, when arranged as it is in the Ferranti mains, is not in the least likely to catch fire.

At a meeting of the Society of Telegraph Engineers on May 9, 1877, Prof. Abel in the chair, a communication was made by Mr. J. Sivewright, the then acting secretary, on "A new form of electric light." This was the Jablochkoff candle. In the course of the description, the following words are to be found :—"He introduced into the centre circuit of the machine the primary wires of a series of induction coils, and sent the electric current from the induced current on to a slip of kaolin placed between the two ends of the outside wire of each coil. . . . . . The result thus obtained between the two ends of the wire of the coil is a splendid band of light. . . . . . As to its power, that only depends on the number of the spirals and the diameter of the coils used. . . By using alternating currents the interrupter and condenser of the coils are not required." This communication was well known, but it was generally thought that it had been made seven days *after* the date of Jablochkoff's patent, for the blue book bears the date May 2, 1877. It now appears plainly enough that this is a misprint, for the real date, May 22nd, is to be found three times on the first page of the specification. The petition for prolongation of this patent, a report of the proceedings in connection with which will be found in another column, is to be amended by adding thereto a prayer for confirmation, without which the patent is invalid.

There would hardly seem to be enough in the subject of screening of electric and magnetic forces to yield matter for two Papers before the Royal Society, and a discourse on the following day before the Royal Institution, but Sir William Thomson made three such communications last week. The manner in which the subject was handled varied from the very stiff mathematical Paper which appeared in our last issue, to the popular lecture, which was of a typical "Friday evening" character.

It is to be feared that some of the delicate pleasantry of the discourse was lost upon many of the audience at the Royal Institution. The fifth kind of screens—fire-screens and window-blinds—was merely alluded to, and the lecturer did not explain that the radiations which are obstructed by such screens are, in fact, electro-magnetic. Of a similar character was the neat remark that it was fitting that opticians should sell magnets.

The screening of electric and magnetic force has not attracted much attention from those who are concerned with the practical applications of these forces. Faraday's cage has been looked upon as an elaborate experiment which merely proves that a passive condition exists within a conductor, and as a type of a building thoroughly protected from lightning. Wire and tinfoil cages have been used in electrometer work, and there practical electrostatic screening has ended. Magnetostatic screening has been exemplified in the Thomson marine galvanometer and in iron-cased watches.

Digitized by Google

THE apparent permeability of all ordinary substances to magnetic force has always been a mystery to the uninitiated, and has frequently been confounded with electrical conductivity. Many persons imagine that the red sealing-wax varnish on an ordinary horse-shoe magnet is a magnetic insulator, and accounts for the absence of any free magnetism along the parts thus protected. We have seen a perpetual-motion machine consisting of six magnets and seven iron balls suspended on a frame. One side of each ball was covered with sealing-wax varnish, the idea being that when a ball had passed a magnet it would no longer be attracted owing to the interposition of the varnish. The inventor wanted financial assistance to procure stronger magnets.

THE facts put forward by Sir W. THOMSON with regard to the variation of the screening power of substances for periodically varying electrostatic forces of different frequencies, are of great interest. A body may be opaque to very slow vibrations, transparent to quick ones, and again opaque to excessively rapid vibrations, such as occur in light. We are here fringing on the subject of the colour of bodies, since colour is merely due to the selective absorption of substances for light waves of different periods. The reason why a body should permit waves of certain frequencies to pass through it unchanged, while absorbing others altogether, is a mystery which is likely to remain unexplained for a long while.

THE new method of measuring electrical power, described in the Paper by Prof. AYRTON and Dr. SUMPNER, at the Royal Society, last week, is remarkable in two respects—first, that it had not been thought of before; and secondly, that while the Paper was yet unread the method had been published in the columns of our contemporary, *Industries*. It is, we believe, unusual to allude to the contents of Papers which have been presented to the Royal Society before they have been read; but allusion having been made during the discussion on Mr. SWINBURNE's Paper at the Institution of Electrical Engineers, he at once set to work, and, in consequence probably of the well recognised way in which discoveries seem to hang in the air and occur to several minds almost simultaneously, he hit on the very method, and lost no time in publishing it. The authors of the Paper are perhaps to be congratulated that under the circumstances of previous publication their Paper was read; but there was probably no precedent for such a case. The fact that the method only requires the use of an ordinary alternate-current voltmeter, and that it is applicable to all kinds of currents, however complex the law of their variation may be, are great points in its favour. It is a pity that the resistance required should absorb as much power and as many volts as the part of the circuit under test, but this happens in nearly all tests of electrical power.

A MATTER incidentally alluded to during the discussion on this Paper at the Royal Society was the need for some general word denoting a portion of an electrical circuit. It is desirable to reserve the word "circuit" for the complete path of the current, and the words "resistance" or "conductor" are hardly comprehensive enough to designate any portion of the circuit absorbing power.

THE experiments on arc lamps, referred to by Prof. AYRTON and Dr. SUMPNER, are of great interest, and show the need of some such a method of test for investigating the phenomena of the arc. It is difficult to understand how an arc can act as an inductive coil, unless, as Sir W. THOMSON suggested, the arc can be regarded as an intermittent series of spark discharges. The experiments conclusively show that the current through an arc is far from sinuous, and in estimating the power by any ordinary method serious errors may arise.

WHATEVER may be the exact amount of importance which should be attached to the meeting held at Cannon-street Hotel, on Wednesday afternoon, the objects of the proposed Telephone Association, and the course which it is intended to pursue in order to attain them, are worthy of general support. An Association is not, indeed, required to convince London telephone subscribers that either the rates should come down or the efficiency of the service go up; but united action *is* requisite to give effect to this wide-spread feeling. Mere agitation would not, however, have much chance of success, and the promoters of the Association have, therefore, done well to draw the following oracular pronouncement from the only quarter likely to influence the National Company. "As to any action which the Post Office itself might be prepared to take," writes the Secretary to the Post Office, "I am to say that the POSTMASTER-GENERAL could not be indifferent to a clearly expressed demand for the establishment of a telephonic service in London, but he regards it as premature at present to state what the charge for such service would be." In short, the Association proposes first of all to test the efficacy of "sticking together," but should that fail to secure metallic circuits and reduced rates for the long-suffering Londoner, the aid of the Post Office will be invoked, and that department, we are told, will not be "indifferent to a clearly expressed demand."

THE result of the dispute between the POSTMASTER-GENERAL and the Boy Messenger Companies, as announced in our Legal Intelligence, must certainly be considered eminently satisfactory to all concerned. The Companies have received a gratuitous advertisement, and the licences they have been fighting for; the ATTORNEY-GENERAL has vindicated the majesty of the law, the POSTMASTER-GENERAL has levied his tribute, and last, but not least, the public will get an efficient express service. All's well that ends well, so that it is unprofitable to inquire why the present arrangement could not have been arrived at in a less tempestuous manner.

THE series of articles by Mr. SPRAGUE is concluded in the present issue. They originated in a letter which appeared in *The Electrician*, January 16th, p. 340, and gave rise to a correspondence which seemed likely to go on indefinitely. We therefore asked Mr. SPRAGUE to state his case, and suggested that his opponents should just hear him and then reply. His views are of a thoroughly common-sense character, but are not in accordance with the received teachings of the present day. Mr. SPRAGUE has done his best to shake the orthodox doctrines, and has not hesitated to reject definitions and to coin new expressions. The controversy is on this

Digitized by Google

account in danger of degenerating into a difference of opinion as to the use of words. Dr. OLIVER LODGE, in alluding to Mr. SPRAGUE's first letter, remarked that "the best service that one can do to a true theory after its promulgation is to pick holes in it, or suggest a rival one." If Mr. SPRAGUE's articles induce electrical students to think out the *pros* and *cons* of the present orthodox theories for themselves, instead of receiving them on faith, they will have served a good purpose.

**Our Telephonic Defences.**—The Spithead forts are about to be placed in telephonic communication with the head-quarters of the Royal Artillery, at Portsmouth.

**Electrical Bills in Parliament.**—In the House of Commons on Tuesday, the London Overhead Wires Bill was ordered for third reading, and the West Metropolitan Tramways Bill was read a second time.

**National Telephone Electrical Society.**—On Friday, April 10th, Mr. W. Johnstone, inspector-in-charge of Kidderminster, and late Secretary of the Society, read a Paper on "Some forms of Switchboards for small Exchanges."

**Brazilian Submarine Telegraph Company.**—The fifth drawing for payment of the Five per Cent. Debentures of this Company will take place on Friday next. Further particulars will be found in our advertisement columns.

**Proposed Universal Exhibition at Berlin.**—A proposal to hold a universal exhibition at Berlin in 1894 or 1895 has been favourably received. The Minister of Commerce approves of the idea, as do nearly all the Chambers of Commerce throughout the Empire.

**Leamington.**—At the last meeting of the Town Council the Watch Committee reported that the contract with the Midland Electric Light and Power Company for street lighting expired on March 25th, and the Parade and Bath-street were once more lighted with gas.

**The Junior Engineering Society.**—On Monday, 6th inst., a large party of members of this Society visited Messrs. Siemens Bros. and Co.'s electrical engineering works at Charlton. Every facility was afforded for enabling the numerous departments of the extensive establishment to be seen.

**Damage by Lightning.**—Needwood Church, near Burton-on-Trent, was struck by lightning during service on Sunday last. It was found that the lightning conductor had been destroyed, some of the lead on the roof had been torn up, and the stone step at the entrance door had been smashed.

**Bath.**—A fatal accident occurred at the Bath Electric Light Works on Saturday morning last. An engine-driver had ascended a short ladder for the purpose of lubricating. The ladder slipped, the driver overbalanced and fell upon the rope gear, and was immediately drawn under the fly-wheel.

**Bristol.**—Arrangements have been made by Mr. Preece by which Mr. Gisbert Kapp will co-operate with him in preparing plans and specifications for the electric lighting of this city. High-pressure alternate currents will be used with sub-stations for distributing, and nothing will be omitted in either the mechanical or the electrical work to make this a model central station.

**Institution of Electrical Engineers.**—A general meeting of the students was held on Friday, April 10th, when a Paper was read by Messrs. Matthews and Seaman on "Photometry," some apparatus being kindly lent by Messrs. Alex. Wright and Co., Westminster. The next meeting will be held on the 24th inst., when a Paper will be read on "Alternate Current Motors," by Mr. G. U. Yule.

**Davis and Stokes' Safety Commutator.**—We are informed that a motor fitted with Davis and Stokes' safety commutator is working satisfactorily at All Saints' Works, Derby. A number of electrical engineers have been to view the machine; and, as the motor will be running until the 24th inst., it is possible that others may like to avail themselves of this opportunity of inspecting a motor so fitted in actual operation.

**Hull.**—At a meeting of the Electric Light Committee of the Town Council last week a letter was read from the Board of Trade asking the Corporation what system of lighting they had adopted. After considerable discussion, it was resolved, "That the sub-committee be requested to report to the committee at an early date as to the system they would recommend the Council to adopt, and that they be authorised to retain such professional assistance in the matter as they see fit."

**Transvaal Telegraphic Statistics.**—The statistics published by the General Manager of Telegraphs in the last Transvaal *Staatscourant* for the year 1890, show that the total number of telegrams despatched during that year was 513,479, while 486,929 were received. The total number of telegrams received and despatched from the different offices of the Republic, including Government messages, were 1,445,336. At Johannesburg 230,819 telegrams were despatched and 217,561 received. Pretoria comes second in the list with 97,225 despatched and 100,392 received.

**The Suez Canal Traffic and the Electric Light.**—During the years the electric light has been permitted for transit, the number of vessels using the canal and the light are as follows:—

| | Total transit. Vessels. | Using electric light. Vessels. | Using electric light. Per centage of total Vessels. |
|---|---|---|---|
| 1887 | 3,137 | 395 | 12·7% |
| 1888 | 3,440 | 1,611 | 47·0% |
| 1889 | 3,425 | 2,445 | 71·4% |
| 1890 | 3,389 | 2,836 | 83·5% |

**The International Railway Congress.**—The fourth meeting of this Congress will take place in June next year, at St. Petersburg. The following items of the programme are of electrical interest:—*Signal Lighting:* Methods of increasing the visibility of signal and train lights in foggy weather, and of avoiding extinctions; the employment of electricity. *Special Modes of Tractions:* What are the results obtained since the last Congress with the various special modes of traction, and especially with electric traction? The progress of electricity as a motive power from the practical, technical, and economical point of view.

**The West End Street Railway of Boston.**—The West End Street Railway of Boston seems to neglect nothing which is likely to render its service efficient. On the occasion of a great fall of snow in March, arragements having been made for such contingencies, it had an hour and a-half notice from the Blue Hill Observatory of the approach of the snow, and had its track sweepers, snow ploughs, and patrol sleds in readiness, and the snow flakes were whisked from the track almost as soon as they fell; so that no delay occurred directly on account of the storm. In this, as in previous storms, the trolley wires were oiled, and what little ice formed on them readily dropped at a light stroke.

**Leeds.**—At a meeting of the Parliamentry Committee of the Leeds County Council, held on Friday last week, the following resolution was moved and carried unanimously:—"That the Council be recommended, as the Local Authority for the Borough of Leeds, under the Electric Lighting Acts, 1882 and 1888, to consent to the grant by the Board of Trade of a Provisional Order authorising the Yorkshire House-to-House Electricity Company (Limited) to construct and maintain electric lines and works, and to supply electricity within the Borough on such terms and conditions as the Parliamentary Committee may approve." The resolution will be submitted to the Council to-day.

**A Fountain of Electricity.**—An amusing report, says the *Electrical World*, comes from Boston that the much-abused trolley wire has appeared in the *rôle* of a public benefactor. This romance states that a certain citizen living along the line of the West End road found an ever-active and unceasing fount of electricity in his cellar, coming from one of the iron posts of the railway company, and flowing into his private domain. He promptly corraled the current, and, charging a storage battery with it, lights his house, runs motors, bells and burglar alarms. The item further states that the railway company is powerless to prevent the leak. A thoroughly trained and well-

Digitized by Google

educated reporter (says our contemporary) would not have stopped at such common-place and altogether prosaic evidence of electrical leakage. He would have seen the magnificent possibilities of the situation, and developed them.

**Waste Cork Lagging for Steam Pipes.**—Messrs. R. Bolton and Co., of Leadenhall-street, have recently made some experiments on the comparative efficiency of asbestos lagging and the cork lagging which they have introduced into this country. This material is made from the waste cork from the Spanish cork factories by compressing it into slabs with some glutinous material. The experiments were made by connecting three closed vertical tubes, each 5in. in diameter, with a supply of steam. One pipe was uncovered, another was covered with asbestos lagging, and the third with the cork lagging. The amount of steam condensed in 10 minutes was $11\frac{1}{2}$oz. of water in the uncovered tube, 6oz. in the asbestos-coated tube, and $3\frac{1}{2}$oz. in the cork-lagged tube. The material can be obtained in sheets of from $\frac{3}{16}$in. to $\frac{3}{4}$in. thick, and in widths of from $2\frac{3}{8}$in. to 10in.

**Leclanche Cells without Manganese.**—In the *English Mechanic* for March 27th, Mr. T. H. Nash states that for the last four or five years he has had cells ringing bells containing no manganese, and they have done their work well. He has tried broken carbon in a calico bag surrounding an ordinary Leclanché carbon, though the best results were obtained by using two carbon plates with a zinc plate between them—in fact, a bichromate, but using salammoniac solution as the exciting fluid. Two cells of this description worked well for 16 months, and were still good at the end of that period. In order to gain some information as to the recuperative power of such cells, Mr. Nash took one, and connected it up to a bell, which it rang well. He then connected the carbons and zinc by a wire, and left it all night. In the morning it had, of course, run down, and would not ring the bell at all. At five o'clock in the afternoon, after resting, it rang the bell as strongly as ever.

**The Manchester Exchange of the Mutual Telephone Company.**—We have received from the Mutual Telephone Company a list of some twenty testimonials received by them from their more important Manchester subscribers. In considering these testimonials it should be remembered, the Company remark, that they refer to a service which was declared to be impossible until after the lapse of the Edison Patent next July, and that the service, good as it already is, will be markedly improved when the use of carbon, now prohibited, becomes free towards the close of the month named. The following testimonial from Messrs. Goldschmidt, Hablo and Co. is a sample of the rest:—"We have much pleasure in informing you that after about six weeks' experience with your telephone, we find the same most satisfactory in every respect. Firstly, the instruments speak clear and the sound is distinct. Secondly, there is no overhearing of others speaking, hence conversations are absolutely private. Thirdly, the instruments are clear, and there are no disagreeable or rasping sounds. Fourthly, we find the attention at the Exchange most prompt."

**Patent Fees.**—In the House of Commons last week Mr. Morton asked the President of the Board of Trade whether it was correct that a patentee in this country had to pay a sum of £154 for 14 years' protection, whereas in the United States of America the cost was only £7 for 17 years' protection; and, if correct, would the Government, having regard to the keen competition between this country and the United States, take steps to put British inventors in a more favourable position. In reply, Sir M. Hicks-Beach said that the sums stated were accurate as regards the whole period of protection, but the position was not quite fairly represented, because protection was given for periods less than 14 years for sums less than the amount set out. Protection for four years, for instance, was given in an ordinary case for £4, whereas the payments required to be made within the same period in the United States amounted to £6 or £7. The whole scale of fees was carefully considered in 1883 when the Act was passed, and it was held that there were reasons, from the point of view both of the public and of inventors, against encouraging a lengthened protection of patents which were not likely to be worked. It did not appear desirable that a patentee who could not make his patent available for public use should occupy the ground for a long time to the exclusion of others.

**The Granting of Competing Provisional Orders.**—In the House of Commons last week, Mr. Spencer Balfour asked the President of the Board of Trade whether the Board intended to grant a third Provisional Order under the Electric Lighting Acts in any district in London where there were already two electric lighting companies empowered by Provisional Orders to supply electricity; and whether, if so, he would explain why it was now intended to depart from the principle laid down by the Board of Trade, after the Westminster Inquiry of 1889, that there should only be two companies, each on a different system, in one district, and also from the policy of the Board of Trade as stated by the President on May 12th last. Sir M. Hicks-Beach stated, in reply, that it was not intended to grant a third Provisional Order under the Electric Lighting Acts in any urban district where there were already two electric lighting companies empowered by Provisional Orders to supply electricity, unless there were strong reasons to suppose that one of such electric lighting companies would be unable to exercise their powers within a reasonable time. Where, however, this was the case, he did not think that it was desirable that the inhabitants of a district should be entirely debarred from all advantage of competition.

**Athens.**—The electric light, which made its first public appearance in Athens in September, 1888, when it was temporarily employed to light the Greek National Exhibition, has met with considerable favour there. Such was the demand for current that after endeavouring to meet it by the erection of several small improvised stations, it was found necessary in August, 1889, to commence a large central station, which came into operation in the autumn of that year. The present plant comprises six 60 kilowatt Edison dynamos, each pair being driven by a 150 H.P. compound vertical Pelong engine, by Weyher and Richemond, of Paris, and four 30 kilowatt Edison dynamos. During the hours of small output the load is taken by a battery of 130 Julien accumulators. The boilers are of the Babcock and Wilcox type. The feed water is drawn from the Ilissus, $1\frac{1}{4}$ miles distant. In summer this supply is somewhat short, and water has to be obtained from a still greater distance. The three-wire system is employed. The mains are almost entirely underground, and are run largely along the sewers, though where no sewers exist lead-covered cables run in asphalted wooden conduits are employed. Edison meters are employed throughout, the charge per 1,000 watt hours being a little over a shilling.

**American Patent Office Statistics.**—The following table, prepared by the American Patent Office, shows the number of patents issued during the year 1890 to citizens of the different States, with the ratio of such patents to the population:—

| | One patent to every | | One patent to every |
|---|---|---|---|
| Alabama | 14,689 | Nebraska | 4,706 |
| Arkansas | 11,875 | Nevada | 3,813 |
| California | 1,887 | New Hampshire | 2,189 |
| Colorado | 2,240 | New Jersey | 1,299 |
| Connecticut | 796 | New Mexico | 9,599 |
| Delaware | 3,303 | New York | 1,308 |
| Dist. of Columbia | 980 | North Carolina | 21,864 |
| Florida | 7,674 | North Dakota | 4,567 |
| Georgia | 11,135 | Ohio | 2,084 |
| Idaho | 7,032 | Oklahoma | 15,458 |
| Illinois | 1,778 | Oregon | 3,826 |
| Indiana | 3,272 | Pennsylvania | 1,990 |
| Iowa | 4,375 | Rhode Island | 1,235 |
| Kansas | 4,054 | South Carolina | 15,348 |
| Kentucky | 7,375 | South Dakota | 5,573 |
| Louisiana | 8,164 | Tennessee | 9,819 |
| Maine | 3,443 | Texas | 7,258 |
| Maryland | 3,509 | Utah | 6,930 |
| Massachusetts | 1,068 | Vermont | 3,291 |
| Michigan | 2,136 | Virginia | 9,355 |
| Minnesota | 3,434 | Washington | 5,459 |
| Mississippi | 23,147 | West Virginia | 8,029 |
| Missouri | 3,311 | Wisconsin | 2,660 |
| Montana | 2,493 | Wyoming | 7,588 |

**Electro-chemical Effects on Magnetising Iron.**—In a Paper recently read before the Royal Society, Mr. Thomas Andrews, F.R.S., gave the results of some experiments carried out by him on the effect of magnetisation on the relative electro-chemical position of a pair of bright iron bars, one magnetised by a coil, the other unmagnetised, when simultaneously exposed to the action of various powerful oxidising agents and saline solutions. He employed long polished rods of soft wrought scrap iron 0·261in. in diameter. Each pair of pieces was adjacently cut from the same iron rod, so that they might as near as practicable be of identical chemical composition and molecular constitution. The pieces were placed in the legs of a U tube containing the electrolyte, every care being taken to check any E.M.F. which might occur owing to the rise of temperature in one leg caused by the current in the magnetising coil. The solutions employed were potassium chlorate + one-fifth and one-third nitric acid, potassium chlorate and hydrochloric acid, 25 per cent. and 20 per cent. aqueous solutions of nitric acid, a 50 per cent. aqueous solution of hydrochloric acid, concentrated sulphuric acid (Sp. gr. 1·84). The magneto-chemical effects were very small, being usually of the order of $1 \times 10^{-3}$ volt. The magnetised rod was in every instance, except when dilute hydrochloric and concentrated sulphuric acid were employed, the positive element. In the exceptional instances alluded to, the electro-negative effect occurs, possibly owing to the presence in the solution of such reducing agents as nascent hydrogen.

**The Ferranti System at Havre.**—To carry out electric lighting at Havre, with its numerous docks, and suburbs scattered along the coast, no other system than that of the alternate current transformer was feasible, unless a large number of small separate stations were to be erected. The Société l'Energie Électrique, which had obtained a 40 years' concession, during the first 14 of which they were given exclusive rights, therefore decided to employ the Ferranti system. The central station is near the railway station, and in close proximity to coal yards and to the sea, whence it is proposed to draw the water necessary for condensing purposes. The plant at present comprises four Berendorff boilers working at 114lbs. pressure; two single cylinder Corliss engines, taking steam at 86lbs. pressure, and capable of developing 350 H.P or 450 H.P. at one-ninth and four-tenths cut-off respectively; two 224 kilowatt (2,400 volts) Ferranti alternators, excited by small six-pole Sautter-Lemonnier machines mounted on the same bed-plate. The dynamos are driven direct through rope gearing (10 ropes of 1·4in. diameter). Each engine is fitted with a fly-wheel 22ft. in diameter, and weighing 15 tons. Special arrangements are made for running non-condensing in times of neap tides and when otherwise necessary. Great attention has been paid to securing efficient lubrication. A small pump, fitted to each dynamo, takes the lubricant from the large reservoir in the pedestal, which holds some 1,800lbs. of oil, and forces it into the bearings at a considerable pressure. The measuring instruments comprise a Sir William Thomson electrostatic voltmeter, and a Carpentier dead-beat electrometer.

**Reduction of Telegraph Rates to Australia.**—The Eastern Extension Telegraph Company (in connection with the Indo-European Telegraph Department of Her Majesty's Indian Government and the Eastern and Indo-European Telegraph Companies) notify that the negotiations with the Australasian Colonies for a substantial lowering of the tariffs, have resulted in an agreement being concluded with the Governments of Victoria, New South Wales, South Australia, Western Australia, and Tasmania, and that the rates to those Colonies will consequently be reduced from May 1st proximo, as follows:—For ordinary telegrams:—From 9s. 4d. to 4s. per word for South and Western Australia; 9s. 4d. to 4s. 1d. for Victoria; 9s. 6d. to 4s. 2d. for New South Wales; 9s. 11d. to 4s. 8d. for Tasmania. For Press telegrams:—From 2s. 8d. to 1s. 10d. per word for South and Western Australia; 2s. 9d. to 1s. 11d. for Victoria; 2s. 9d. to 1s. 11d. for New South Wales; 3s. 4d. to 2s. 6d. for Tasmania. The contracting Colonies guarantee the Indo-European Telegraph Department and the Companies against one-half the risk of any loss should the receipts at the reduced rates fall short of the present earnings from the Australasian traffic, and the Indo-European Telegraph Department and the Companies undertake the other half. The agreement is for a tenative period of one year, to be extended if found to work satisfactorily; consequently, the continuance of the reduced rates depends upon the telegraphing public making the experiment a success by giving it their hearty support. It was hoped that Queensland and New Zealand would have taken part in the arrangement, but as they have declined to do so, the rates to these Colonies will remain unchanged.

**Exeter.**—At a recent meeting of the Town Council a report was presented by the Parliamentary Committee, in which it was stated that they had submitted the following terms to the Electric Lighting Company:—"That the Council have the option of purchasing the works and undertaking of the Company at the end of 25, 30, and 35 years from the time of the granting of the Order, upon the terms set out in section 2 of the Electric Lighting Act, 1888, with the following additions:—If the option is exercised at the end of 25 years, the Council to pay the Company a sum equal to the net profits made by the Company during the preceding five years. If at the end of 30 years, a sum equal to the net profits made by the Company for the preceding three years. If at the end of 35 years, a sum equal to the net profits made by the Company in the preceding two years." The Company replied that they would agree to the Council's proposal if the earliest period for the option of purchase was fixed at 28 years, the option only to arise at 28 and 35 years. The Committee resolved to recommend the Council to accept the proposal submitted by the Company. The adoption of the report having been moved, an amendment was proposed to the effect that, while retaining the first period of optional purchase by the Council of the Company's undertaking at 25 years, the Council were willing to make the second optional to arise at the end of 32 years instead of 30 years; thus giving the interval of seven years for which the Company ask. The added profits at the two periods to be those of five years and three years respectively. The amendment was carried by 22 votes to 16. The Company being unable to accede to this proposal, the matter has, by mutual consent, been left to the Board of Trade to settle.

**The Interior Conduit System.**—Considerable mention has recently been made in the American electrical press of a method of indoor wiring known as the interior conduit system, great advantages being claimed for it. The following particulars, taken from a report of the Science and Arts Committee of the Franklin Institute, and from a Paper read at that Institute, may be of interest:—The system is merely a carefully worked-out scheme of supplanting the usual practice of attaching insulation to the wire itself, by a system of insulated raceways, into which the wires can be drawn. The tubes are made of paper or similar material soaked in a hot bath of bituminous compounds. They are hard, strong, and tough. The tubes are secured in position by brass clips. For large mains there is one tube for the positive and one for the negative conductor, but for small branches the two wires are run in the same tube. The wires have merely a light textile insulation. Frequent experiments have shown that it is difficult, owing to the want of air, for a short circuit to start a fire in these tubes. A similar system has now been extended to underground work. In this case a series of tubes is racked in a frame so as to be held at a uniform distance apart. The bundle of tubes is then pushed into a cast-iron pipe and the whole is immersed in a bath of hot insulating compound. When withdrawn from this bath, only that portion of the compound which has entered the interior of the tubes is allowed to escape, the portion which has filled the interstices solidifying. In addition to this consolidated section, individual tubes, the length of which is the same as the consolidated ducts, are employed. These individual tubes are coated at the moment of laying with an insulating compound, and are then telescoped into the consolidated ducts to the depth of just one-half their length in each section. The abutting individual tubes at one end of a section are then telescoped into the consolidated ducts of the adjacent section, and the joints cemented with insulating compound. A complete system of manholes has also been worked out to suit the requirements of this method of laying mains.

## ELECTROMAGNETIC THEORY.—VIII.

BY OLIVER HEAVISIDE.

*(Continued from page 634.)*

§ **46.** A second way of arriving at the motional electric force is by a consideration of the work done in moving a conducting circuit in a magnetic field. It results from Ampère's researches, and may be independently proved in a variety of ways, that the forcive (or system of forces) acting upon a conducting circuit supporting a current, may be accounted for by supposing that every element of the conductor is subject to what Maxwell termed "the electromagnetic force." This is a force perpendicular to the vector current and to the vector induction, and its magnitude equals the product of their tensors multiplied by the sine of the angle between them. In short, the electromagnetic force is the vector-product of the current and the induction. Or, by the definition of a vector-product,

$$\mathbf{F} = \mathrm{V}\mathbf{CB}, \qquad (9)$$

if **F** is the force per unit volume, **C** the current, and **B** the induction. Here **F** is the force arising from the stress in the magnetic field. Its negative, say **f**, is therefore the impressed mechanical force, or

$$\mathbf{f} = \mathrm{V}\mathbf{BC}, \qquad (10)$$

to be used when we desire to consider work done upon the electromagnetic system.

The activity of **f** is **fq**, if **q** be the velocity; or, by (10),

$$\mathbf{fq} = \mathbf{q}\mathrm{V}\mathbf{BC}, \qquad (11)$$

This is identically the same as

$$\mathbf{fq} = \mathbf{C}\mathrm{V}\mathbf{qB}, \qquad (12)$$

by a fundamental formula in vector-analysis. Here, on the left side, the activity is expressed mechanically; on the right side, on the other hand, it is expressed electrically, as the scalar product of the current and another vector, which is the corresponding force; it is necessarily an electric force, and necessarily impressed. So, calling it **e**, we have

$$\mathbf{e} = \mathrm{V}\mathbf{qB}, \qquad (13)$$

again, to express the motional electric force.

It should be observed that we are not concerned in this mode of reasoning with the explicit connection between **e** and **C**; and in this respect the process is remarkably simple. As it, however, rests upon a knowledge of the electromagnetic force, we depart from the method of deriving relations previously pursued. But, conversely, we may by (11) and (12) derive the electromagnetic force from the motional electric force.

§ **47.** A third method of arriving at (13) is by considering the rate of change of the amount of induction through a moving circuit. We need not think of a conducting circuit, but, more generally, of any circuit. Let it be moving in any way whatever, changing in shape and size arbitrarily. The induction through it is altering in two entirely distinct ways. First, there is the magnetic current before considered, due to the time-variation of the induction, so that, if the circuit were at rest in its momentary position, we should have the second law of circuitation true in its primitive form

$$-\operatorname{curl} \mathbf{E} = \mathbf{G}, \qquad (14)$$

when expressed for a unit circuit. But now, in addition, the motion of the elements of the circuit in the magnetic field causes, independently of the time-variation of the field, additional induction to pass through the circuit. Let its rate of increase due to this cause be **g** per unit area. If, then, we assume that the circuitation of the electric force **E** (of the flux) equals the rate of decrease of the induction through the circuit *always*, whether it be at rest or in motion, the equation (14) becomes altered to

$$-\operatorname{curl} \mathbf{E} = \mathbf{G} + \mathbf{g}, \qquad (15)$$

where the additional **g** may be regarded as a fictitious magnetic current. That it is also expressible as the curl of a vector is obvious, because it depends upon the velocity of each part of the circuit, and is therefore a line-integral. Examination in detail shows that

$$\mathbf{g} = -\operatorname{curl} \mathrm{V}\mathbf{qB}, \qquad (16)$$

so that we have, by inserting (16) in (15),

$$-\operatorname{curl} (\mathbf{E} - \mathbf{e}) = \mathbf{G}, \qquad (17)$$

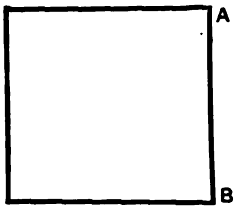
the standard form of the second law of circuitation, when we use (13) to express the impressed force.

The method by which Maxwell deduced (13) is substantially the same in principle; he, however, makes use of an auxiliary function, the vector-potential of the electric current, and this rather complicates the matter, especially as regards the physical meaning of the process. It is always desirable when possible to keep as near as one can to first principles. The above may, without any formal change, be applied to the case of assumed magnetic conductivity, when **G** involves dissipation of energy; the auxiliary **g** in (15), depending merely upon the motion of the circuit across the induction, does not itself involve dissipation.

§ **48.** Perhaps the matter may be put in a somewhat clearer light by converting the case of a moving circuit into that of a circuit at rest, and then employing the law of circuitation in its primitive form. The moving circuit has at any instant a definite position. Imagine it to be momentarily fixed in that position, by stopping the motion of its parts. In order that the relation of the circuit to the induction should be the same as when it was moving, we must now communicate momentarily to the lines of induction the identically opposite motion to the (abolished) motion of the part of the circuit they touch.

We now get equation (15), on the understanding that **g** means the additional magnetic current through a *fixed* circuit due to a given motion of the lines of induction across its boundary, such motion being the negative of the (abolished) motion of the circuit. The matter, is, therefore simplified in treatment. For, in the former way, the process of demonstrating (15) which I have referred to as an "examination in detail," is really considerably complex, involving the translation, rotation, and distortion of an elementary circuit (or equivalently for any circuit). Fixing the circuit does away with this, and we have merely to examine what happens at a single element of the circuit, as induction sweeps across it, in increasing the induction through the circuit, and then apply the resulting formula to every element.

In the consideration of a single element, it is immaterial what the shape of the circuit may be; it may, therefore, be chosen to be



a unit square in the plane of the paper, one of whose sides, AB, is the element of unit length. Now, suppose the induction at AB is perpendicular to the plane of the paper, directed downwards, and that it moves from right to left perpendicularly across AB. Let also from A to B be the positive sense in the circuit. It is evident, without any argumentation, that the directions chosen for **q** and **B** are the most favourable ones possible for increasing the induction through the circuit, and that the rate of its increase, so far as AB alone is concerned, is simply $qB$, the product of the tensors of the velocity **q** of transverse motion of the induction **B**. Further, if the velocity **q** be not wholly transverse to **B** as described, but still be wholly transverse to AB, we must take, instead of $q$, the effective transverse component $q \sin \theta$, if $\theta$ be the angle between **q** and **B**, making our result to be $qB \sin \theta$. Now, this is the tensor of V**qB**, whose direction is from A to B. The motional electric force in the element AB is therefore from B to A, and is V**Bq**, because it is the negative circuitation which measures the magnetic current through a circuit. Lastly, if the motion of **B** be not wholly transverse to AB, we must further multiply by the cosine of the angle between V**Bq** and the element AB.

Digitized by Google

This merely amounts to taking the effective part of **VBq** along the circuit. So, finally, we see that **VBq** fully represents the impressed electric force per unit length in AB when it is fixed, and the induction moves across it, or that its negative

$$\mathbf{e} = \mathbf{VqB}$$

represents the motional electric force when it is the element AB that moves with velocity **q** through the induction **B**. Now, apply the process of circuitation, and we see that **e** is such that its curl represents the rate of increase of induction through the unit circuit due to the motion alone.

This may seem rather laboured, but is perhaps quite as much to the point as a complete analytical demonstration, where one may get lost in the maze of differential coefficients, and have some difficulty in interpreting the analytical steps electromagnetically.

The fictitious motion of the induction above assumed has nothing to do with the real motion of the induction through the medium. If there be any, its effect is fully included in the term **G**, the real magnetic current.

§ 49. The motional magnetic force **h** may be similarly deduced. First we have the primitive form of the first law of circuitation

$$\text{curl } \mathbf{H} = \mathbf{J}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

when the unit circuit is at rest, where **J** is the complete electric current-density, and next

$$\text{curl } \mathbf{H} = \mathbf{J} + \mathbf{j}, \quad . \quad . \quad . \quad . \quad . \quad (19)$$

when the circuit moves; where the auxiliary **j** is a fictitious electric current equivalent to the increase of displacement through the circuit by its motion only. Next show that

$$\mathbf{j} = \text{curl } \mathbf{h}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (20)$$

and

$$\mathbf{h} = \mathbf{VDq}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

by similar reasoning to that concerning **e**; so that by insertion in (19) the first law of circuitation is reduced to the standard form

$$\text{curl } (\mathbf{H} - \mathbf{h}) = \mathbf{J}, \quad . \quad . \quad . \quad . \quad . \quad (22)$$

with the special form of the impressed force **h** stated.

Comparing the form of **h** with that of **e** we observe that there is a reversal of direction in the vector-products, the flux being before the velocity in one and after it in the other. This arises from the opposite senses of circuitation of the electric and the magnetic force to represent the magnetic and electric currents.

§ 50. The activity of the motional **h** is found by multiplying it by the magnetic current, and is, therefore,

$$\mathbf{hG} = \mathbf{GVDq},$$
$$= \mathbf{qVGD},$$

by the same transformation as from (11) to (12).

We conclude that **VGD** is an impressed mechanical force, per unit volume, and, therefore, that **VDG** is a mechanical force, that is, of the Newtonian type, arising from the electric stress. By analogy with the electromagnetic force it may be termed the magnetoelectric force, acting on dielectrics supporting displacement when the induction varies with the time. Of this more hereafter.

§ 51. So far nothing has been laid down about electrification. But the laws of circuitation cannot be completed without including electrification and its suggested magnetic analogue.

Describe a closed surface in a dielectric, and observe the net amount of displacement leaving it. This, of course, means the excess of the quantity leaving over that entering it. If the net amount be zero, there is no electrification within the region bounded by the surface. If the amount be finite, there is just that amount of electrification in the region. This is independent altogether of its distribution within the region, and of the size and shape of the region.

More formally, the surface-integral of the displacement leaving any closed surface measures the electrification within it.

This being general, if we wish to find the distribution of electrification we must break up the region into smaller regions, and in the same manner determine the electrifications in them. Carrying this on down to the infinitely small unit volume, we, by the same process of surface-integration, find the volume-density of the electrification. It is then called the divergence of the displacement.

That is, in general, the divergence of any flux is the amount of the flux leaving the unit volume.

And in particular, the divergence of the displacement measures the density of electrification.

Similarly, the divergence of the induction measures the "magnetification," if there is any to measure, which is a very doubtful matter indeed. There is no evidence that the flux induction has any divergence; it is purely a circuital flux, so far as is *certainly* known, and this is most intimately connected with the other missing link in a symmetrical electromagnetic scheme, the (unknown) magnetic conductivity.

Divergence is represented by div, thus:—

$$\text{div } \mathbf{D} = \rho, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$
$$\text{div } \mathbf{B} = \sigma, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

if $\rho$ and $\sigma$ are the electrification and magnetification densities, respectively.

In another form, electrification is the source of displacement, and magnetification the source of induction. How these fluxes are distributed after leaving their sources is a perfectly indifferent matter, so far as concerns the measure of the strength of the sources. In an isotropic uniform medium at rest, the fluxes naturally spread out uniformly and radially from point-sources of displacement or of induction. The density of the fluxes then varies as the inverse square of the distance, because the concentric spherical surfaces through which they pass vary in area directly as the square of the distance. Thus

$$D = \frac{\rho}{4\pi r^2}, \qquad B = \frac{\sigma}{4\pi r^2}, \quad . \quad . \quad . \quad . \quad (3)$$

are the tensors of the displacement and induction at distance $r$ from point-sources $\rho$ and $\sigma$.

If the source be spread uniformly over a plane in a uniform isotropic medium to surface-density $\rho$ or $\sigma$, then, by the mere symmetry, we see that half the flux goes one way and half the other, perpendicularly to the plane, so that

$$D = \tfrac{1}{2}\rho, \qquad B = \tfrac{1}{2}\sigma, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

at any distance from the plane. But if we by any means make the source send all the flux one way only, then

$$D = \rho, \qquad B = \sigma, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

at any distance.

§ 52. The above being merely to concisely explain the essential meaning of electrification in relation to displacement, and how it is to be measured, consider a point-source or charge to be in motion through a dielectric at rest. Starting with the charge at rest at one place, the displacement is radial and stationary. When permanently at rest in another place, the displacement is the same with reference to it. In the transition, therefore, the displacement has changed its distribution. There must, therefore, be electric current. Now, the only place where the displacement diverges, however the source may be moving, is at the source itself, and therefore the only place where the displacement current diverges is at the source, because it is the time-variation of the displacement. The displacement current is therefore circuital, with the exception of a missing link at the moving charge. If we suppose that the charge $\rho$ moving with velocity **u** constitutes a current $\mathbf{u}\rho$, that is, in the same sense as the motion, and such that the volume-integral of the current density is $\mathbf{u}\rho$, then the complete system of this "convection" current, and the displacement current together form a circuital flux.

Thus, suppose the charge to be first outside a closed surface and then move across it to its inside. When outside, if the displacement goes through the surface to the inner region, it leaves it again. On the other hand, when the charge is inside, the whole displacement passes outward. Therefore, when the charge is in the very act of crossing the surface, the

Digitized by Google

displacement through it outward changes from 0 to $\rho$, and this is the time-integral of the displacement current outward whilst the charge crosses. This is perfectly and simultaneously compensated by the convection current, making the whole current always circuital.

The electric current is, therefore, made up of three parts, the conduction current, the displacement current, and the convection current; thus,

$$\mathbf{J} = \mathbf{C} + \mathbf{D} + \rho\mathbf{u}, \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

$\rho$ being the volume-density of electrification moving through the stationary medium with the velocity $\mathbf{u}$.

If the medium be also moving at velocity $\mathbf{q}$ referred to fixed space, we must understand by $\mathbf{u}$ above the velocity also referred to fixed space. The velocities $\mathbf{q}$ and $\mathbf{u}$ are only the same when the medium and the charge move together. Thus it will come to the same thing if we stop the motion of the charge altogether, and let the medium have the motion equivalent to the former relative motion.

Similarly, if there should be such a thing as diverging induction, or the "magnetification" denoted by $\sigma$ above, then we shall be obliged to consider a moving magnetic charge as contributing to the magnetic current, making the complete magnetic current be expressed by

$$\mathbf{G} = \mathbf{K} + \dot{\mathbf{B}} + \sigma\mathbf{w} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

if $\mathbf{w}$ be the velocity of the magnetification of density $\sigma$.

(*To be continued.*)

## ELECTRIC AND MAGNETIC SCREENING.*

BY SIR WILLIAM THOMSON.

There are five kinds of screening against electric and magnetic influences, which are quite distinct in our primary knowledge of them, but which must all be seen in connected relation with one another when we know more of electricity than we know at present:—I. Electrostatic screening; II. Magnetostatic screening; III. Variational screening against electromotive force; IV. Variational screening against magnetomotive force; V. Fire-screens and window-blinds or shutters.

### I.

Electrostatic screening is of fundamental significance throughout electric theory. It has also an important place in the history of Natural Philosophy, inasmuch as consideration of it led Faraday from Snow Harris's crudely approximate but most interestingly suggestive doctrine of non-influence of unopposed parts and action in parallel straight lines between the mutually visible parts of mutually attracting conductors, to his own splendid theory of inductive attraction transmitted along curved lines of force by specific action in and of the medium intervening between the conductors.

A continuous metallic surface completely separating enclosed air from the air surrounding it acts as a perfect screen against all electro-static influence between electrified bodies in the portions of air so separated. This proposition, which had been established as a theorem of the mathematical theory of electricity by Green, in the ninth article of his now celebrated essay (see pp. 14 and 48 of the reprint edited by Ferrers), was admirably illustrated by Faraday, by the observations which he made inside the wooden cube covered all around with wire netting and bands of tinfoil, which he insulated within this lecture-room; ("Experimental Researches," 1173—1174). "I went into the cube and lived in it; and, using lighted candles, electrometers, and all other tests of electrical states, I could not find the least influence upon them, or indication of anything particular given by them, though all the time the outside of the cube was powerfully charged, and large sparks and brushes were darting off from every point of its outer surface."

The doctrine of electric images is slightly alluded to, and an illustrative experiment performed, showing the fixing of an electric image. The electroscope used for the experiments is an electrified pith ball, suspended by a varnished double-silk fibre of about 9 or 10 feet long. Figs. 1—4 represent experimental illustrations, in which the pith ball, positively electrified, experiences a force due to electrified bodies, optically screened from it by a thin sheet of tin-plate. In Figs. 1 and 2 the pith ball is attracted round a corner by a stick of rubbed sealing-wax, and in Figs. 3 and 4 repelled round a corner by a stick of rubbed glass. In Fig. 2 the sealing-wax *seems* to repel the pith ball, and in Fig. 4 rubbed glass *seems* to attract it. This

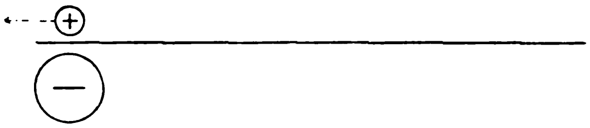


Fig. 1.

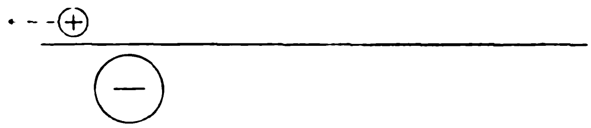

Fig 2.

Fig. 3.

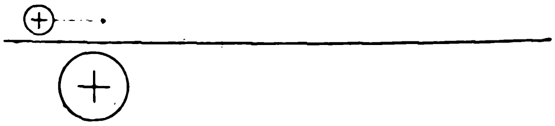

Fig. 4.

experiment constituted a very palpable illustration of Faraday's induction in curved lines of force.

In the present lecture some experimental illustrations were given of electrostatic screening by incomplete plane sheets and curved surfaces of continuous metal, and of imperfectly conducting material, such as paper, slate, wood, and a sheet of vulcanite, moist or dry, window glass at ordinary temperatures in air of ordinary moisture, and by perforated metal screens and screens of network, or gratings of parallel bars.

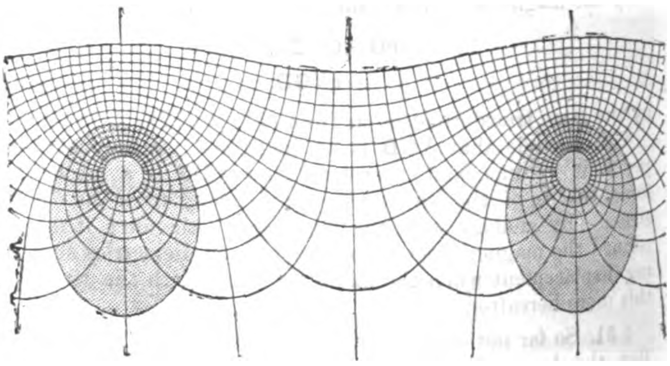

Fig. 5.

The fixing of an electric image is shown in two experiments: (1) the image of a stick of sealing-wax in a thin plane sheet of vulcanite, moistened, warmed, and dried under the electric influence by the application and removal of a spirit-lamp flame; (2) the glass jar of a quadrant electrometer with a rubbed stick of sealing-wax held projecting into it, while the outer surface is moistened, warmed, and dried by the application and removal of a ring of flame produced by cotton wick wrapped on an iron ring and moistened in alcohol.

Fig. 5 is copied from a diagram of Clerk Maxwell's to illustrate screening by a plane grating of parallel bars of approxi-

* Friday Evening Discourse, delivered at the Royal Institution, April 10, 1891.

Digitized by Google

mately circular cross section, with distance from centre to centre 12 times the diameter of each bar. ("Electricity and Magnetism," Vol. I., Art. 203, Fig. XIII.) It represents the lines of force due to equal quantities of opposite electricities on the grating itself, and a parallel plane of continuous metal (not shown in the diagram) at a distance from the grating of not less than one and a-half times the distance from bar to bar. The shading shows the lines of force for the same circumstances, but with oval bars instead of the small circular bars of Maxwell's grating. It is interesting to see how every line of force ends in a bar of the grating, none straying to an infinite distance beyond it, which is necessarily the case when the quantities of electricity on the grating and on the continuous plane are equal and opposite. If an insulated electrified body, with electricity of the same name as that of the grating, for example, is brought up from below, it experiences no electric force differing sensibly from that which would be produced by its own inductive effect on the grating, till it is within a less distance from the grating than the distance from bar to bar, when it experiences repulsion or attraction, according as it is under a bar of the grating or under the middle of a space between two bars. If there be a parallel metal plane below the grating, kept at the same potential as the grating, it takes no sensible proportion of the electricity from the grating, and experiences no sensible force when its distance from the grating exceeds a limit depending on the ratio of the diameter of each bar to the distance from bar to bar. The mathematical theory of this action was partially given by Maxwell (Arts. 203—205), and yesterday I communicated an extension of it to the Royal Society.

II.

Magnetostatic screening by soft iron would follow the same law as electrostatic screening, if the magnetic susceptibility of

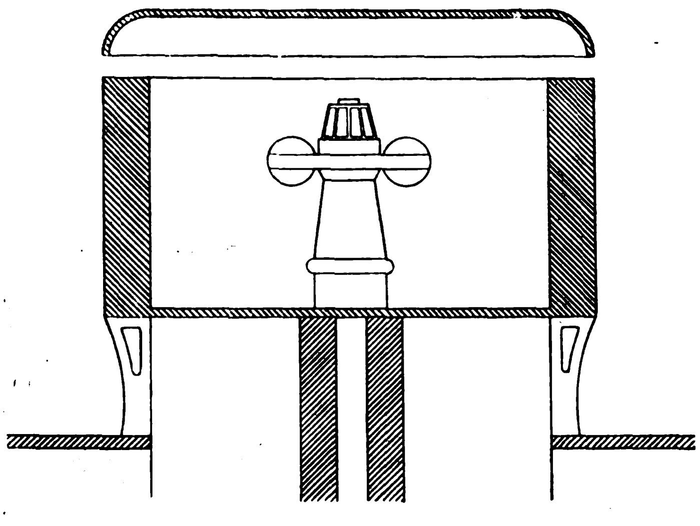

Fig. 6.

the iron were infinitely great. It is not great enough to even approximately fulfil this condition in any practical case. The nearest approach to fulfilment is presented when we have a thick iron shell completely enclosing a hollow space, but the thickness must be a considerable proportion of the smallest diameter, not less than $\frac{1}{10}$, perhaps, for iron of ordinary magnetic susceptibility to produce so much of screening effect that the magnetic force in the interior should be anything less than 5 per cent. of the force at a distance outside, when the shell is placed in a uniform magnetic field. The accompanying diagram, Fig. 6, representing the conning-tower of H.M.S. "Orlando," and the position of the compass within it, has been kindly sent to me by Captain Creak, R.N., for this lecture, by permission of the Controller of the Navy. It gives an interesting illustration of magnetic screening effect by the case of a belt of iron, 1ft. thick, 5ft. high, and 10ft. in internal diameter, with roof and floor of comparatively thin iron. Captain Creak informs me that the average horizontal component of the magnetic directing force on the compass in the centre of this conning-tower is only about one-fifth of that of the undisturbed terrestrial magnetism.

An evil practice, against which careful theoretical and practical warnings were published two or three years ago,* and which is now nearly, though, I believe, not at this moment quite thoroughly, stopped, of what is called single wiring in the electric lighting of ships, has been fallaciously defended by various bad reasons, among them an erroneous argument that the ship's iron produced a sufficient screening effect against disturbance of the ship's compasses, by the electric light currents, when that plan of wiring is adopted. The argument would be good for a ship 50ft. broad and 30ft. deep, if the deck and hull were of iron 3ft. thick. As it is, mathematical calculation shows that the screening effect is quite small in comparison with what the disturbance of the compass would be if the ship and her decks were all of wood. Actual observation, on ships electrically lighted on the single wire system by some of the best electrical engineers in the world, has shown, in many cases, disturbance of the compass of from 3deg. to 7deg., produced by throwing off and on the groups of lights in various parts of the ship, which are thrown on and off habitually in the evenings and nights, in ordinary and necessary practice of sea-going passenger ships. When the facts become known to shipowners, single wiring will never again be admitted at sea unless the alternating current system of electric lighting is again adopted. But, although this system was largely used when electric lighting was first introduced into ships, the economy and other advantages of the direct-current system are so great that no one would think of using the alternate system for the trivial economy, *if any economy there is*, in the single wire, as compared with the double insulated wire system.

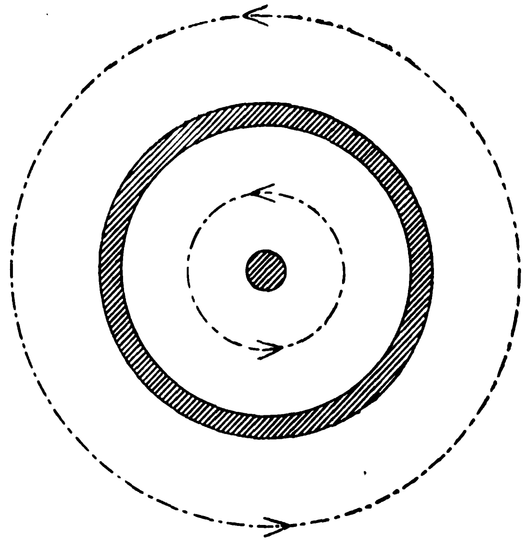

Fig. 7.

An interesting illustration of a case in which iron, of any thickness, however great, produces *no screening effect* on an electric current, steady or alternating, is shown by the accompanying diagram, Fig. 7, which represents in section an electric current along the axis of a circular iron tube, completely surrounding it. Whether the tube be long or short, it exercises no screening effect whatever. A single circular iron ring, supported in the air, with its plane perpendicular to the length of a straight conductor conveying an electric current, produces absolutely no disturbance of the circular endless lines of magnetic force which surround the wire; neither does any piece of iron, wholly bounded by a surface of revolution, with a straight conductor conveying electricity along its axis.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 692.*)

§ 61. In the same volume of *Proceedings* a most interesting Paper by Prof. Ryan is published in which the effect of temperature on core hysteresis is described, and in addition, the observed energy loss from hysteresis when various cores were magnetised by an alternating current is compared with the loss calculated from Ewing's **B-H** curves for slow cycles. One of the most remarkable of these results is here reproduced in Fig. 20,

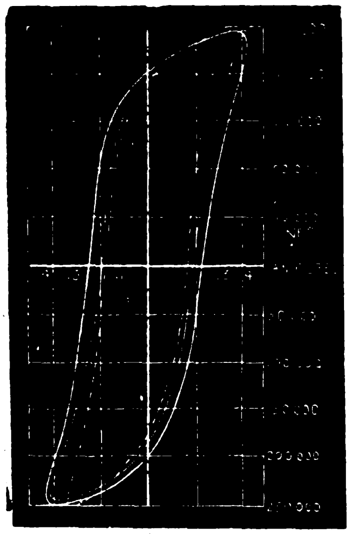

FIG. 20.—Result of Ryan's Experiments. Fine line shows Ewing's Static Hysteresis. Full line shows observed result at 138 ∿ with 10-light Transformer.

where the fine line is the **B-H** curve obtained by Ewing for "static" hysteresis, and the outer thick line is that deduced by Prof. Ryan by working back from the electromotive force and current waves to the induction wave and **B-H** cycle. The observed result includes any eddy currents there may have been in the core of iron plates on which the experiment was made, and is therefore naturally somewhat larger than the static curve, and slightly rounded at the turning-points. As Prof. Ryan well says, "A study of these cards does not reveal that which can be recognised as a trace of viscous hysteresis." Speaking of his method generally, Prof. Ryan remarks with pardonable pride: "This method is found to be fully as accurate, and requires much less time and is more simplified than the analytic method making use of Fourier's theorem." Less

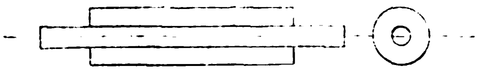

FIG. 21.—Small Open Transformer, one-tenth full size.

time indeed, for our own professors spent years and covered acres of blackboards with the "analytic method," and after all had not discovered that the exciting current was other than a sine function! It takes about 45 minutes to obtain a diagram from a transformer, and everyone can understand it when it is drawn. So far as they go, then, actual diagrams from live transformers agree broadly and substantially with our predicted diagrams. Unfortunately the authors of the Papers we have referred to give no dimensions and details of the transformers, so that we are unable to work out the predicted diagram and so make an accurate comparison between theory and fact.

§ 62. The calculation of the exciting current for open magnetic circuits is of sufficient general interest to warrant a short comparison between the calculated values and actual results. Fig. 21 shows the core and primary coil of a small transformer designed by the writer. The details and dimensions are as follows:—

**Table 16.**—*Open Transformer. Output 200 watts.*
Maximum $B = 8{,}600$ $F = 75$.

| | | |
|---|---|---|
| Iron wire core, total length | = | 40·4 cms. |
| ,, ,, area | = | 4·5 ,, |
| Core projecting outside coil | = | 7·0 ,, |
| Average diameter of primary coil | = | 5·5 ,, |

| | Volts. | Turns. | Resistance. |
|---|---|---|---|
| Primary coil | 2,000 | 15,000 | 470ω |

The usual formula gives 40,500 thoms* as the total induction required to produce 2,000 volts. Since the primary winding occupies so much space outside the core, the whole induction path may be divided in imagination into two parallel portions threading the primary winding, one *viâ* the iron core, the other in the space between the core and the average turns of the coil, to which may be added the small interstices between the wires forming the core. Calculate the magnetic resistance of these two paths separately. The circumference of the core is 8·5 cms, and as 7 cms. project outside the coil at each end, there are 59·5 sq. cms. of cylindrical surface, plus 5·7 cms. on the end, or 65·2 sq. cms. in all. A sphere of this surface has a radius of 2·28 cms., so that the resistance from pole to pole is $\frac{1}{2\pi \times 2{\cdot}28} = {\cdot}07$. The area enclosed by an average turn of the primary coil is 24·5 cms., of which 4·5 is occupied by iron, leaving an air path of 20 cms. area and about 27 cms. in length, the resistance of which is $\frac{27}{20} = 1{\cdot}35$, and if ·07 is added for the external air path, we have a total of 1·42 for that part of the induction path which is composed entirely of air.

Since the core is traversed by something like 40,000 thoms, the density is nearly 9,000 gausses, and we may put **H** at about 10, or $H\,l = 400$, and the ratio of force to induction will be ·01 for the core. This added to ·07 for the external air path gives ·08 as the magnetic resistance *viâ* the core. If ·08 and 1·42 are combined we arrive at the net magnetic resistance of the whole induction path; thus $\frac{{\cdot}08 \times 1{\cdot}42}{{\cdot}08 + 1{\cdot}42} = {\cdot}076$. Since the whole induction is 40,500, we can estimate the exciting current as follows:—

$$\cdot 4\pi \; N \; C' = 40{,}500 \times {\cdot}076 \times 3{,}070,$$

$$\text{and } C = \frac{C'}{\sqrt{2}} = \frac{3{,}070}{1{\cdot}26 \times 15{,}000 \times \sqrt{2}} = {\cdot}115 \text{ ampere.}$$

§ 63. When tested it was found that it required between ·09 and ·1 ampere to excite the transformer to 2,000 volts at a frequency of 75; the volts were measured by an electrometer which had been carefully calibrated and probably read within one, certainly within two, per cent. The current was measured by means of a Cardew voltmeter used as an ammeter, and the reading being very small was somewhat vague, but the current was certainly within the limits named. The method of "equivalent spheres" might be expected to over-estimate the required current, for every assumption made tends to increase the calculated magnetic resistance. The induction is assumed to spread radially from each pole to infinity; it really takes a shorter path curving round from pole to pole. The convention by which the whole induction is supposed to emerge from the core through so much of the ends as project from the core also leads to an over-estimate; obviously a considerable fraction will leave the core a short distance within the coil at each end, and since it threads the greater portion of the whole coil it counts as useful induction. Practically, the calculation by "equivalent spheres" enables us to predict the exciting current required in a coil to produce any given induction in its core with sufficient accuracy for most purposes, and with the certainty that the actual will be rather smaller than the predicted current. A rough method of this sort is frequently of great service in designing electrical apparatus.

§ 64. If the exciting current for a Hedgehog transformer is calculated on precisely the same assumption as to the surface

*One thom = one magnetic line of force.

Digitized by Google

of the equivalent spheres and so on, the resulting value is still somewhat higher than the observed value. Taking Messrs. Swinburne's 10 H.P. Hedgehog as an example, we will calculate the exciting current. The dimensions of the transformer are almost identical in every respect save that of core area, with those of No. 3, as an open transformer (Fig. 7):—

**Table 17.**—*Messrs. Swinburne's 10 H.P. Hedgehog Transformer.*

Maximum $B = 6{,}800$ $F = 100$.

| | | |
|---|---|---|
| Length of core .................. | =73 cms. | |
| Area ,, ,, .................. | 40 ,, | approximately. |
| Volume .................. | 3,000 cub. cms. | approximately. |
| Radius of spherical ends...... | 13 cms. | approximately. |

The core is composed of iron wires, diam. = ·056 cms.

| | Volts. | Turns. | Resistance. |
|---|---|---|---|
| Primary .................. | 2,000 | 1,670 | 3·87 |
| Secondary .................. | 100 | 84 | ·0072 |

It will be noticed that although the primary winding has fewer turns than No. 3 (Fig. 7), the maximum induction is under 7,000, as against 10,000; this is due, of course, to the higher frequency and greater core area. The only other striking difference between the genuine Hedgehog and our imitation is in the resistance of the coils, which are only about one-half the amounts given for (Fig. 7). This merely shows that Mr. Swinburne makes a smaller allowance for insulating space than that adopted by Mr. Ravenshaw, for in designing the coils for No. 3 we made the ratio of the spaces occupied by copper and insulation the same as we found them in the Ravenshaw transformer.

§ 65. The surface over each spherical end of the core will be $2\pi r^2$, and if to this is added the flat surface next the coil cheek, we have $3\pi r^2$ as the surface of the equivalent sphere; and $x$ being the radius of the latter, $3\pi r^2 = 4\pi x^2$. Since $r = 13$ cms. $x$ must be 11·3cms. and the magnetic resistance of the air path is $\frac{1}{2\pi\, 11{\cdot}3} = \frac{1}{71}$. The total induction is $6800 \times 40 = 272{,}000$ thoms, so that [H] required for the air path is $\frac{272{,}000}{71} = 3840$. The maximum H for the core may be safely put at about 7 C.G.S. units, and [H] for the core will be $7 \times 73 = 510$. The total [H] is therefore $3{,}840 + 510 = 4{,}350$, which, divided by $\cdot 4\pi N$, gives the maximum value of the exciting current, or $C' = \frac{4{,}350}{1{\cdot}26 \times 1{,}670} = 2{\cdot}07$ amperes, and the effective value may be taken as $\frac{2{\cdot}07}{\sqrt{2}} = 1{\cdot}46$ amperes. The observed exciting current required to give 2,000 volts on the primary terminals at the frequency of 100 ∿ is 1·35 amperes, or nearly eight per cent. less than the calculated value. This clearly shows that even in the apparently hopelessly complex case of spherical ends formed of radial wires the equivalent sphere, based on the assumption that the spherical end is solid without making deductions for ineffective surface, leads to a sufficiently close approximation to the true exciting current.

§ 66. To return from this digression on the calculation of exciting currents to the subject more immediately concerning us in these Papers; the open transformer is a good thing so far as core waste goes, but there is the large exciting current still weighing like an incubus on our minds. Can it be induced to take some other path than the armature coils of the alternators at the supply station? This is not so difficult a problem as it seems at first sight. Think of electricity flowing along one main from the transformer to the alternator. If before it reaches the alternator it can escape into an elastic reservoir, it will rush into the latter until the pressure from the mains is balanced by the elastic recoil. The reservoir being just so large that the elastic recoil pressure is at each instant equal to the main pressure, when the electric tide sets in in the opposite direction the electricity will be squeezed out again along the main towards the transformer, and not a drop will have been able to get beyond the reservoir to the alternator. Condensers are nothing more or less than elastic reservoirs, and Mr. Swinburne has been experimenting with them with a view to supplying idle current for his transformers. In order to understand their true function when used on alternate current circuits it will be necessary to devote a little space to the theory of condenser currents.

§ 67. The discharge of condensers has been the subject of a great deal of attention for several years, and a recognition of its oscillatory nature under certain conditions (first explained by Sir William Thomson many years ago) has led to brilliant experimental verifications of the electro-magnetic theory of light. It is probable that when once practical men who have to deal with electrical matters on an engineering basis, have had it made clear to them what a condenser will do and why it does it we shall see them taking up this, to them novel, apparatus and turning it to some practical account for electric light and power purposes. It has of course long been an indispensable adjunct in telegraphy.

§ 68. It is usual in discussing the laws of condenser currents to assume that the discharge takes place in a circuit having a resistance R and inductance L, and then determine what values must be given to R and L to make the current oscillatory, and when one is writing a mathematical essay that is no doubt the most interesting course to pursue. When the principal object in view is a clear explanation of the laws governing any complex phenomena, it is perhaps preferable to consider the simplest possible case first, and when that is made clear we may introduce the complicating conditions one at a time, and so arrive by easy and natural steps at the desired end—not necessarily the complete solution of the problem so dear to the heart of the mathematician, but a sufficiently clear conception of the general laws underlying the facts to enable us to make practical applications. That must always be the aim of the practical man who tries to grasp a theory, and he looks to the mathematical physicists to aid him in translating the dry bones of analytics into the flesh and blood of facts. But too often "the hungry sheep look up and are not fed"—hence we see practical men out of their depth in a sea of mathematics—hence these articles!

*(To be continued.)*

## TWISTED TELEPHONE LINES.

While the perfection of talking through the London and Paris Telephone Line is said by Mr. Preece to be due to the fact that he has kept the product of the electrostatic capacity into the resistance as small as possible, and while from theoretical grounds it is thought by some that this theory is not altogether sound, the absence of cross-talk and of the disturbing effects of telegraphic and other electric circuits is undoubtedly due to the method of twisting the lines throughout the whole length of the circuit. But we have on a former occasion remarked that the line from the General Post Office to St. Margaret's Bay is an absolutely silent one, and that as much cannot be said for the longer land line between Sangatte and Paris. Even this section, however, while short of perfection, is far superior to the majority, indeed to almost all of the telephone lines in this country, other than those erected under the supervision of the General Post Office.

There are numerous methods of arranging this twist. The general principle, of course, is to expose each wire in turn to the disturbing influence, and thus to cancel out the induced currents at every complete twist of the wires. When this system was first proposed to the Midland Railway Company, it was objected to on the ground that it would be very difficult for the linesman to detect contacts, since the wires cannot be easily followed by the eye in inspecting them. For this reason some lines were arranged with ordinary parallel wires between post and post. At each post the crossing takes place from insulator to insulator, and the wires proceed to the next post parallel as before. These crossings, as might have been expected, gave rise to more defects than the simple method which has been carried out in numerous instances.

Digitized by Google

Two twists are illustrated in Figs. 1 and 2; in each of these the two pairs of wires are kept distinct, one on each side of the posts. The numbers refer to the wire in each case, the successive diagrams showing the successive posts in the line. The position of the wire may thus be traced from one post to the other. In Fig. 1, will be observed that

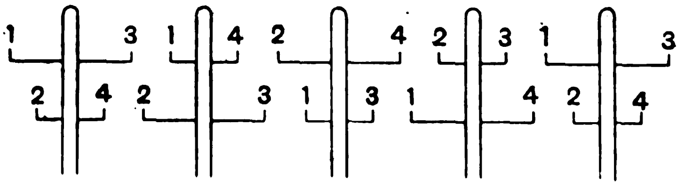

Fig. 1.

1 and 2 rotate about a common axis clockwise, and 3 and 4 rotate in the same direction. This fails to extinguish the induction, but in Fig. 2 it will be noticed that wires 3 and 4 revolve counter-clockwise, and this arrangement acts well. Fig. 3 represents the method of twist adopted in the English land section of the London-Paris Tele-

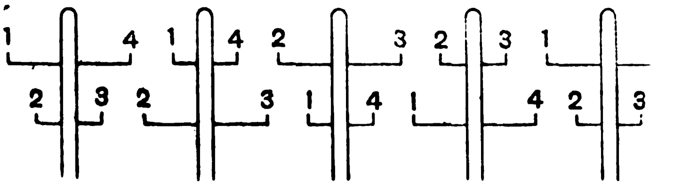

Fig. 2.

phone line. Here the separate conductors are kept at a uniform distance of 14in. apart, and revolve clockwise about a common axis, the whole arrangement being perfectly symmetrical, and the pitch of the twist being four posts' lengths. These wires are conspicuous from the street as they cross from the telegraph building of the General Post Office, passing on

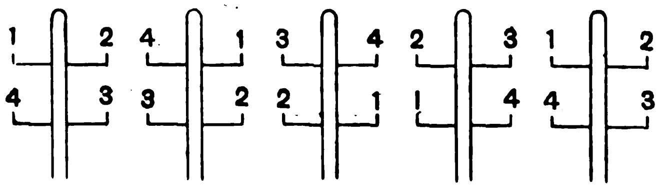

Fig. 3.

to the Stock Exchange and to Cannon-street, and thence on their way to Dover, and the want of parallelism is very noticeable. This square symmetrical twist is like a double wound resistance coil, and is "inductionless." This is Mr. Preece's strong point, for where there is self-induction K.R. is only empirically true within limits, but when L is nothing, he maintains that it is absolutely true.

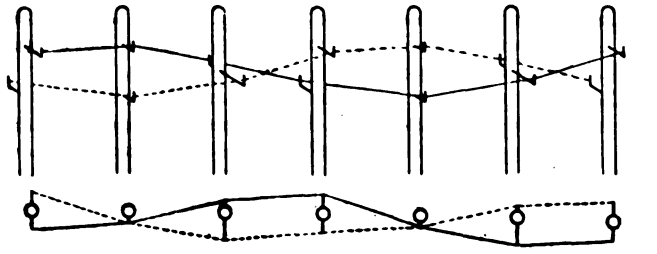

Fig. 4.

It was objected, however, by the French engineers that the wires so disposed might be brought into contact by the wind, and accordingly an arrangement partly shown in Fig. 4 was adopted. The objection was a theoretical one, since such contacts have never been observed in practice, and the device is more ingenious than symmetrical. Only two wires are shown in the two views, one being a plan and the other a perspective diagram. Another pair of wires, revolving in exactly the same manner, is placed below on the same posts. It will be noticed that a complete revolution is made in six posts, and the varying length of the arms keeps the wires at the same distance apart; but the absence of geometrical symmetry entails an absence of electrical balance, and it is found that this portion of the circuit is not altogether free from inductive disturbances caused by neighbouring telegraph and other circuits.

For all ordinary cases these methods of twisting or causing the wires to revolve round each other are probably sufficient to neutralise the effect of extraneous disturbance, but this can only be the case if the disturbing causes extend over a considerable area. If a line conveying a telegraphic or electric lighting current were to run alongside of the telephone line for a portion of its length, considerably less than the pitch of the twist, it would obviously give rise to induced currents. Such a case is very unlikely, but if a disturbing circuit cuts across the telephone circuit obliquely, the resolved component of the surrounding electro-magnetic disturbances might affect the telephone line locally, and thus give rise to induced currents.

## REPLY TO MR. ROBERT SHAND ON "VARIATIONS OF CURRENT IN THE PRIMARY OF OPEN CIRCUIT TRANSFORMERS."*

BY WM. STANLEY, JUN.

The point in question is the accuracy of a statement. In order to clearly state the facts under discussion, I quote the point mentioned:—"In these transformers (open magnetic circuit) the value of the primary current varies comparatively little with the load derived from the secondary circuit, and when such a transformer is gradually loaded, the primary current will remain, roughly speaking, constant, possibly varying 10 to 20 per cent." Mr. Shand questions the accuracy of this statement, furnishing figures from tests made by himself to substantiate his position. Neglecting other results, his conclusion, as shown by Table V. of his article, gives the following data:—

| | |
|---|---|
| Size of transformer | 1,550 watts. |
| Frequency | not given. |
| No. turns in primary | „ „ |
| „ „ „ secondary | „ „ |
| Resistance of coils | „ „ |
| Size of primary and secondary wires | „ „ |

Primary E.M.F., 100 volts; primary current, 3·27 amperes; secondary open. Primary E.M.F., 100 volts; primary current, 16·3 amperes; full load. Drop of secondary potential below normal, 3·5 volts, or 3·5 per cent.

In short, in a transformer of 1,550 watts output with a 3·5 per cent. drop, the variation of primary current was from 16·3 amperes at full load to 3·27 amperes at no load; that is to say, the current fell one-fifth of its full load value when the transformer was not doing useful work. This would certainly seem to conflict with my statement, that the variation was but 20 per cent. But how about the regulation? Certainly no station can use a transformer of 1,500 watts capacity having a drop of 3·5 per cent. Suppose that this transformer was compelled to regulate as well as others of standard make, the permissible drop would then be 1·5 per cent. What, then, would be the "leakage" current at a frequency of 130 periods per second? The resistance of the coils would evidently have to be decreased in the ratio of 3·5 to 1·5, or would be about 43 per cent. of the present value. Maintaining the same size of wire as used in Mr. Shand's experiment would give 43 per cent. of the turns, and with this number of turns the "leakage" current would be about $\left(\frac{100^2}{43^2}=5\right)$ five times as great as he found it—viz., 17·5 amperes. So that if the same fall of potential upon the secondary circuit were allowed for the open as for the closed type of transformer, the current upon the primary circuit when the secondary was open would be as great as when the transformer was doing its full duty.

Of course this reduction of the drop of the transformer cannot be accomplished by simply taking off wire as indicated; the magnetisation of the core given at 6,300 per centimetre gives a hysteresis

* From the *Electrical World* of New York. For Mr. Shand's article, see also *The Electrician*, April 3, 1891, p. 674.

Digitized by Google

loss of about 2·75 watts per pound at a frequency of 133 periods per second. The core is already magnetised too high; reducing the turns to 43 would raise the magnetisation to 14,600 per centimetre, and would give an enormous loss by hysteresis, while the permeability of the core would fall so as to reduce the magnetisation. In short, the transformer made by Mr. Shand cannot be compared with the commercial apparatus; it must be redesigned for 1·5 per cent. drop. In order to compare two types of transformers, it is necessary that they should be designed for the same output; should have the same fall of potential or drop, and the radiating surface per watt lost in the transformer should be the same; they should be subjected to E.M.F's. of the same frequency, and then the "comparison" should be made upon the basis of efficiency and leakage current.

I am now in receipt of a letter from Swinburne and Co. stating that they can make a Hedgehog transformer of 2,000 watts output, having a drop of 2·4 per cent., which will reduce the primary current to about 40 per cent. full load value when the load is taken off. Such a transformer does not regulate sufficiently well for one of 40-light capacity, as it has about 1 per cent. more drop than found in all standard closed circuit transformers of the same size now in use in this country.

## ON THE POTENTIAL DIFFERENCE NEEDED TO PRODUCE A SPARK.*

BY F. PASCHEN.

The author has experimented with spheres of different diameters placed at various distances apart. The gases selected for testing were air, hydrogen, and carbonic acid, and the influence of the pressure under which those gases were examined was also investigated.

With spheres of one centimetre radius the potentials in electrostatic units (300 volts) required for sparking distances of 1, 2, 3, up to 7 millimetres, are found to be 16·1, 27·7, 38·8, 49·4, 60·0, 69·4, and 78·9 respectively, and the sparking potential is slightly less in summer than in winter. The potential required is less the smaller the radius of the balls, except at very short-sparking distances, when a greater voltage is needed. Thus, for a sparking distance of one-tenth of a millimetre the potentials required for balls of 1 cm. and 0·25cm. radius, are respectively 3·35 and 3·67; for a distance of 3mm. the corresponding numbers are 38·8 and 38·7, and for 8 mm. they are 87·8 and 66·8. The diameter of the wires leading to the sparking knobs also exercises an appreciable influence, more especially at long-sparking distances. Thus, with a distance of one centimetre separating balls of one quarter centimetre radius, the sparking potential was 68·9 for leading wires of 0·07cm. diameter, and 73·9 for wires of 0·50 cm. diameter.

The principal result of the experiments is to evidence the following law:—For a given gas at a given temperature the voltage required to produce a spark depends only on the product PD, if the pressure P of the gas, and the sparking distance D are varied, that is to say, the voltage is constant if the product PD is so.

A great number of experiments were made on the three gases for pressures varying from P = 100mm. of mercury to 750mm.; the corresponding values of D varying from 0·75cm to 0.10cm, so that the product PD was in all cases equal to 75. The mean values of the sparking potentials needed under these circumstances for air, hydrogen, and carbonic acid, were found to be respectively 16·65, 9·68, and 17·37. The average divergence of each observation from the mean value was about two per cent. for the first two gases, and three per cent. for the third.

A further set of experiments were made on the gases under various pressures with sparking distances, so arranged that the product PD was 200. Under these circumstances the mean potentials required were 34·64 for air, 19·45 for hydrogen, and 33·37 for carbonic acid. The average divergences of the different observations from each other were about the same as before.

As the density of the gas is proportional to its pressure, we may state the law given above in the following form:—

The difference of potential necessary to produce a spark is a function merely of the product of the density and the sparking distance; or, in other words, this difference of potential depends only on the number of molecules encountered in the path of discharge, and not on the average distance of these molecules from each other.

As M. Cardani has shown that the sparking distance is constant in an atmosphere consisting of a quantity of air kept at constant volume, while its temperature is raised to 300°C., it may also be concluded that the sparking potential does not depend on the relative velocity of the gaseous molecules.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, April 17th** (To-Night).

PHYSICAL SOCIETY.

*5 p.m.* Papers to be read: (1) "On a Property of Magnetic Shunts." By Prof. SILVANUS P. THOMPSON. (2) "An Alternating Current Influence Machine." By JAMES WIMSHURST.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse. "Magnetic Rocks." By Prof. A. W. RÜCKER, F.R.S.

**SATURDAY, April 18th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture. "The Dynamo." By Prof. SILVANUS P. THOMPSON, D.Sc.

**MONDAY, April 20th.**

SOCIETY OF CHEMICAL INDUSTRY.

*8 p.m.* Paper to be read and discussed at Burlington House: "Tanning by the Aid of Electricity." By Dr. S. RIDEAL and A. P. TROTTER.

SOCIETY OF ARTS.

*8 p.m.* Cantor Lecture—II. "The Decorative Treatment of Natural Foliage." By HUGH STANNUS, F.R.I.B.A.

**TUESDAY, April 21st.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture. "The Geography of Africa." By J. SCOTT KELTIE, F.R.G.S.

SOCIETY OF ARTS.

*4.30 p.m.* Foreign and Colonial Section. Paper to be read: "China." By Sir THOMAS WADE, G.C.M.G.

INSTITUTION OF CIVIL ENGINEERS.

*8 p.m.* Ordinary Meeting. Paper to be further discussed: "The Cost of the Generation and Distribution of Electrical Energy." By R. E. B. CROMPTON, M. Inst. C.E.

**WEDNESDAY, April 22nd.**

SOCIETY OF ARTS

*8 p.m.* Ordinary Meeting. Paper to be read: "Bimetallism." By Sir GUILFORD MOLESWORTH, K.C.I.E.

**THURSDAY, April 23rd.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "Recent Spectroscopic Investigations." By Prof. DEWAR, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS.

*8 p.m.* Ordinary General Meeting. Papers to be read: (1) "On Some Effects of Alternating-Current Flow in Conductors having Capacity and Self-Induction." By Dr. J. A. FLEMING, Member. (2) "A Few Calculations on Electrical Shocks from Contact with High-Pressure Conductors." By Major P. CARDEW, R.E., Member.

**FRIDAY, April 24th.**

INSTITUTION OF CIVIL ENGINEERS.

*7.30 p.m.* Students' Meeting. Papers to be read: (1) "A New Type of Water-Motor." By A. SEALY-ALLIN, Stud. Inst. C.E. (2) "Hydraulic Power as applied to Pressing-Machinery." By H. EVINGTON, Stud. Inst. C.E.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse. "Euphuism—Past and Present." By Rev. CANON AINGER, LL.D.

**SATURDAY, April 25th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture. "The Dynamo." By Prof. SILVANUS P. THOMPSON, D.Sc.

*** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "*Coutts and Co.*" *All other letters to be addressed to the Editor.*

*All letters intended for insertion in* "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of* "THE ELECTRICIAN" *commence in May and November.*

## SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS.

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## REDUCTION OF AUSTRALASIAN CABLE RATES.

The substantial reduction announced to take place on May 1st in the rates for telegrams over the Australasian Cables, is an event of hardly less importance to the Mother Country than to the Colonies themselves. It is to be regretted that two of the seven Colonial Governments have withheld their assent to the understanding by which this valuable concession has been brought about; but it is not likely that the colonists of Queensland and New Zealand will for any length of time submit to being excluded from such manifest advantages accruing to their neighbours. Meantime the Colonies of South and Western Australia, of Victoria, New South Wales, and Tasmania will, in the course of a few days, begin to enjoy the benefits of a more enlightened policy, resulting in a reduction of their expenditure on cablegrams to the extent of about 60 per cent. On the other hand, the two dissentient Colonies are left to pay what they have paid heretofore, the rates remaining unaltered for those places, the respective Governments claiming, only by way of set-off, exemption from the risk guarantee which the other Colonies have undertaken. Whatever may be the reasons which induced the New Zealand and Tasmanian Colonies to hold aloof, those reasons do not weigh with the people of this country, who are thus compelled to pay higher rates to those places than to the adjacent Colonies, and who consequently will do their utmost to bring the unwilling members into line with the rest.

Apart, however, from this trifling defect in the symmetry of the scheme as a whole, it is one on which the countries interested and the great cable companies of the East are to be heartily congratulated. The negotiations have been somewhat prolonged, and, for a time, were embarrassed by the obtrusive interference of outsiders, whose only object was to advertise

Digitized by Google

themselves as telegraph reformers. Fortunately, the companies on the one hand were not to be terrified into yielding unduly by the clamour for impossible concessions; and, on the other hand, the accredited Colonial Agents were not deceived into pressing their demands to the bounds of positive rejection. There has been give and take on both sides; and, as is usual in purely business transactions between business men when left to themselves, the result is a fair and workmanlike agreement, which has every chance of becoming a lasting one, although, in the first instance, it is an experiment for only twelve months certain. The adhesion of the two Colonies above referred to will probably depend upon the success of the first year's trial; but whether successful or not, it will be watched with extreme interest throughout the telegraph world as a test of the increase of telegraph traffic over very long lines, corresponding to the reduction of charges. To the Colonies the result will be of not less importance; and although we cannot expect customers to use the cables more for the mere purpose of keeping down the rates, it may be confidently expected they will do so from motives of their own, and that the several Colonial Governments will afford every privilege possible to prevent the experiment failing.

That the Colonies are immensely interested in its success will be seen from the nature of the undertaking into which they have entered with the companies. On their side the Eastern Extension, the Eastern, the Indo-European Telegraph Companies, and the Indo-European Telegraph Department of the Indian Government agree conjointly to reduce the rates for South Australia from 9s. 4d. to 4s.; and for Tasmania from 9s. 11d. to 4s. 8d., and for the intermediate Colonies proportionately. Press telegrams are treated with even greater liberality considering that the existing rate is already only one-third of the charge for ordinary messages, the reduction being respectively for the Colonies just named from 2s. 8d. to 1s. 10d. and from 3s. 4d. to 2s. 6d. According to all the calculations of experience, the loss to the companies consequent on reductions of such magnitude, must be very considerable, and will not be overtaken until a long period has been allowed for growth of traffic—a growth which cannot be expected to be very rapid seeing that the data applicable to cheap and popular tariffs do not hold good for tariffs which are necessarily expensive at their cheapest. To protect themselves, partially at least, from this certain loss of revenue, was the chief anxiety of the cable companies whilst frankly desiring to meet the colonists with substantial concessions. At first it was proposed that they should bear three-fourths of the risk, the companies accepting one-fourth, and this for a term of eleven years. Finally, however, the parties agreed to divide the liability equally between them, and to confine the undertaking to a tentative period of one year. If at the end of that time the result is encouraging, a further period of trial may, and probably will, be agreed upon. But should this not prove to be the case, the companies have the right of reverting to the present tariff.

Thus it will be seen that the Colonies have ensured for themselves this large reduction of rates for a period of a year, the companies enjoying the advantage of a much lower tariff meanwhile to enlarge the area and extent of their traffic—an advantage which would no doubt in time repay them their proportion of the first year's loss, as well as that upon the subsequent tariff. It is hoped, however, that it may be possible to sustain the lower rates; for even if the revenue does not tend to rapidly improve in consequence of these great reductions, the fact will demonstrate to the Colonies that the companies have been justified in maintaining their high charges, and will render the argument for Government subsidy unassailable. In other words it will prove that the companies, who have to make a profit out of their business, must either get it out of the traffic or from the Governments who benefit by the service being efficiently maintained. If, however, the traffic increases to the extent anticipated by them, the loss they will have to make good will be proportionately small, and they will be satisfied with the accuracy of their prognostications. The guarantee on the side of the Colonies is distributed over the five who have assented to it, in proportion of their respective populations, and the charge will not be alarmingly heavy on any of them, even should the experiment fail; and will be reduced to extremely small dimensions if it approach anywhere near the point of absolute recovery. This, as we have said, cannot be looked for in the short space of a year; but, whatever happens, the contracting parties will have learnt something very useful by the end of that time to guide them in the course they will then be called upon to adopt. As regards the companies, and perhaps more especially the Chairman of the foremost of them, nothing but praise can be said of the manner in which a critical crisis has been bridged over by firmness, good management, and tact. Some substantial concession had, perhaps, become inevitable; the right moment was seized, and although the experiment is not unattended with risk, it is one that in the end must result in material advantage to all the cable companies concerned, as well as to the Colonial Empire, with which their interests are so closely bound up.

## THE ELECTRIC CURRENT AND ITS LAWS.—VII.

BY JOHN T. SPRAGUE.

(*Concluded from p. 699.*)

§ 59. There are many analogies between electrical transmission and various mechanical modes; but the most perfect and the most easily shown is that of the hydraulic closed circuit transmitting a current of water, which never leaves the system, and energy which is expended in doing work. Fig. 6 is

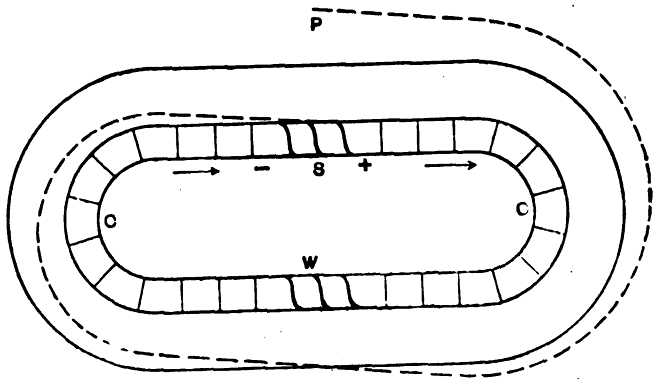

FIG. 6.—Diagram of the Hydraulic Analogue of the Electric Circuit.

intended to show this analogy. C C is the continuous pipe or conductor; S is a turbine, the source of current and energy; W is a similar turbine, doing work when driven by the stream of water.

It will be clearly seen that each revolution of S must drive a fixed (unit) quantity of water (assuming no slip), which corresponds to the amperage equivalence of electric current, and the cross marks in the pipe are intended to show this, as resembling the links of the polar chain. Here, then, we have the material basis, the quantitative element of both currents. It is equal at every section of the circuit; a meter anywhere would read the same, as a galvanometer does in the electric circuit, assuming no leakage. In both cases work done consumes no current; the same quantity enters and leaves the source and every portion of the circuit.

Digitized by Google

§ 60. In the electric circuit we have inductance and magnetance to deal with, but in very different degrees in different circuits, according as they are advantageous or evil. We have just the same, treating them simply as initial absorbed energy, § 32, in the water current. In the practical hydraulic systems this would be an evil, and it is represented only by the elasticity of the pipes and the small compressibility of water. Presently, for theoretical purposes, we may introduce this element into the hydraulic system, but at present we must consider that an initial pressure exists in the conductor which is shown in the external full line, which represents the equal reading of pressure gauges along the circuit, and which corresponds to the zero reading of electrometers on an electric circuit not working.

Directly the source operates we have pressure set up on one side, and suction on the other; that is to say, we have + and − pressure in the circuit, which the pressure gauges will show, precisely as the electrometers would on the electric circuit; the dotted line P shows this, and corresponds in all respects to the line of fall of potential, shown in more full detail than is possible here in Fig. 5, p. 698 (*The Electrician*, April 10th). But here also, according to the nature of the work done, we should find sudden drops due to counter-pressures, and also gradual slopes due to resistance in the circuit.

§ 61. A formula corresponding to Ohm's law could be drawn for hydraulic current, but one element would not be so simple. Electric conductance is a matter purely of sectional area, in any given substance, because the true frictional resistance is equal at every part of that area; it is a function of atomic motions. In the case of a water pipe it is not so; there is the skin friction of the pipe, and there is the friction of the viscosity of water, and neither is related purely to sectional area; but if we once expressed this, for any pipe, in terms of conductance per unit length, its reciprocal would give us the correlative of ohmage in electricity. Here, then, is my answer to questions put me by Professor S. P. Thompson, on p. 375 of *The Electrician* of January 23rd. I consider that Ohm's *formula* applies in its simplest form to constant electric currents; but I hold that Ohm's *law* is the expression of a universal mechanical truth, and can be applied to all cases of mechanical motion and stress; that it does "represent the facts of gravity or of static electricity," whether it professes to do so or not, or whatever may have been in the mind of Ohm himself. It is no uncommon thing for a truth to be far more wide-reaching than the prophet who reveals it, perceives for himself. I do not think that Ohm's law does give us the facts of steady currents; it gives us the current "ordinate" for the conditions of the instant; it, therefore, gives us the constant current practically, because that is one of unchanging conditions of equal ordinates, and consequently a "curve of current," which is a horizontal straight line. But equally the *law* gives us the changing ordinates of the variable period if we put the varying conditions into the formula which applies the law. I shall come to this subject again.

§ 62. To return to Fig. 6, + and − pressure, that is pressure and suction, push and pull can equally transmit energy, do work and generate current. The hydraulic circuit, like the electric, can be subdivided into branches (multiple arc, derived, or shunt circuits) of various sizes and lengths, and the same laws will govern them as control the corresponding electric subdivisions of circuit. Work can be done in series or in arc, the machines being placed on an outgoing conductor and the conductance adapted to let the current pass at once to the return circuit. In fact, the distribution of energy by a water current, under pressure in a closed pipe, goes on under conditions absolutely identical with those of the electric current. If, in this latter, the wire is a mere waste-pipe and the energy goes by an outside medium, there is no escape from the conclusion that the energy of a hydraulic engine is taken to the motors, not by the water, but by some mysterious outer agent having the properties of a dielectric. I doubt whether any hydraulic engineer will swallow that, whatever educated electricians may do.

§ 63. Now let us bring the phenomena of the variable period into the hydraulic main. To do this we must provide a dielectric. That is, something possessing elastance, permittance, reluctance, and so on. In other words, the conductor must first expend energy upon something external to the current, which must be first satisfied, and will, therefore, *retard* the real current. This is easy when we need only to manufacture abstract ideas, and need not call for capital expenditure. We have only to make the conductor elastic, and this is merely the same thing as using an electric circuit with large "inductance and magnetance;" instead of a rigid steel pipe, let us lay down a strong india-rubber one, and put it under pressure till it fills the external full line in Fig. 6.

§ 64. Directly the source acts, the + and − pressures will convert this cylinder into a long conical pipe, having the outline of line P. In electrical phrase, the first effort of the source will be all engaged in producing external stresses; none the less, the energy of the source will travel inside the conductor. Why should we say it does not do so in the electric case? The conditions are the same. Let us now reproduce Fig. 4 as Fig. 7, which was drawn for this use, and see what happens in this initial variable period.

This shows the earliest effect of + pressure. The water, shown by arrows entering the pipe, meets an obstacle,—the inertia of the water in the pipe, shown in the shaded lines I. The elastic pipe yields to the pressure and expands. The energy of the source is first employed in setting up stresses, and actual "current" is limited to a superficial skin, and is itself employed, not in propagating true current in the conductor, but purely in setting up external stresses. The same conditions, but reversed, are set up on the opposite side of the source by suction, or − pressure. The actual current of the source is local; does not appear in the distant parts of the conductor until the full limit of stress, corresponding to the

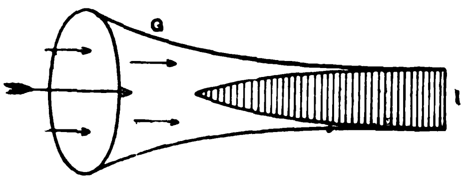

FIG. 7.

pressure of the source, is charged upon the external "inductive" field, and is propagated along the conductor in a wave of impulse. Let the source cease to act; this stored energy returns to the conductor, and produces an "extra current," equalising the pressures along the whole circuit, even though that circuit is broken; that is, no passage is open through the source. In what way do the conditions differ from those of an electric circuit?

§ 65. Oscillations? Frequency? Separate induced circuit and current? Yes, we will have them all—*theoretically*. I do not advise practical applications.

Let us lay down two such elastic circuits as that of § 60, and enclose them in a rigid casing so as to create a field of force. Let the primary circuit, with its source, correspond to C C, Fig. 6, made elastic; let the secondary circuit be an identical one placed upon and pressed to the other. Now let the source work, and convert the primary into the conical form resulting from pressure. The secondary, which forms part of the external field—that is, the dielectric field of the primary—receives a transmitted stress which converts it also into a conical tube, but in a reverse direction; the corresponding stresses are set up in it, by the energy of the source, which is in no way in its circuit, and a momentary current is induced which will work its turbine.

A reverse action and current will come into existence as soon as the pressure of the source ceases; but just so long as the source maintains its action, neither the stresses in its own conductor, nor the stresses in the secondary, will have any influence whatever upon the current in the primary.

Set up oscillations, reversals, or intermittent action of the source, and you will have alternating currents following each other in the secondary. A little ingenuity, and we could so "commutate" the motor in the secondary as to get a suc-

Digitized by Google

cession of direct impulses through it, out of the alternating impulses in the conductor, just as we do in the H armature type of dynamo machines; and we could do work in the motor as we do with the dynamo; or we could convert the to-and-fro motion of the motor itself into a direct rotary motion.

Again, I ask, in what way do the conditions differ from those of the electric circuit? Why need we seek some hypothetical mode for the transfer of energy, when our common-sense shows us the simple truth in natural actions, which we can test practically, instead of groping among abstract ideas and inexplicable symbols?

§ 66. Let us examine these corresponding conditions in the primary and secondary electric circuits, and settle Prof. S. P. Thompson's Fifth Proposition, p. 464 (*The Electrician*, February 13th). Let Fig. 8 represent two circuits, the primary one *a a*—from which energy is in some way transmitted through the insulating medium, to the separate secondary, or induced circuit, *b b*, closed through the galvanometer G. I show them wound side by side upon a magnetisable core; in fact, as a crude transformer or induction coil.

Before we ask how the energy gets to the secondary, let us inquire how it gets to the primary? We have Mr. Heaviside telling us, p. 388, § 15 (*The Electrician*, January 30th), "the source of energy must, therefore, first supply the dielectric surrounding the wire (primary) before the substance of the wire itself can be influenced, that is the dielectric must be the real primary agent;" again, p. 389, § 16, "the battery acts upon the dielectric primarily—electrical conductors act, as regards internal propagation, not as conductors, but rather as obstructors." Very well, only I wish someone would answer my question, § 18, p, 576 (*The Electrician*, March 13th), how does the current which cannot exist till energy is supplied, control this external energy, and so create itself?

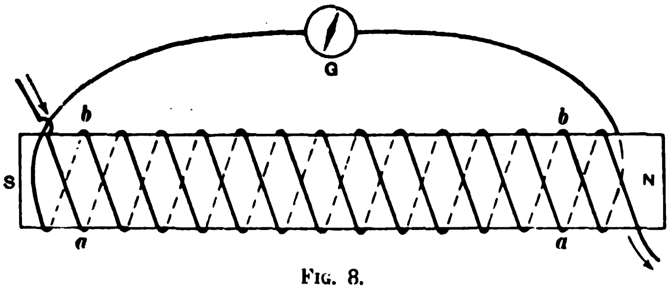

Fig. 8.

However, this theory means clearly that the energy of the source forms a sheath surrounding the coils in Fig. 8, whether it goes round and round, led by the wire, or whether it flows across the wires, I do not see; but it seems to me the latter is the meaning of "lateral transmission."

§ 67. The conductor is an obstructor and a waste-pipe. Very good; but here are *two waste-pipes.* What is the principle of selection? Both are closed, both are equally capable of dissipating energy; *both have currents in them,* and it may even happen that the current in the secondary may be earlier in phase than the retarded current in the primary. I want to know why the actual initial current in the secondary stops at once? Why does it not draw upon the obliging energy in the "medium" and keep itself going? It does not; it acts just like our secondary hydraulic current; the energy of the source traversing the dielectric at the speed of light, first sets up stresses in the medium, with an incidental current in the secondary, magnetises the core, taking its time to do this thoroughly, and then, "like a bird that seeketh its mother's nest," coolly gets into its own conductor and patiently expends itself wholly in maintaining a current in that conductor. Now, why *does* it select only that waste-pipe which is connected to the source?

Why should it not? it never was out of it. If there were the smallest break in that primary conductor no energy would go into the dielectric, no magnetism be set up in the core, and no energy issue from the source at all, except what is needed to charge the small inductive circuit between its terminals, and possibly, set up some small static charge in the dielectric. A break in the other waste-pipe available, the secondary circuit would have no effect except to reduce the initial absorption of energy.

§ 68. Now let us examine the relations of the two-wire coil in the light of common-sense theory, treating the wire connected to the source as the sole outlet of energy from, and the conduit of current from the source, on the principles of current already discussed. First, let us note that although we do get "current" with all its phenomena of amperage equivalence in the secondary, this current is not derived from the source at all; the whole of the amperage generated in the source is retained in the primary wire. That is to say, the secondary current is a new and independent evolution. But its energy is derived from the source.

If we wind our two hydraulic circuits into a similar coil instead of treating them as in § 65, the result will be precisely the same, and will correspond with the electric facts. And why? Because our elastic pipes are the true correlatives and analogues of inductance in electricity, fields of force, absorbing energy from the source, and delivering it up as conditions permit.

The first effort of the source is to charge these fields, to set up the static stresses of inductance, and to charge the magnetic field. Make two exactly similar systems as regards wires, but giving one a higher inductance by using insulation of higher capacity, and higher magnetance by putting iron in one of the cores. The currents in primary and secondary will be wholly different in the two. Higher inductance and magnetance will retard current in the primary, because more energy is absorbed in the charges. They will give increased current in the secondary, because it is there that the stored energy goes.

§ 69. I have already shown that the momentary current on closing circuit is due to the secondary wire forming part of the

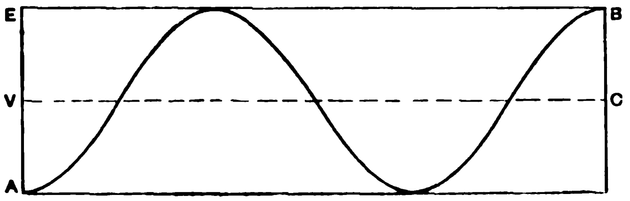

Fig. 9.

static inductive field, and also of the magnetic field, and having to range its atoms in the corresponding order, just as the current is produced in the dynamo. And it must be remembered that this polar order is no hypothesis. Polarised light reveals the structural change which occurs whenever a substance is made to form part of the lines of force. The experiments, new and old, mentioned in Dr. Fleming's excellent Paper on "Electromagnetic Repulsion" (see *The Electrician*, March 13th, *et seq.*), prove it to demonstration; for they all depend on something happening in the interior of bodies, proved to be motions, because they produce heat, these bodies being forced into lines of force.

The current at break is produced by the stored energy, the inductance and magnetance; it is a result similar to the extra current in a single wire. Why does it appear in the secondary wire, instead of the primary, from which it issued? Because the circuit of the primary is broken, and, therefore, resists the evolution of current in it. As a matter of fact, current does form in both wires, but chiefly in that which favours its evolution. We must regard the field of force as a momentary source, with a "voltance" due to the contained energy, and, therefore, with a rapidly vanishing voltage. It is this energy, this voltance, which acts as an E.M.F. upon any outlet available to it, and so generates a current in the secondary wire entirely independent of the current of the original source, excepting in so far as that current originally controlled, by its amperage, the manner in which the energy was stored and the kind of stress set up.*

§ 70. It is necessary now to consider some other facts of the variable periods. Let Fig. 9 represent a succession of current impulses; they may be either intermittent direct currents, or

* A charged condenser acts in the same way as a temporary source, and secondary batteries work on the same principles.

Digitized by Google

they may be alternating currents, and these may be either commutated into one direction, or left alternating, except where employed in electrolysis; but if alternating we must consider that suitable instruments are used.

Prof. S. P. Thompson asked, p. 375 (*The Electrician*, January 23rd), if I held that Ohm's law applies to alternating currents, and if an alternating E.M.F. of 100 volts as measured by a Cardew's voltmeter acting in an ohmage of 5, would give a current = 20 amperes. Now, that does not admit an answer, yes or no; it involves some very serious points of theory and practice. Cardew's voltmeter, while a most valuable instrument, does not measure volts, nor does any voltmeter which is not an electrometer. It measures the last of a series of transformations of energy, viz., the expansion of a wire, resulting from heat generated by a current in a derived circuit (the wire) under the voltage it has to estimate.

But let us go to the root of the matter; an alternating current has *no* definite voltage, no true definite current which can be expressed as one value. Granted we can get at something, the average voltage and current, the square root of the mean of the squares of all the ordinates of the curves, which may be of great practical use, but which, when we examine it, is merely a convenient fiction. Precisely the same thing is true of the new unit of inductance, the Henry. It will express the inductance in terms of an average; it will be very useful; but in the light of truth it is nothing but a "dodge." Inductance may be called a "length," and measured in secohms or quadrants; but nothing of the kind really exists in nature. If it takes a minute to bore a hole an inch deep, would there be any fact in the statement that the average depth during that minute was half an inch? Of course it would be a true statement in a column of statistics, and possibly in mathematics.

§ 71. The case is identical with that so clearly stated by Mr. Evershed, §§ 35-6, p. 597, "the mathematical clothiers calmly cut down the infinite series to one solitary term." Now let us study Fig. 9.

Where is *the* voltage or *the* current in these curves. You can integrate them. Yes, for some purposes; but only as a dodge. Nature will not integrate them. The actual voltages and currents are incessantly varying in portions of the ordinate, or line A E, and the true current is varying on the curve A C. Let A V be the voltage read on a Cardew's voltmeter, and let us imagine that by Ohm's formula we can get the curve into the line V C. Pass your current into a suitable galvanometer with a needle which will remain fairly steady, and into a recording meter, and let us find that these instruments record an average current agreeing with the voltmeter (we may suppose proper corrections applied to Ohm's formula). Pass your current, if made direct, into a copper depositing cell, and admit that it also agrees, and that we have the same result in an incandescent lamp. Surely we have got a truth; the measure of voltage and current prove it. Not a bit of it. They only prove the utility of the dodge for some practical purposes.

§ 72. But now pass your current into an electrolytic cell, the re-voltage of which is equal to the Cardew voltage; let us call these both volt 1·5 for the purpose of illustration. Now, according to formula

$$\frac{1\cdot5 - 1\cdot5}{R} = 0,$$

we ought to have no current at all. But what does happen is that we get a considerable current. All the current below the line V C in the curve A C is extinguished; but all the curve above the line is effective, and that is a very considerable part of it, because, of course, it is not the linear curve, but its height above zero A, which measures the current; in this part of the current time, therefore, we have a + voltage ranging from 1·5 to 3, with a − re-voltage of 1·5 to generate current according to Ohm's law.

I will make a prediction of great practical importance, based on this. If we have incandescent lamps giving a life of, say, 1,000 hours at a fixed voltage, when worked from a battery, they will have a much shorter life when worked by an alternating current under the same voltage, shown by Cardew's or other voltmeter.

§ 73. I have not said much about the process of conduction in wires, except in regard to the formation of polar chains; but it is evident that modern physicists are tending to the belief that it is of the same nature as conduction in electrolytes; and as Mr. Heaviside evidently looks with some favour upon the idea, § 40, p. 633 (*The Electrician*, March 27th), it may not be long before it has a suitable mathematical outfit. Well, I taught and published that conception over 23 years ago, and have consistently held it, as part of my theory of electricity, as now afresh laid out in these articles; so it appears that "modern views" are coming up to the line I have held for a quarter of a century and more.

Many think that there is some specific entity, which they call "electricity," which forms a part of the molecules of matter, and by its transfer effects changes in matter and energy. I see no need for such an entity, and even if it exists, as part of matter, and cause of its functions, then it is included in my "concept" of matter! If we recognise that the ultimate atoms, or, rather, equivalents of matter, are, in fact, "polar" bodies, we need not hypothesize about the cause of the polarity, any more than about the essence of matter. It is simply the extension to all matter of the idea of atomic magnetism which Prof. Ewing has made prominent of late, as regards specially magnetic substances. We can see that certain consequences follow, which bear upon the structure of matter. The union of two atoms by their opposite polarities constitutes a monad molecule, while three or many would build up the more complex molecules.

The formation of a polar chain means simply the opening out of these molecules into atomic order, by an impressed force, itself of a polar nature. Then, as I long ago pointed out, the internal attractions, which constitute the actual molecule, are necessarily weakened, and partly diverted to external atoms, thus constituting the chain. All this we can easily reproduce

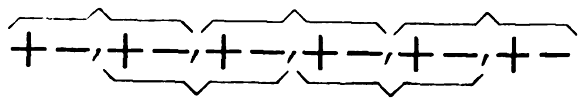

Fig. 10.

(I did it for myself more than 30 years ago) by means of small magnetic needles, with which we can form an actual polar chain, such as I drew on p. 332 of my "Electricity."

A step further and a general interchange occurs along the lines, and a semi-rotation of each new formed molecule, each such action being the accompaniment and consequence of one ultimate equivalent of zinc dissolving and sending its energy or voltance into the polar chain, acting as an impressed force. It is easily pictured (Fig. 10), each + − being one polar atom, the freed end ones at once uniting with those of other chains to reform molecules, and the whole row turning over to range themselves afresh in rank with the polar order of the source.

§ 74. A few words now about the velocity of electricity. A chief reason for the invention of etherial electricity is that matter is said to be not capable of such motions. We know nothing abou the capacity for *atomic* motions, and have not right to argue from mechanical or mass motions of matter. The evidence of the spectroscope is that atoms do really make these motions. Neither do we know anything of the actual velocity of electric transmission, and we have good reason to believe that pure vacuum, our nearest approach to ether, does not transmit electric action at all.

But we have long known that the so-called velocity of electricity in wires is much the same as that of light in the ether, and we are told that Mr. Lecher has recently shown this again experimentally. But if we had a perfectly rigid and frictionless wire, without inertia, 1,000 miles long, and pulled one end through, say, three inches, that motion would be transmitted the 1,000 miles with, say, the velocity of light, and would do work. But the real motion at any point would only be three inches, and the actual velocity in the 1,000 miles a mere trifle. Well, an electric conductor acts as a nearly frictionless and rigid transmitter. The actual motion is rotation of molecules, and we have no evidence that any sal transfer or linear motion occurs at all.

Now I have finished, and listen to hear the other side. I only ask them to give us something to be understood; and, as far as I am concerned, to accept my plain meaning, and to use my allegories and illustrations within my own limits. No allegory or illustration will endure over-driving. Like hobbies, they are serviceable while kept in hand, but just as the tiger, pleasant enough to hunt, is inconvenient when it takes its turn at hunting, allegories and hobbies, when they bolt, are apt to end their journey in a ditch.

## NOTES ON THE DESIGN OF MULTIPOLAR DYNAMOS.*

BY W. B. ESSON.

*(Concluded from page 705.)*

### 7. *Dimensions of the Field Magnets.*

It will be apparent, from the foregoing considerations, that the employment of two, or more than two, poles for direct-current machines of moderate dimensions resolves itself mainly into a deliberation regarding the most economical shape to give to the field magnets. As regards the armature, considered by itself, we may say that the choice of dimensions is mostly a matter of convenience, seeing that the amount of copper required and efficiency are for a given output practically unaltered by variations in this respect, while the reduction in the weight of the core due to an increased

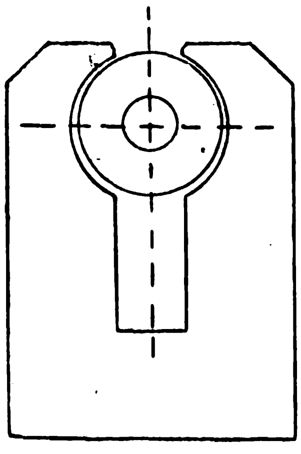

FIG. 3.

number of poles is to some extent compensated by the extra expense of larger plates and increased weight of the armature supports. Again, the cost of labour is increased by the larger diameter; but, everything being taken into account, considerations respecting the armature do not influence the design to a very great extent. One thing in favour of increasing the poles, as far as the armature is concerned, must, however, be remembered, and that is the reduction, consequent on a smaller conductor being used, of the losses arising from parasitic currents. We now turn our attention to the magnets.

I have said that for the prevention of sparking it is necessary that, the induction per square centimetre remaining the same, the air-gap increases proportionally to the diameter, whether the space is necessary for conductors and clearance or not, but that the coefficient by which the diameter has to be multiplied to give the length of the gap necessary to prevent sparking, diminishes directly as the pole angle. In comparing the magnetic system of a four or six-pole machine with that of a two-pole one, it is necessary to adopt dimensions for the armature in accordance with the considerations already mentioned; hence, if the two-pole armature had a length of core equal to one and a-half times its diameter, in a four-pole one the length should be about half the diameter. The diagrams (Figs. 3 and 4) show the cross sections of two such machines. The diameter of the four-pole armature is 1·4, and its length ·5 times that of the two-pole one, consequently both machines give the same output. The weight of the two horse-shoe magnets in the four-pole machine comes to 56 per cent. of the weight of the single horse-shoe magnet, which indicates in this particular case a considerable saving in wrought iron. In taking the copper weight it is necessary to bear in mind that this does not vary simply as the length of the wire if the machines are of the some efficiency, but as the square of the length; so in this particular comparison the copper on the two horse-shoes would be, roughly, 30 per cent. more than on the single horse-shoe, assuming the length of the air-gaps to be the same. Now, if it were possible to reduce the gaps by 12 per cent. or so, the copper weight would be similar in both machines, and we should have credit for a certain amount of iron saved in the construction of the four-pole one, which could be balanced against the increased expenditure for labour. If the gap can be reduced by more than 12 per cent.—always retaining the depth of the winding the same—there is a saving of copper as well as iron, and it is simply the comparison between the value of the copper and other materials used and the cost of the labour in the two cases which determines, at least in machines of moderate size, whether two or more poles should be adopted.

In getting out the best relation of L to $d$ in the different types of armatures, it is assumed, of course, that, the volume being proportional to the diameter, the depth of the winding remains unaltered, as that is the condition which gives uniform rise in temperature. Accordingly, for a given output, the layer of copper on the armature will be of the same depth whether the machine has two poles and an armature having a length of one and a-half times its diameter, or four poles and an armature having a length of only half the diameter. But whether it is possible to reduce the gap to an extent which, with an increased number of poles, will lead to a less costly construction, is a question which for machines of moderate dimensions must receive careful consideration in each individual case. The answer depends upon how much larger the gap has to be to prevent sparking in the case of two poles only, than is requisite to accommodate the conductors and allow the necessary clearance. If the difference is considerable, it may pay better to add poles, and reduce the gaps that way, than to do the same thing by diminishing the pole angle or increasing the induction, or both. The question, it appears, is answered in different ways by different people. It is somewhat interesting to note, for instance, that one engineer, distinguished for the past six years as an ardent advocate of multipolar machines, has, after reducing from six poles to four, lately arrived at two, while another has jumped straight away from two to six without a halt at the intermediate number.

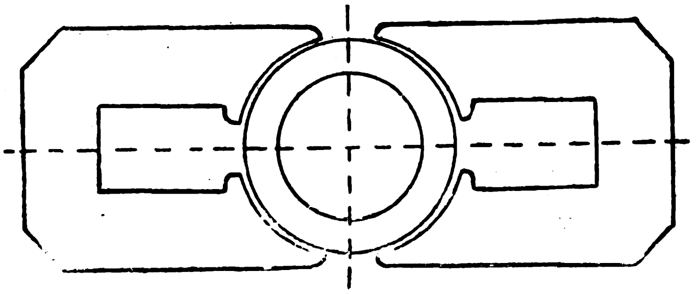

FIG. 4.

But when we come to machines of a certain size there is undoubtedly a gain in employing more than two poles, while very large machines become impossible of construction with two poles only. Consider the case of a two-pole armature of 60 centimetres diameter. Assuming the induction in the gap to be 5,000 C.G.S. lines per square centimetre, and the pole angle 130 deg., our calculations show that the length of air-gap would require to be 3·24 centimetres. This is some 40 per cent. in excess of the requirements of conductors and clearance; so, if the gap is reduced until it just allows of the requisite clearance, the induction must be increased from 5,000 to 7,000. Keeping the output of the machine the same, however, we can reduce the diameter of the armature to 54 centimetres, and work with an induction in the gap of 6,500. Observe, the magnetising force spent in the gap has now been reduced by about 7 per cent., but the total field through the armature has been increased by 15 per cent., and the induction in the armature per square centimetre by more than 25 per cent. If we retain the same section of iron in the fields, it may be assumed then that about the same total magnetising force is required, whether the machine has an armature 60 centimetres diameter, with a gap induction of 5,000 C.G.S. units, or one 54 centimetres diameter, with a gap induction of 6,500. The latter might turn out to be impossible owing to the greater heating of the armature core; any way, what I am attempting to show now is, that by pressing up the induction with a view of reducing the gap, little, if any, advantage is obtained. But by increasing the number of poles, and reducing the gap in that way, we effect, without increasing the gap induction, a marked economy. As it is unnecessary to go into a mass of figures to prove what each can readily prove for himself from the data already before you, I will just give here the results. If we substitute for the two-pole armature of 60 or 54 centimetres diameter and 90 centimetres long a four-pole one of 84 centimetres

* Paper read before the Institution of Electrical Engineers, April 9, 1891.

Digitized by Google

diameter and 45 centimetres long, with a gap induction of 5,000, we require for the magnetising coils while working at the same sparking limit, and with the same efficiency, rather under 70 per cent. of the copper on the two-pole field. When to the saving in copper there is added the saving in iron, there will be, after the extra labour is debited against the four-pole machine, a considerable balance in its favour. But to go beyond four poles in this case would be a mistake.

Having discussed the design of multipolar machines as influenced by both theory and practice, it remains to conclude this communication by calling attention to some of the ordinary forms of multipolar fields. The double wrought-iron horse-shoe (Fig. 4) is not very frequently used, being rather costly; but a similar machine with magnets of cast iron, lately made by my firm for the National Line s.s. "America," is shown in Fig. 5. The

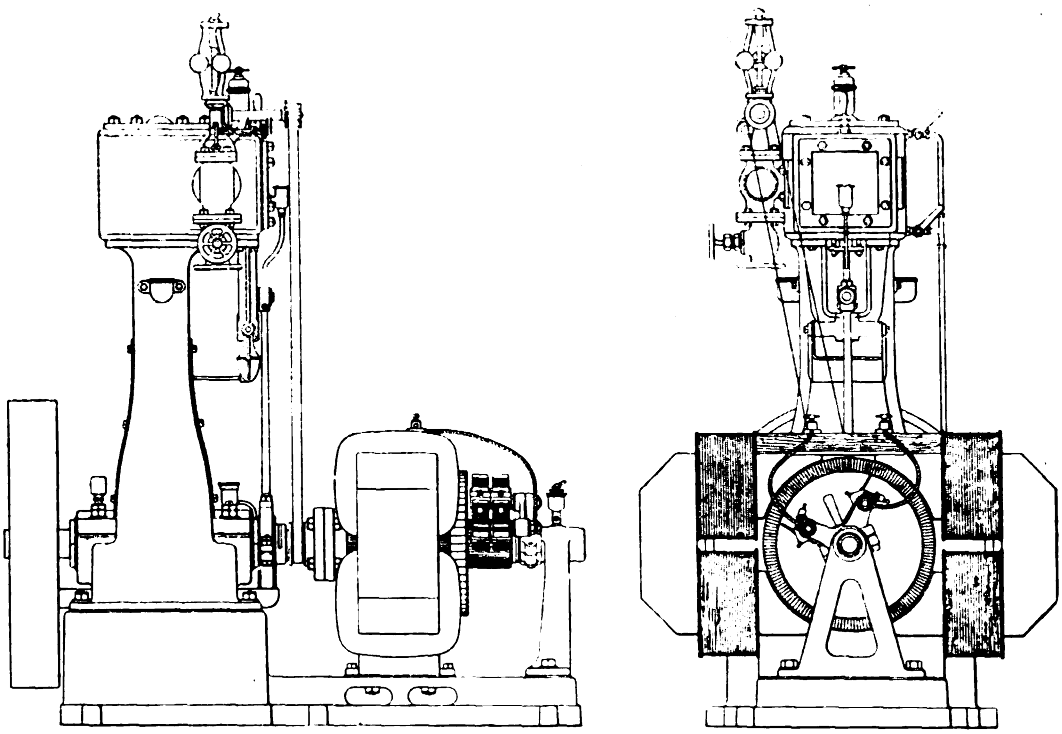

Fig. 5.—Engine and Dynamo for ss. "America.'

Increasing the poles always results in an actual increase of copper, unless at the same time the power spent in the gap is reduced, and this latter must be effected without reducing the thickness of the armature winding. The economy shown above is simply due to the fact that in a two-pole machine of the dimensions specified the gap necessary for the prevention of sparking must be much larger than the conductors require unless pressed up to a high induction. If

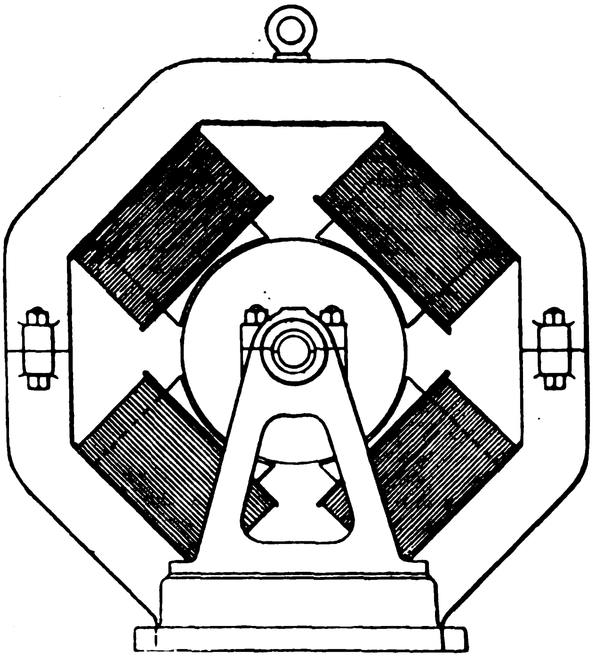

Fig. 6.

with four poles the gap is still larger than necessary, we go to six poles, and so on. But when we arrive at a point where increasing the number admits of no reduction in the gap, we go no farther. It may be mentioned, however, that even in sizes where a four-pole construction showed no actual economy in first cost, it might still be preferable to the two-pole on account of its symmetrical field and the absence of magnetic pull.

armature core in this case was formed by winding square annealed-iron wires on a gun-metal flanged cylinder. The winding was of the Gramme type, and the machine was coupled direct to an inverted engine, as shown in the figure. This design, introduced by Gramme in 1869, generally gives place to the arrangement shown in Fig. 6, a form designed by the same inventor in 1885, and since adopted for cylinder-wound armatures

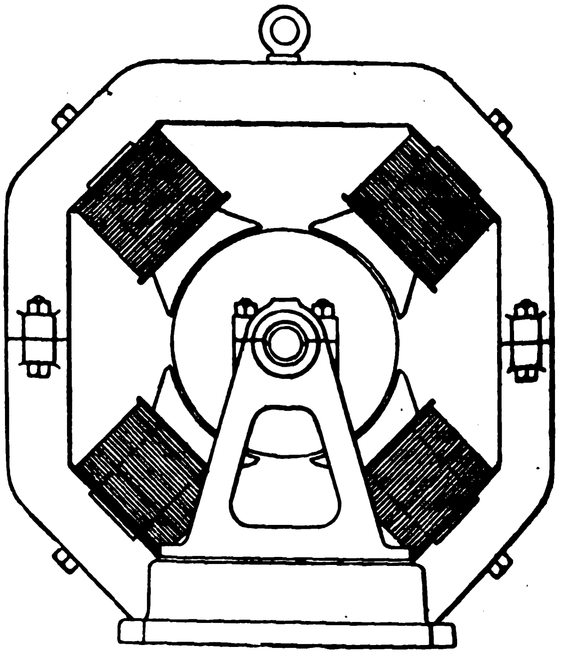

Fig. 7.

by many makers, including Mr. Jasper, in Belgium; Mr. Brown, of the Œrlikon Works, in Switzerland; and Messrs. Paterson and Cooper, in England. Lately Mr. Kapp has used the same form for six and eight-pole machines with drum armatures. The magnets and octagonal yoke in Fig. 6 are of cast iron, in two pieces, the lower limbs, the bottom half of the yoke-ring, and bed-plate being one casting, and the top limbs and upper part of the yoke being

Digitized by Google

another. Fig. 7 represents a similar field in which the magnet cores are of wrought iron, fitted with cast iron pole-pieces, as used by Mr. Kapp in the machines above-mentioned. The decision as to whether cast iron or wrought iron should be used is arrived at in a very simple manner—by comparing the excess of copper required on one hand with the extra machining required on the other.

It will be observed that in the designs Figs. 6 and 7 the yokes are considerably longer than those shown in Fig. 4 ; and the weight of the former, if made of the same material, would be, roughly, twice that of the latter, though even then the complete magnet system would be but 75 per cent. of the weight of Fig. 3.

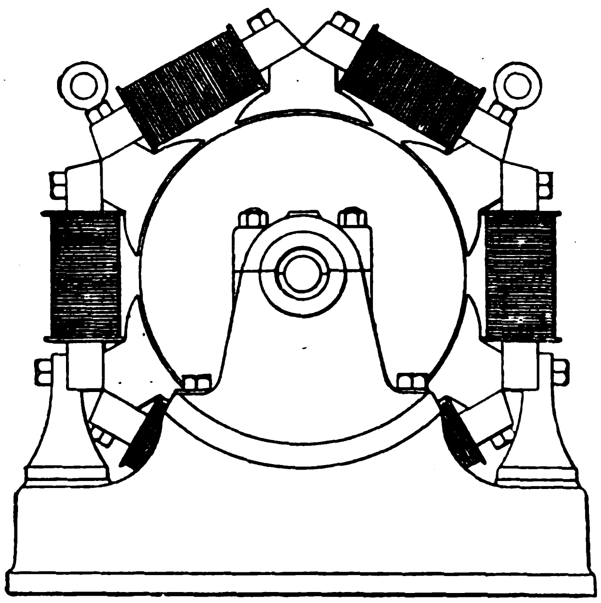

Fig. 8.

The yokes being of cast iron, however, the system really comes about 20 per cent. heavier than Fig. 3 ; the less expensive character of the material compensating, of course, for the increased weight.

All these are examples of single magnetic circuits, where the lines of force from each pole remain undivided in their paths through the magnetising coils ; but in Figs. 8 and 9 are shown examples of double magnetic circuits, in which the lines from each pole take two paths through separate coils. Fig. 8 is a type of magnet used by Sautter-Lemmonier, of Paris, for Gramme-wound armatures, and by Cuenod-Sautter, of Geneva, for armatures having a Siemens winding as modified by Thury. The magnetising coils are wound upon the parts of the system constituting in Fig. 7 the yokes, and a greater amount of copper is in consequence required. It looks at first sight as if the weight of copper were not very different in the two types, but in this respect appearances are deceptive, for, as a matter of fact, the field of a four-pole machine made to Fig. 8 would require about 125 per cent. more copper than if made according to Fig. 7. It will be observed, however, that the magnet cores and pole-pieces, which are made throughout of the softest wrought iron, are very light. In Fig. 9 the magnets are a series of wrought-iron bars lying parallel to the armature, each fitted with a cast pole-piece in the middle of its length, and having two magnetising coils, one on each side of this piece. It is a structure which may be frequently met with, though not precisely in the form shown, and the observations regarding the copper made with reference to Fig. 8 apply equally here.

The cost of a four-pole machine is approximately represented by the cost of a couple of two-pole machines of the same efficiency

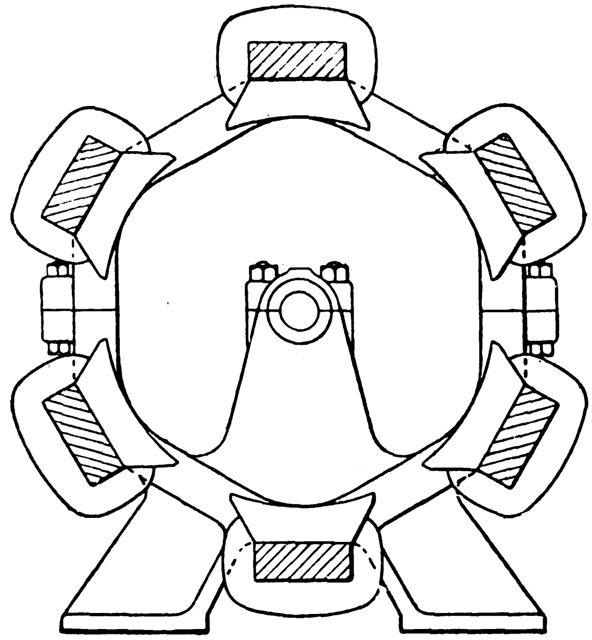

Fig. 9.

which give each half the output at twice the speed ; the cost of a six-pole by that of three two-pole machines which give one-third of the output at three times the speed ; and so on. For comparison, the fields must be in both the multipolar machines and two-pole machines of the same character—that is, with single or double magnetic circuits.

The fields of alternators may be similarly divided into those having single and those having double magnetic circuits ; the former requiring, as in the fields of direct-current machines, much less copper than the latter. Amongst those having single magnetic circuits are the machines of Siemens, Ferranti, Mordey, Westinghouse, Elwell-Parker, and Paterson and Cooper. Mr. Kapp possesses the distinction of having the only alternator with double magnetic circuits. The "Phœnix" alternator, shown in Fig. 10, possesses some features which may be of interest as illustrating the way in which the commercial aspect of designing has to be considered. The yoke-ring is of cast iron, but the magnets are of tooled wrought iron, shaped as shown. If the magnets had a breadth equal all the way up to the length of the armature core, they might as well have been of cast iron, for the little advan-

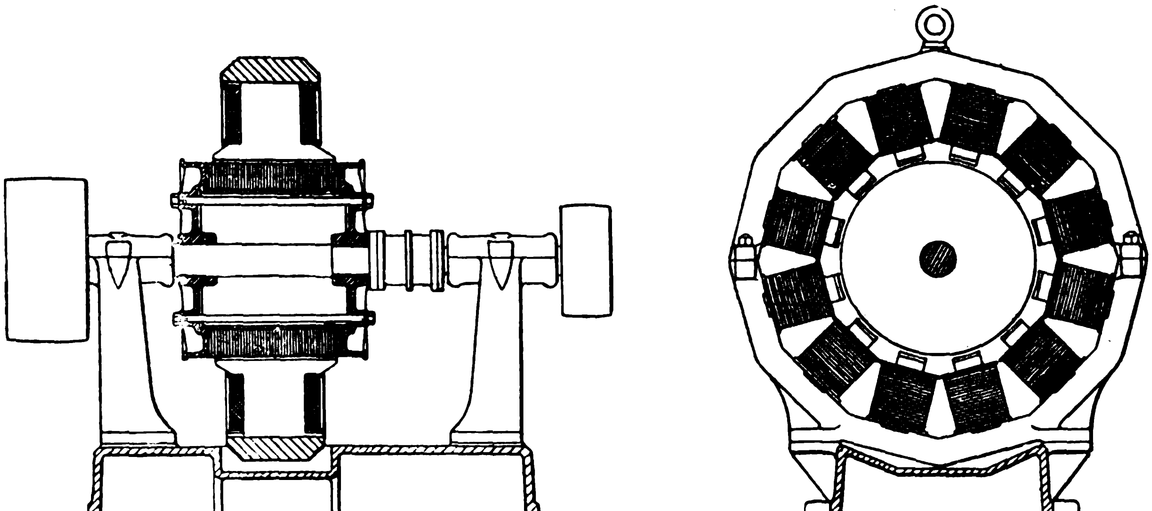

Fig. 10.

Digitized by Google

tage consequent on the reduction of copper obtained by narrowing them would not have paid for the extra work in tooling wrought iron. But when we reduce the breadth where the magnetising coils are, as shown, we at once diminish the copper on the fields by 60 per cent., greatly reduce the leakage area, and get a good balance after paying for extra tooling. The machine, as will be seen, has 12 radial magnets, and there are on the armature six flat coils, each equal to three times the width of the magnet cores, and laid on the periphery with a space equal to the core between them.

The length of the Paper prohibits me from dealing with many special types of machine, to which, however, all the reasoning here used may be applied without difficulty.

## THE MEASUREMENT OF THE POWER GIVEN BY ANY ELECTRIC CURRENT TO ANY CIRCUIT.*

BY PROF. W. E. AYRTON, F.R.S., AND W. E. SUMPNER, D.SC.

### I.

There are three well-known methods of measuring the electrical power supplied by alternating currents. The first of these is the electrometer method† the accuracy of which is entirely independent of the way in which the currents vary with time, or of the nature of the circuit the power given to which it is desired to measure. As the method is unique in this respect, it might have been expected that its use would have been extensive. Unfortunately, however, the application of the method is restricted by the fact that Sir W. Thomson's quadrant electrometers do not generally obey the law given for these instruments in the text books. A method of an entirely different kind was published by Mr. Blakesley in 1888, and consists of an ingenious use of three dynamometers. The original proof given by the inventor was based on several hypotheses, many of which have since been shown to be unnecessary. There, however, still remain two grave objections to the method. It is only applicable to the case of a transformer, and it moreover assumes that in the transformer tested there is no magnetic leakage, *i.e.*, every line of force is supposed to go through each convolution of both primary

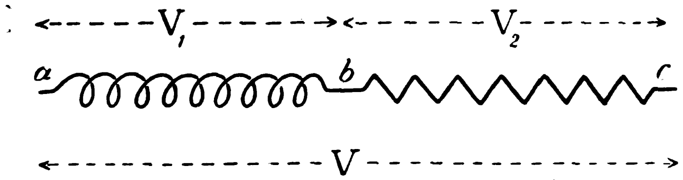

FIG. 1.

and secondary coils. The remaining method, that of the electromagnetic wattmeter, is perhaps the commonest of all, but here errors are introduced in consequence of the self-induction of the fine wire coil, and several investigators have devoted their attention to the discovery of devices by means of which these errors may be reduced to a minimum.

Several months ago, however, while working at alternate current interference, we noticed that it was possible to employ an extremely simple method, based on the difference of phase of the P.D. and the current for measuring the power by *any* current to *any* circuit. This method, which has since been in regular use in the laboratories of the Central Institution, is quite independent of any assumptions as to the nature of the current, or of the circuit, the power given to which it is desired to measure, and it has the further great advantage that the only measuring instrument required is the ordinary alternate-current voltmeter of commerce.

In series with the circuit *ab* (Fig. 1) the power given to which we desire to measure, connect a non-inductive resistance *bc* of *r* ohms.

Let $V_1$, $V_2$, and V be the readings of the voltmeter when applied between *a* and *b*, *b* and *c*, and *a* and *c* respectively; then, if W be the mean watts supplied to the circuit *ab*, we have in all cases, whatever the nature of the current, or of the circuit *ab*—

$$W = \frac{1}{2r}(V^2 - V_1^2 - V_2^2) \quad . \quad . \quad . \quad . \quad . \quad (1).$$

For, let $v_1$, $v_2$, and $v$ be the instantaneous values of the P.D. between *a* and *b*, *b* and *c*, and *a* and *c* at some moment *t*,

then $$v = v_1 + v_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

If *a* be the current in amperes flowing through the circuit at time *t*, then $a\,v_1$ equals the watts *w* given to *ab* at that time. But

$$a = \frac{v_2}{r},$$

since the resistance *b c* is non-inductive:

$$\therefore w = \frac{v_1 v_2}{r}.$$

Then, squaring (2) we have

$$v^2 = v_1^2 + 2\,v_1\,v_2 + v_2^2$$

$$\therefore w = \frac{1}{2r}(v^2 - v_1^2 - v_2^2).$$

Consequently $$\int_0^T w\,d\,t = \frac{1}{2r}\left(\int_0^T v^2\,d\,t - \int_0^T v_1^2\,d\,t - \int_0^T v_2^2\,d\,t\right),$$

or $$W = \frac{1}{2r}(V^2 - V_1^2 - V_2^2),$$

the equation given above.

If the resistance of *b c* be not known, or if there be any fear that it may be changed by the passage of the current, then an ammeter (an alternate current ammeter, of course, if alternate currents be employed) can be inserted in the circuit. Let A be the reading of this ammeter, and which represents the square root of the mean square of the current, then, for *r* in (1) we may substitute $V_2/A$, or

$$W = \frac{A}{2\,V_2}(V^2 - V_1^2 - V_2^2) \quad . \quad . \quad . \quad . \quad . \quad (3).$$

When employing this last formula, the non-inductive resistance *bc* may be that offered by incandescent lamps, since there is no objection to the resistance varying with different mean strengths of the current employed.

This voltmeter method of measuring power was arrived at quite independently of the electrometer method referred to above, but an examination of the electrometer method shows that it is practically equivalent to simultaneous measurements of three P.D's.

### II.

The method which we have described for measuring the power given by *any* current to *any* circuit may be conveniently employed for measuring the power given to an alternating-current arc, or to an alternating-current arc lamp. It is known that an alternating-current arc requires a greater current than a direct-current arc to produce the same light with similar carbons; for example, a 10-ampere direct-current lamp requires 12½ amperes, or 25 per cent. larger current, when used with an alternating current. In a masterly Paper on "The Theory of Alternating Currents," read before the Society of Telegraph Engineers on November 13, 1884, Dr. Hopkinson refers to a law given by Joubert, that the difference of potentials between the carbons in an alternating arc is of approximately constant numerical value throughout the period, and that it reverses sign discontinuously at each reversal of the current. Using this law as his basis, he works out mathematically some very curious relationships between the variations of current and P.D. time.

Three of our senior students, Messrs. Kolkhorst, Thornton, and Weekes, have been making a number of experiments on the power supplied to alternating-current arcs by using the method of measuring power described above. From these experiments it would appear that the quality of the carbon employed affects materially the difference in phase between the currents passing through the arc and the P.D. between the carbons. If the arc be quite steady and only give out the rhythmic hum that accompanies a good arc, such as can be obtained with cored carbons of proper quality, the arc appears to act practically as a simple resistance, and M. Joubert's law does not hold. But if the arc be maintained between uncored carbons of poor quality, and be hissing, there is considerable difference in phase between the current and the P.D. between the terminals; further, the experiments show that the current is very far from being a sine function of the time, although produced by a dynamo whose E.M.F. normally follows a harmonic law.

We do not purpose, in this communication, to enter at length into these experiments on alternate-current arcs, but a few examples of the experimental results that have been obtained will be interesting as illustrating the ready applicability of this new method of measuring power to such investigations.

In addition to the difference of phase of P.D. and current that may be produced in the arc itself, there is the electro-magnet to be considered by which the distance between the carbons is usually regulated in arc lamps. This electro-magnet will introduce lag between the P.D. at the terminals of the lamp and the current passing through the electro-magnet and the arc in series; and hence, even although the arc be perfectly steady, we find, even in the case of a Brush lamp especially intended for alternate currents, that the true power supplied to the electro-magnet and arc is 20 per cent.

* Abstract of Paper read before the Royal Society, April 9, 1891.

† Suggested simultaneously by Profs. Ayrton and Fitzgerald, at the Paris Congress, in 1881.

Digitized by Google

less than the product of the readings of the ammeter and the voltmeter attached to the lamp terminals, and which gives the square root of the mean product of the squares of the current and P.D.

If, however, the arc be between common carbons and be hissing, the difference, we find, is much greater. With cored carbons this Brush lamp requires a P.D. of about 35 volts to be maintained between its terminals, but if these cored carbons be replaced by common carbons and the arc be hissing, the P.D. between the terminals of the lamp at once rises to 45 or even 50 volts, although the current passing through the lamp and the amount of light given out remain practically as before. And then we find that the true power supplied to the lamp may be only one-half of the square root of the mean product of the squares of the current and P.D., so that the readings of the ammeter and voltmeter alone make the apparent power twice as great as the true power.

For the purpose of easily estimating the ratio of the true to the apparent power supplied, formula (3) may be thus written,

$$W = AV_1\left\{1 - \frac{(V_1+V_2-V)(V_1+V_2+V)}{2V_1V_2}\right\} \quad . \quad . \quad (4),$$

from which we see that the expression in the brackets represents the ratio of the true to the apparent power supplied to the lamp or other circuit *a b* (Fig. 1). Hence the percentage error made in assuming that the power supplied to any circuit was the product of the ammeter and voltmeter readings would be in all cases, whatever the nature of the current or of the circuit,

$$100\frac{(V_1+V_2-V)(V_1+V_2+V)}{2V_1V_2} \quad . \quad . \quad . \quad (5).$$

The following are samples of the results obtained with a hand-regulated lamp, there being no electromagnet at all in series with

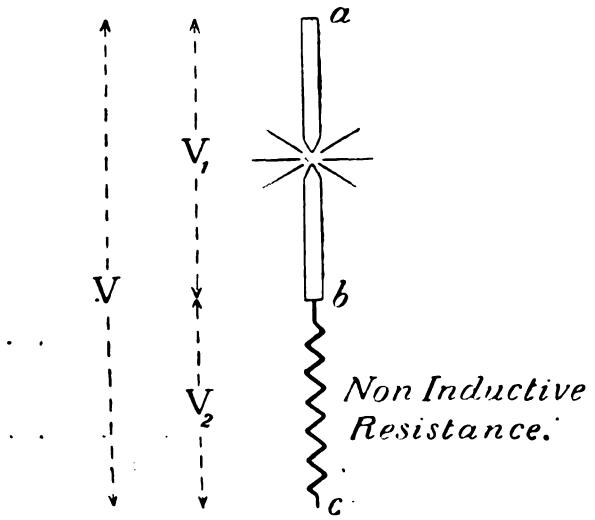

FIG. 2.

the arc (Fig. 2). The carbons were not cored and the arc was hissing. The frequency was maintained at 200 periods per second.

**Table I.**

| Square root of mean square. | | | | Percentage error in estimating power formula (5). |
|---|---|---|---|---|
| Of P.D. in volts between. | | | Of current in amperes. | |
| *a* and *b*. $V_1$. | *b* and *c*. $V_2$. | *a* and *c*. V. | A. | |
| 55·0 | 60·0 | 108·0 | 12·3 | 24·0 |
| 45·4 | 75·4 | 107·3 | 11·8 | 45·8 |

For the purpose of obtaining an idea of $\phi$, the angle of phase difference produced by the hissing arc, between the current and the P.D., we may assume that the P.D. and current are sine functions of the time; then, as may be easily proved,

$$\cos\phi = \frac{V^2 - V_1^2 - V_2^2}{2V_1V_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6),$$

and the values of $\phi$ for the two tests given above come out as 40° 20′ and 57° 10′. It will, of course, be observed that this assumption of a harmonic law for the P.D. and current for the purpose of obtaining some idea of the value of $\phi$ in no way affects the generality of the method for the measurement of the power, since this is based on no such assumption.

The following are samples of the results obtained with a Brush alternate-current lamp regulated by an electro-magnet (Fig. 3), the carbons not being cored, and the arc hissing. The frequency was maintained at 200 periods per second.

**Table II.**

| Square root of the mean square. | | | | Percentage error in estimating power formula (5). | Lag between current and P.D. |
|---|---|---|---|---|---|
| Of P.D. in volts between | | | Of current in amperes. | | |
| *a* and *b*. $V_1$. | *b* and *c*. $V_2$. | *a* and *c*. V. | | | $\phi$. |
| 64·8 | 58·0 | 108·4 | 13·0 | 44·0 | 56° 0′ |
| 59·8 | 64·2 | 107·4 | 12·0 | 50·5 | 60° 20′ |
| 55·0 | 67·3 | 107·4 | 10·6 | 47·0 | 58° 30′ |

The experiments already described tell us that a hissing arc may cause a considerable phase difference between the P.D. and the

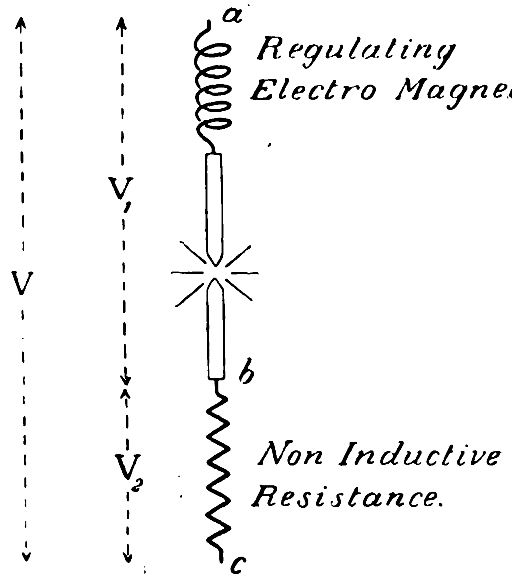

FIG. 3.

current, but they do not enable us to decide whether such an arc causes the current to lag behind the P.D., or to lead in front of it. To decide this point, that is, to decide whether a hissing arc acts like an inductive coil, or a condenser, a variety of experiments were

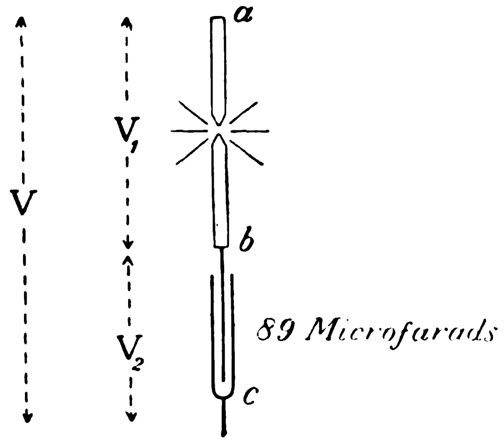

FIG. 4.

made by putting induction or capacity in series with the arc. The following gives the result of one such experiment:—In series with a hand-regulated lamp (and, therefore, containing no electromagnet), was placed a condenser of 80 microfarads (Fig. 4). Uncored carbons were used, and they were adjusted so that the arc was very short at first; the carbons were then not touched, and, as they burnt away, the arc grew longer and longer until it finally went out. The frequency was maintained at 200 periods per second.

Digitized by Google

**Table III.**

| E.M.F. of dynamo in volts. | Square root of mean square. Of P.D. in volts between a and b. $V_1$. | b and c. $V_2$. | a and c. V. | Of current in amperes. A. | Sum of $V_1+V_2$. | Lag between current and P.D. $\phi$ |
|---|---|---|---|---|---|---|
| 59 | 35·4 | 89·0 | 72·3 | 12·0 | 124·4 | 129° |
| | 38·0 | 92·0 | 73·3 | 12·5 | 130·0 | 133° |
| | 51·2 | 104·5 | 74·3 | 14·0 | 155·7 | 135° |
| | 69·2 | 86·5 | 67·5 | 13·4 | 155·7 | 131° |

Comparing V with the E.M.F. of the dynamo, we see that the arc and the condenser together acted as a condenser on the whole; but comparing V with $V_1 + V_2$, we see that the arc acted as an induction and not as a capacity.

It having been conclusively proved that a hissing arc with uncored carbons acts as an induction, it was interesting to compare the impedance it produces with the impedance produced by the ordinary regulating electro-magnet of the lamp. The arc itself seen in Fig. 3 was, therefore, short-circuited, and the following measurements made, $V_1$ now being the square root of the mean square of the P.D. between the terminals of the regulating electro-magnet, $V_2$ as before that between the terminals of the non-inductive resistance, and V that between *a* and *c*, the arc, as already explained, being short-circuited. The frequency was maintained at 200 periods per second.

**Table IV.**

| $V_1$. | $V_2$. | V. | A. |
|---|---|---|---|
| 35·4 | 69·2 | 82·0 | 11·3 |
| 35·4 | 65·6 | 80·0 | 11·4 |

We have, then, P.D. measurements giving the phase difference of current and P.D. with the arc alone (Table I. and Fig. 2); with the arc and regulating electro-magnet (Table II. and Fig. 3); and with the electro-magnet alone (Table IV.). Defining impedance in the usual way as the ratio of the square root of mean square of P.D. to the square root of mean square of current, we find from the two sets of results given on Table I., that

the impedance of the arc alone equals .................... $\begin{cases}4{\cdot}47\\3{\cdot}78\end{cases}$;

from the three sets of results given in Table II., that

the impedance of the arc and electro-magnet equals ... $\begin{cases}5{\cdot}87\\5{\cdot}15\\5{\cdot}14\end{cases}$;

and from the two sets of results given in Table IV., that

the impedance of the electro-magnetic alone equals ... $\begin{cases}3{\cdot}14\\3{\cdot}16\end{cases}$

In order to test whether the current follows a harmonic law, let us assume that it does, then find what result this assumption leads to, and, lastly, see whether the experiments confirm this result or not. Let, therefore, the instantaneous current at any moment be of the form

$$\frac{V_0}{\sqrt{(r^2+L^2p^2)}}\sin(pt-q),$$

where *r* is the effective resistance in each case, viz., the ratio of the *true* watts given to the circuit divided by the mean square of the current in amperes, and where *p* equals $2\pi n$, *n* being the number of periods per second. In each of the seven experiments referred to in Tables I., II., and IV., *n* was 200.

The seven values of *r* in ohms corresponding with the seven values of the impedance given above are for the

Arc alone ............................ $\begin{cases}3{\cdot}42\\2{\cdot}07.\end{cases}$

Arc and electro-magnet ......... $\begin{cases}2{\cdot}65\\2{\cdot}66\\2{\cdot}71.\end{cases}$

Electro-magnet alone ............ $\begin{cases}0{\cdot}44\\0{\cdot}54\end{cases}$;

and, since the impedance equals $\sqrt{(r^2+L^2p^2)}$, if the harmonic law be true, the corresponding values of L *p* are, for

Arc alone ............................ $\begin{cases}2{\cdot}88\\3{\cdot}16.\end{cases}$

Arc and electro-magnet ......... $\begin{cases}4{\cdot}08\\4{\cdot}41\\4{\cdot}37.\end{cases}$

Electro-magnet alone ............ $\begin{cases}3{\cdot}12\\3{\cdot}11.\end{cases}$

But if the harmonic law hold for the current, the sum of L *p* for the arc alone, plus the L *p* for the electro-magnet alone, must equal the L *p* for the arc and electro-magnet, since *p* has the same value in each case. Now it is obvious that the condition is far from being fulfilled with the numbers just given. Hence the current does not follow a harmonic law.

It is interesting to notice that the L *p* for the hissing arc alone is actually greater than the L *p* for the regulating electro-magnet.

The values given above for *r*, being obtained by dividing the *true* watts by the mean square of the current in amperes, are the effective resistances in ohms—whether the current follows a harmonic law or not. Hence, by comparing the value of *r* for the regulating electro-magnet alone with its resistance in ohms, measured with a steady current, we have a true measure of the waste of energy in the iron core of the electro-magnet due to hysteresis and Foucault currents. Now the resistance of this electro-magnet for a steady current is only 0·065 ohm; hence 90 per cent. of the energy given to the regulating electro-magnet of this Brush lamp is wasted in heating its iron core when the frequency is 200. Here again we have a further illustration of the importance of being able to measure, by means of the simple method we have described, the power given by any current to any circuit.

III.

*The Best Conditions for Use of the Method.*

In cases where great accuracy is required in the measurement of the power, it is important to consider what value should be given to the non-inductive resistance (Fig. 1), in order to reduce to a minimum any error that may arise from inaccurate reading of the voltmeter or on the graduation of its scale.

Since
$$W=\frac{1}{2r}(V^2-V_1^2-V_2^2),$$
$$dW=\frac{1}{r}(V\,dV-V_1\,dV_1-V_2\,dV_2),$$

where $dV$, $dV_1$, $dV_2$ are the errors made in the estimation of the three P.D.'s.

Let $dV=\pm eV$; $dV_1=\pm eV_1$; $dV=\pm eV_2$,

where *e* is a small fraction, *i.e.*, let the errors be each the same small fraction of the correct value, then the probable value of $(dW)^2$ is

$$\frac{1}{r^2}(V^2e^2V^2+V_1^2e^2V_1^2+V_2^2e^2V_2^2),$$

so that
$$\left(\frac{dW}{W}\right)^2=4e^2\frac{V^4+V_1^4+V_2^4}{(V^2-V_1^2-V_2)^2}\quad\ldots\quad(7).$$

Let the non-inductive resistance have such a value that

$$V_2=xV_1\quad\ldots\ldots\ldots\quad(8).$$

We then want to find the value of *x* for which $\frac{dW}{W}$ will be a minimum.

Now suppose for simplicity that the currents follow a sine law, and that $\phi$ is the angle of lag between $V_1$ and $V_2$.

Then
$$V^2=V_1^2+V_2^2+2V_1V_2\cos\phi\quad\ldots\quad(9),$$

and from this equation together with (7) and (8) we get

$$\left(\frac{dW}{W}\right)^2=4e^2\frac{(1+x^2+2x\cos\phi)^2+1+x^4}{4x^2\cos^2\phi}$$

Now $\cos\phi$ depends on the circuit, the power given to which we desire to measure, and is independent of *x*. Hence differentiating with respect to *x* and equating to nought in the usual manner, we find that *x* equal to unity makes $\frac{dW}{W}$ a minimum.

Hence, inaccuracies in the three readings of the voltmeter, or in the graduation of its scale, produce the least effect in this method of measuring power when the P.D. between the terminals of the non-inductive resistance is equal to the P.D. at the terminals of the circuit under test.

The next point to consider is, what is the percentage error made in measuring the power by this method compared with the percentage error made in reading one of the P.D.'s.

Let *x* equal unity, then we find

$$\frac{dW}{We}=\frac{\sqrt{2+4(1+\cos\phi)^2}}{\cos\phi}$$

Now, $dW/We$ is the ratio of the percentage error made in measuring the power to the percentage error made in one of the P.D.'s, and the right-hand side of the last equation we find equals from 4 to 5 for the values of the lag angle $\phi$ that occur in ordinary practice. An error of one per cent. in each of the mea-

Digitized by Google

surements of V, $V_1$ and $V_2$ would therefore introduce a probable error of from 4 to 5 per cent. in the measurement of the power. The error would be reduced to half its amount if the voltmeters were graduated to read directly the mean square of the volts instead of the square root of the mean square.

It is, of course, clear that these errors to which we have been referring are not errors in any way essential to the method proposed for measuring power, since by the employment of an accurately graduated voltmeter, by exercising care in taking the readings, and if necessary, by repeating the measurements two or three times and taking the means of the observations, the power can be measured to any degree of accuracy desired.

As in practice, the sum of the potentials $V_1$ and $V_2$ will not, as a rule, be much in excess of V, we may very conveniently express the true power W in terms of the excess in question.

Let
$$y = \frac{V_1 + V_2 - V}{V_1}.$$

Then the true power W is
$$W = V_1 A \cos\phi,$$

where
$$\cos\phi = \frac{V^2 - V_1^2 - V_2^2}{2 V_1 V_2},$$

and A is the current through $ab$ (Fig. 1) as read by an alternate current ammeter.

Now if $V_1 = V_2$ it is easy to show that
$$\cos\phi = 1 - 2y + \frac{y^2}{2},$$

or, as $y$ is very small, generally
$$W = V_1 A (1 - 2y).$$

For example, if $V_1$ and $V_2$ were 50 volts each, and V were 98 volts, so that $y = 2/50$, or 4 per cent., the true power would be 8 per cent. less than the apparent power $V_1 A$ obtained by multiplying the volts by the amperes. The same expression shows that if due to any uncertainty about the graduation, or reading of the instrument, the value of the number $y$ is uncertain to ·01, the error one is liable to in the measurement of the power W is twice this, or 2 per cent.

## THE LONDON TELEPHONE RATES.

A meeting convened by circular, dated the 8th inst., signed "Hasties," and emanating from 65, Lincoln's Inn-fields, was held at the Cannon-street Hotel, on Wednesday, "for the purpose of taking such steps as may then appear advisable in the interests of the subscribers to the telephone." In a previous circular, similarly signed, and dated last month, subscribers to the telephone were invited to join an association so that their interests might be secured "especially by lowering the rate and obtaining a double-wire system, by which alone the voice can clearly be heard in London."

Mr. HASTIES, on taking the chair, read the notice convening the meeting, as above referred to. He had, he said, been a subscriber to the telephone for several years, not only at his offices, but also at his private house. There were a great many complaints with regard to the inconveniences and inefficiency of the service afforded by the Telephone Company. Personally, he was very well served, but at a very high price. What had brought him to take action was that he had happened to come across in *The Times* the report of the last meeting of the National Telephone Company, and he then saw that the Chairman at that meeting ventured to tell his shareholders that the Company had no occasion to reduce their price in London, as the subscribers were prepared to pay what the Company asked them for the service which they rendered. He himself paid £20 a year for the telephone at his office, and for the one at his house he paid £12. He felt sure that the Telephone Company lost nothing in connection with this second telephone, and he believed that they could afford to supply telephones at £12 a year in London. It was to this price as a maximum that he proposed they should insist on the Company reducing their charges. He would like to say at once, as it might remove some misapprehension, that he had no wish to promote a new company. His desire in calling that meeting was that the subscribers might be induced by sticking together to have the same power towards the Company in regard to the charges as the Company had towards the subscribers. He had received contributions—all in sums of 5s., in accordance with the invitation contained in his first circular — amounting together to £98, representing, as nearly as possible, 400 members; and he had since found that there would be no difficulty whatever in getting one-half of the subscribers to the Telephone Company to join in the movement which he had initiated. It would be a question for them that day to decide whether they should establish a permanent Association to which complaints could be addressed, and which would permanently keep the Telephone Company in order, or whether they would limit their action to an endeavour to reduce the Company's rates, and insisting on the double wire, and then disbanding. In the latter event he thought that only those who had joined the Association should have the benefit of the reduction in the rates which the Company might consent to, but if they were to maintain their Association the more subscribers they got the better. He had communicated with the Postmaster-General on the subject, and had received a reply; but at the present juncture he did not think it would be advisable to read the whole of the answer which had been forwarded to him. He thought if he read the following part of it it would suffice:—"As to any action which the Post Office itself might be prepared to take, I am to say that the Postmaster-General could not be indifferent to a clearly expressed demand for the establishment of a telephonic service in London, but he regards it as premature at present to state what the charge for such service would be." This showed, he thought, that the Postmaster-General was ready to undertake the work required by the public if the Telephone Company was not ready to meet the demands of their subscribers.

Mr. LEAGE (City Road) said he thought they were all indebted to the Chairman and his firm for having called the meeting together. For some time past the subscribers to the Telephone Company had regarded the charges as excessive and unjust. The service given by the Company was very imperfect, and they had frequently to wait a long time before they could get a reply. He thought that £12 a year was a full and sufficient amount to pay for the service which was rendered by the Company. If the rate were reduced to the amount mentioned, he had no doubt that the Company themselves would be benefited by the increase of business which the reduction would induce. He moved a resolution to the effect that an Association should be formed for the protection of the subscribers to the National Telephone Company in England.

Mr. GODDARD CLARKE (of Messrs. Potter and Clarke) stated that his firm, on receiving the circular from Messrs. Hasties, determined to co-operate with them as much as possible, and they sent round to their friends a letter drawing attention to the circular and requesting their co-operation. They had further communicated with friends of theirs who were connected with provincial exchanges, asking to be informed of the amount of the annual subscription charged for connection with the Telephone Exchange of their towns. In this circular they also said: "If in addition to your Exchange connection you have the facility of communicating with any other towns, be good enough to mention these, and whether such facility involves any extra charge." He held in his hand the replies which he had received, mainly from wholesale druggists in England and Scotland, and the bulk of them stated that within very recent times their rates had been reduced some £20 to £15, others from £15 to £10, and some from £10 to £5; and he maintained that if this could be done in the country, London subscribers ought to have a similar advantage. All the replies he had received showed that the charges imposed upon the London subscribers were much higher than those prevailing in country towns.

The CHAIRMAN put the resolution and it was carried.

Mr. LEAGE then proposed, and Mr. CHARLES R. HAIG seconded, a resolution for the formation of a committee.

Mr. JACKSON thought that before the committee took any active steps they should confer together as to the best mode of approaching the Company in order that the strong weapon of defence which that meeting showed that the telephone subscribers possessed should be used with the most effect. He thought that the committee should not attempt to deal with the Telephone Company until the Association had a large additional number of subscribers. They had many grievances against the Company. To his mind, as a professional man, the point that touched them most was not so much the subscription which they had to pay to the Company, although, no doubt, that was very high, but the dissatisfaction which was caused to them by the inefficiency of the Company's service.

Mr. RAWSON thought that the committee should be a provisional one.

The following gentlemen were then appointed to act on the committee:—Messrs. Hastie, C. R. Haig, Clarke, Jackson, Tyrer, Leage, Collins, Copeman (Provision Exchange), Rawson, and J. J. Ball.

Mr. RAWSON said that comparisons were drawn between the services rendered in London and in provincial towns, but the position in the metropolis was different. Many of the difficulties which existed were not owing to any fault on the part of the Telephone Company. He felt, in fact, that they were not there in opposition to the Telephone Company, but really to appoint a committee which could see that the interests both of the subscribers to and the shareholders of the Telephone Company were protected as far as possible. He afterwards spoke of the importance of communicating with Paris by telephone, and proposed a resolution expressing the opinion of the meeting that the committee should do what they could to further the establishment of direct communication between subscribers' offices in London and Paris.

The resolution was seconded and agreed to.

A vote of thanks to the Chairman brought the meeting to a close.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *April* 3, 1891.

**The Bell Telephone Company.**—The annual report of the Bell Telephone Company for the year ending December 31, 1890, shows that the total earnings of the Company for the year were $4,375,290. Of this amount, $2,913,368 were received from rental of telephones; from dividends, $1,256,274; from extra territorial and branch lines, $89,478; from telegraph commission, $26,491; from interest, $77,447; and from miscellaneous sources, $12,230. The total expenses of the Company were $1,505,872, divided as follows: operation, $311,437; legal, $123,359; interest and taxes, $257,174; commission, $575,221; royalty, $10,000; concession, $228,573; mis-

Digitized by Google

cellaneous, $105. The net earnings were therefore $2,869,418. The report shows that at Dec. 31, 1890, there were total miles of wire, 240,412; increase, 47,199; total circuits, 173,665; increase, 16,885; total employés, 7,845; increase, 1,087; total stations, 202,931; increase, 17,928; of which 2,746 are toll stations, not at fixed annual rates, not heretofore classed with subscribers' stations; total instruments in hand of licensees under rental December 20, 1890, 483,790—increase, 38,929. The estimated number of exchange connections daily in the United States is 1,438,294, or a total per year of over 450,000,000. The average daily number of extra territorial connections is 9,701, or a total per year of about 3,200,000. Extra territorial earnings for the year amounted to $1,116,975.18, of which the Bell Telephone Company's share is $92,261.17, an increase of $7,027.99 over 1889. A material increase in mileage of underground wire was made, equal to 27,573, which gain is more than the total mileage a year ago. Twenty-one places now have underground wires, against thirteen a year ago. The long-distance Company added 4,682 miles of wire to its total, and is earning a moderate rate on the investments above its expenses. The net earnings last year amounted to $120,665, which were invested in extension of the plant. The total capital stock of the Company is given as $32,740,580, and the dividends paid during the year on outstanding stock at 18 per cent. amounted to $2,213,913.

**Slow-Speed Gearless Motors.**—During the past week two of the large companies doing street railway business in this country have published descriptions of new motors, the principal feature of which is the entire absence of all gears, in both cases the armature being placed directly upon the car axle. One of these is the Short Electric Railway Company's motor (see *The Electrician*, April 10th, p. 708). The second motor is that of the Westinghouse Company. This motor is practically an ironclad one. The armature is of the drum type, and is built directly upon the car axle, the armature core being keyed directly to it. The armature is but 16in. in diameter, and the total depth of the motor being but 20in., a clearance of 5in. is obtained between the motor and the rail when car wheels of 30in. diameter are used. Provision is made in the gears of both motors for rapidly dismounting them from the car axle for necessary repairs. Sheet-iron cases are provided for protecting the motors from injury.

**Overhead Wire Raid in New York.**—The official axe has been at work in New York City during the past week removing electric light poles from the streets in certain sections of the metropolis. An order was issued early in the week by Major Grant directing the superintendent of the Bureau of Encumbrances to remove the poles and wires of the United States Electric Lighting Company, on Broadway, between two specified points; and the order also included the removal of housetop wires in a considerable section of the city. In accordance with this order a gang of men began chopping down poles and removing the wires, but upon the promise of the general manager of the Company owning most of the wires, that he would put a force of men at work and remove the obstructions himself at once, the city's force of men ceased work in that particular direction, but the removal of the housetop wires still goes on by the city's employés. The electric light companies are removing, as far as possible, the poles and wires that come under the mayor's order. No injunctions were obtained to prevent the city from removing the poles, and the mayor positively refuses to delay the matter any longer.

## CORRESPONDENCE.

### ANALYSIS OF LOSSES IN ARMATURE CORES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I enclose a few notes on the practical use of my method, together with curves showing the experimental points. There is very little doubt that in practice the greater part of the curve is straight. This is no assumption, three or four points being *always* taken and not two only. There is, however, a slight tendency in the curve to turn up at very slow speeds, but this seems merely a question of lubrication.

It will be seen from the diagram plotted below that, at any rate for 90 per cent. of their length, the curves are for all practical purposes straight lines, any apparent curvature being accidental.

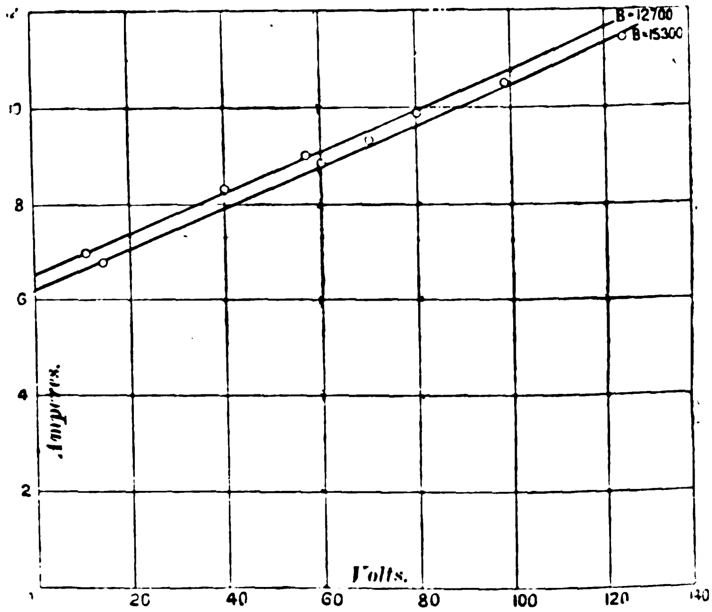
There are, however, some precautions to be taken. Voltmeters are often subject to considerable errors in the lower part of the scale, consequently it is better to use a low reading instrument for the lower readings, or else trust to the volts being proportional to the speed, and only measure the latter.

Variations of friction are often very troublesome, and should always be checked by repeating the readings in inverse order. Friction is generally lower after changing from a high speed to a slow one, and will take some minutes to settle, while the opposite occurs on changing from a slow speed to a high one. It is hardly necessary to add that the bearings should be run down into good condition before these experiments are made.

The brush-friction may easily be determined by raising the brushes in pairs and noting the fall of current.

When cells are not available for supplying the current, it is generally necessary to have a considerable resistance, or, better still, inductance, in the armature circuit, otherwise accurate current-readings are impossible.

When a second machine is available for driving the machine to be tested, friction may be entirely eliminated from the diagram by coupling the two shafts together, driving the one as a motor, and noting the change of current through its armature



when the field of the other is on and off, taking care that the speed is the same. The diagram obtained by plotting the volts and *change of current* in the motor will give the losses by Foucault currents and hysteresis in the other. The efficiency of the motor does not come in appreciably if it is not too small.

This method of analysis may also be applied for separating the losses in transformers, by measuring the waste power with a wattmeter at different frequencies, keeping the maximum induction in the iron constant. The diagram in this case would have Joules per cycle and cycles per second co-ordinated.
—Yours, &c., R. H. Housman.

### CONTROL MAGNETS FOR GALVANOMETERS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: With reference to Dr. Obach's letter on the above subject in your last issue (p. 680), I must crave your indulgence for a few words of explanation.

In working with a ballistic galvanometer recently supplied to me by Messrs. Nalder Brothers and Co., I certainly experienced the inconveniences mentioned in your article of March 20th (p. 610), as well as some others. These I overcame by devices which would occur to anyone engaged in testing, and with which, therefore, I need not trouble you.

Digitized by Google

But as my instrument was one of the earliest of this particular pattern sent out by the makers, they requested me to point out any small details in which it might be improved. After mentioning these inconveniences I therefore made two or three suggestions, and, amongst other things, pointed out that the usual position of the control magnet in *astatic* reflecting galvanometers is not the best that theory would indicate. The almost universal custom is to place the magnet in question *above* the suspended astatic magnetic system. Now, the magnets of the latter are usually some distance apart, and the controlling magnet is therefore nearer to the upper magnets of the system than it is to the lower. Thus the portion of the controlling field due to this magnet, especially if the magnet be low down, may be much greater at the upper needles than at the lower. But this is contrary to the principles on which astatic working is based, for, assuming the whole suspended system to be very nearly astatic, the two astaticising systems, upper and lower, should be placed in controlling fields of the same strength, and therefore the proper position for the controlling magnet is in the horizontal plane bisecting the distance between the suspended astaticised magnets. Thus, *if the magnet be kept horizontal*, the combined controlling field due to it and the earth at the positions of the upper and lower magnets will always be of the same strength. Moreover, by altering the orientation of this magnet in its horizontal plane, the position of the zero can be adjusted. For this purpose the magnet would require to be mounted differently to what it is in fig. 1, p. 610, but the necessary mounting, though more elaborate, is not difficult to devise.

The above argument does not so strictly apply to the particular astatic system in "Nalder's Ballistic Galvanometer," where the suspended magnets may be regarded as being in *three* different horizontal planes. But, even then, I think that the proper position for the controlling magnet is in the central plane of these three.

It may be interesting to note how my suggestion has been modified, and its object to some extent frustrated by the employment of the small and weak top magnet A (fig. 1, p. 610). But after reading the above I hope that Dr. Obach will acquit me of any intention of appropriating his well-known and ingenious device for altering the sensitiveness of tangent (or single needle) galvanometers. His object is "to adjust the constant of the galvanometer to a certain value;" mine is to more nearly fulfil the conditions of *astatic* working, and for this purpose the east and west position, so important for his object, is not absolutely necessary so long as the controlling magnet lies in the proper horizontal plane. For some time when working with astatic reflecting galvanometers I have used this position for the controlling magnet.

In conclusion, I may add that on reading the article under discussion my first impulse was to write to you and point out the modifications made in my suggestion, but on reflection it seemed to me that the point involved was too simple a one to occupy your valuable space with it. The same considerations have probably occurred to other users of astatic galvanometers, though I have never seen an instrument fitted with the control magnet in the position indicated. Dr. Obach's letter must be my apology for troubling you now.—Yours, &c.,

R. Mullineux Walmsley.

Heriot Watt College, Edinburgh, April 9, 1891.

## CAPACITY MEASUREMENTS ON LONG CABLES.

TO THE EDITOR OF THE ELECTRICIAN.

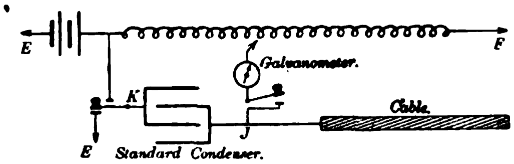
Sir: In their letter *The Electrician* of the 27th of March, Messrs. Ansell and Young refer to a Paper of mine on the above subject, published in your issue of March 6th.

They say they fail to see how the method of correction in question applies to a submarine cable in respect to leakage; with your permission I can, I believe, make this plain.

For purposes of reference I enclose a diagram.

The condenser and cable being arranged as shown in the above diagram, suppose the + pole of the battery to be applied to the armature, K, of the condenser, the potential of that armature will be raised from O to V say, and simultaneously or nearly so the potential of the junction, J, will be raised from O to $p$.

Were there no leakage or absorption, the junction would remain at potential $p$ during the whole of the period of the application of the battery, but owing to leakage the potential of the junction actually falls, during the time requisite for obtaining balance on the slides, from $p$ to $p^1$, $p^1$ being the observed slide reading when balance is obtained.



Now let the armature K be "earthed" and the discharge from the junction observed on the galvanometer.

Just as the junction was raised in potential by $p$ units when the armature K was raised from O to V by the battery, *so will it be reduced in potential by $p$ units*, when the armature is brought from V to O by earthing.

Hence, when the discharge is taken, the potential of the junction is $p^1 - p$ and the discharge is $(p^1 - p)$ $K^1$, where $K^1$ is the total capacity in circuit.

By the third operation described in my Paper, a slide reading is found, say $V^1$, so that $V^1 K^1 = -(p^1 - p) K^1$, which in this case is to be added to the observed slide reading $p^1$.

So that we have the corrected S.R. $= p^1 + p - p^1 = p$, and, as has been shown, $p$ is the required true instantaneous potential of the junction.

The following experiments were made on the 6th April on a length of Muirhead's "artificial line" or cable. The fall of potential when a leak of a Megohm was inserted was exceedingly rapid, and it was difficult to obtain the correct S.R. Each test was, however, repeated several times, to make quite certain that the true reading was obtained:—

| Time of charge in seconds. | Leak in megohms. | S.R. when balance is obtained. | Earthing period in seconds. | Discharge from junction in scale divisions. | Equivalent value of scale divs. in S.R.'s. | Corrected S.R. | Apparent capacity by observed S.R. | True and corrected capacity microfarads. |
|---|---|---|---|---|---|---|---|---|
| *Experiment I.—Standard Condenser = 20 microfarads versus one box artificial line = 60 knots cable.* | | | | | | | | |
| 10 | Infinity | 5133 | 2 | negligible | ... | ... | 18·96 | 18·96 |
| 10 | 1 | 3971 | 2 | 225 | +1162 | 5133 | 30·36 | 18·96 |
| *Experiment II.—20 mfds. v. 2 boxes, equivalent to 150 knots cable (approx.)* | | | | | | | | |
| 5 | Infinity | 2893 | 2 | negligible | ... | ... | 49·14 | 49·14 |
| 5 | 1 | 2680 | 2 | 168 | +207 | 2887 | 54·62 | 49·28 |
| *Experiment III.—20 mfds. v. 3 boxes, equivalent to 240 knots cable (approx.)* | | | | | | | | |
| 5 | Infinity | 2010 | 2 | negligible | ... | ... | 79·50 | 79·50 |
| 5 | 1 | 1900 | 2 | 232 | +108 | 2008 | 85·26 | 79·60 |
| 5 | 1 | 1900 corrected by Messrs. Ansell and Young's formula = 80·06 | | | | | | |

To the last example given I have applied the formula suggested by Messrs. Ansell and Young, and arrived at the value of 80·06 microfarads, which is 0·4 per cent. in excess of the correct value, and not nearly so close an approach to the true capacity as that given by the method of correction under consideration.

The above comparison was made with condensers, all of which had practically the same rate of absorption, and the correction as shown answers perfectly when leakage alone exists. When difference of absorption occurs as well as leakage, the correction as proved by the figures given in my Paper of March 6th is equally valuable.

Messrs. Ansell and Young's suggested correction simply corrects for leakage, and is inapplicable when absorption also exists, as is almost invariably the case when comparing the capacities of a paraffin condenser and a submarine cable.—Yours, &c.,

Arthur Dearlove.

4, Great Winchester-street, E.C., April 8, 1891.

## VISUAL SIGNALLING IN FOGGY WEATHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue you discuss the subject of visual signalling between lighthouse and shore in a fog.

In a light fog and to a short distance this was found possible by our Royal Navy twelve years ago. Ships a mile or so apart directed their projector beam vertically, and a few degrees from vertical made dots, down to about 40° made dashes. In looking upward you have generally very little to obscure partial vision.

I have often thought that in light fogs or misty weather any powerful beam of light would have a better chance of being noticed if flashed vertically over ship or lighthouse.—Yours, &c.,

G. BROWN, ex-Signal Master, Gibraltar.

40, Llanover-road, Woolwich, April 12, 1891.

## LEGAL INTELLIGENCE

### The Jablochkoff Patent.

The Judicial Committee of the Privy Council, represented on the occasion by Lord Hobhouse, Lord Shand, Lord Morris, Lord Watson, and Sir Richard Couch, had under consideration on Wednesday the petition of the Electrical Engineering Corporation (Limited) for the prolongation of the Jablochkoff patent.

Mr. MOULTON, Q.C., and Mr. ROGER WALLACE appeared for the promoters, while Mr. SUTTON represented the Government. Opposition to the petition was alluded to by the counsel for the promoters, but no official reference was made to the opposing parties.

Mr. MOULTON, Q.C., opening the case, wished to preface his remarks by a few words upon the nature of the patent. It was a patent for the division of the electric light by means of what are now known as "transformers." The date of the patent was 14 years ago (No. 1,996, of 1877), at the time that the electric light was in its very infancy. The problem then before the world was a problem that was admitted to be of the greatest possible practical importance, namely, to make the electric light useable in a subdivided form. Now, at that date in 1877, many persons believed that that was practically an insoluble problem. Their lordships would be aware that a solution of that problem had been found by the invention of the incandescent lamp, which did not at the time referred to exist. But the earliest inventor who produced a practical solution of this problem to any amount might, he thought, fairly be said to be the patentee then before the Court, Mr. Jablochkoff, who, early in 1877, invented the Jablochkoff candle. In working out the question with regard to the sub-division of the light, Mr. Jablochkoff had to face the problem of dividing the electricity. It was in investigating this problem that the patentee came on the invention which was the subject of the petition then before the Court. Of course, he would have to enter upon the novelty of the invention, and he would have no difficulty in establishing, first, the enormous practical importance of the invention; and secondly, that this idea of utilising induction for the purpose of secondary generation was a great surprise to the electrical engineers of the time. Having, as he believed established its importance, Mr. Moulton stated also that the patent had been unremunerative, though not by any fault. The chief difficulty in his way he had only learned within about 24 hours. There were originally opponents to the patent's prolongation, with regard to which he felt no difficulty. But late on Monday his clients received a letter from the solicitors of other opponents, stating that they were going to bring before their lordships proof of a certain prior publication, which anticipated the patent of his (Mr. Moulton's) client. On examining the statements of this alleged prior publication he found on examination a Paper was read at a meeting of the Society of Telegraph Engineers on May 9, 1877. Many licenses had been granted for Jablochkoff's patent, and the whole question was looked into very carefully in the litigation before the House of Lords. On referring to the *Journal* of the Telegraphic Engineers his client found, to his great astonishment, that the patent of Mr. Jablochkoff was dated May 22, 1877, while, by a strange accident, the cover of it was, and always had been, dated May 2, 1877. On examining the Paper referred to it was discovered for the first time that Mr. Jablochkoff's invention—as being his invention, without question of there being another inventor—was first communicated on May 9th to the Society of Engineers by some person unknown to Mr. Jablochkoff, and without his having had anything to do with it. The consequence was that, so far as the validity of the patent was concerned, and reasonable and prior publication, he was obliged to admit that this prior publication rendered his client's patent invalid, unless and until there could be a prolongation of the patent under their lordship's order. Their lordships would remember that under the law of 1877, on petition to their lordships, a confirmation might be obtained of a patent of which the patentee believed himself to be the first and true inventor, and who found it was not so. The Statute was 5 and 6 Vic., ch. 83, sec. 2, and applied to patents then existing on January 1, 1884. The Act said:—"If such a patentee on the other side shall discover that some other person had, unknown to such patentee, invented or used the same, or some part thereof, before the date of such patent, it shall and may be lawful for such patentee to petition Her Majesty in Council to confirm the patent, the matter of which petition shall be urged before the Judicial Committee of the Privy Council, and such Committee, on examining the said matter, and being satisfied that such patentee believed himself to be the first and original inventor, and being satisfied that such invention or part thereof had not been publicly or generally used before the date of the first patent, may report to Her Majesty that the purport of such prayer may be granted," &c. Mr. Moulton was obliged to admit that without confirmation the patent was invalid. He would, therefore, be obliged to ask their lordships the favour of being allowed to amend the petition, by adding thereto a prayer for confirmation, and if their lordships thought proper to prolong the petition without that, he would be able to present the petition for confirmation.

A considerable discussion was hereupon gone into relative to the technical notice which Mr. Jablochkoff should have given before the hearing of the petition.

Mr. MOULTON urged that the case should proceed, but

Lord SHAND said the Council could not proceed except in accordance with the statute.

Lord MORRIS thought the only practical way was that the petition should stand over till the technicalities had been complied with, and then a start should again be made *de novo*.

Lord SHAND said his attention had been called to the first of the rules laid down, viz., that the parties intending to apply by petition under Section 2 should give public notice by advertisement in the *London Gazette* three times, in three London papers, and three times in some country paper published in the town where the applicant carried on his manufacture. His lordship said the Committee could no more alter that rule than they could alter the statute.

After the Committee had conferred it was agreed to adjourn the case till Wednesday, May 20th, the necessary formalities of giving notice, &c, to be observed meantime.

Mr. MOULTON then explained to the Committee that Mr. Jablochkoff was in attendance prepared to give evidence, that he was anxious to go to Russia, and therefore he requested that the evidence might be given at once, or be allowed to be presented on affidavit.

The Committee pointed out that Mr. Jablochkoff's evidence without cross-examination would not be very valuable, and that if there was ultimately no opposition then Jablochkoff would have a quiet walk over.

### Savory and Moore v. The London Electric Supply Corporation (Limited).

The above action came before Mr. Justice Kekewich on Tuesday and Wednesday last in the Chancery Division of the High Court of Justice, the plaintiffs, who are the well-known chemists and druggists of Bond-street, being represented by Mr. C. M. Warmington, Q.C., M.P., and Mr. Vernon Smith: while the defendant Corporation had for their counsel Mr. Fletcher Moulton, Q.C., and Mr. Hamilton.

Mr. WARMINGTON, Q.C., in his opening remarks, explained that the action was one to restrain a nuisance, the nuisance in question being that of increased danger from fire caused by the proximity of the defendants' works to the plaintiffs' premises. The plaintiffs' property was in Bond-street, and the defendants were the owners of large buildings adjoining in Bloomfield-place and Grosvenor-mews.

His LORDSHIP: The nuisance is not noise or vibration then?

Mr. WARMINGTON: No. It is the increased danger from fire. This action was one which was almost on all fours with an action which his Lordship had tried some time ago, and where an injunction had been granted. The case he (Mr. Warmington) was referring to was that of McMurray *v.* Caldwell. There the plaintiff was the proprietor of a paper mill at Wandsworth, and he sought an injunction to restrain the defendant, who was the manufacturer of articles called amorces, or toy percussion caps, from so carrying on his business as to be a nuisance, and running the risk of causing explosions in consequence of the dangerous character of his trade. As he had said, the injunction was granted as asked, and in the Court of Appeal the defendant was only allowed to carry on his business on his undertaking to take extra special precautions against explosions, which might cause damage to the plaintiff's paper mill. Up to the autumn of 1890, the London Electric Supply Corporation had used the premises now in question as an electric light generating station, but at that time, in consequence of certain steps taken by Messrs. Savory and Moore, they ceased to do this, and removed their generating plant to a site at Deptford, where they erected very large works, and employed a large number of hands. Having generated their electricity at Deptford, they transmitted it to the Bond-street centre. Well, what the defendants had been doing was to send along their electricity from Deptford to Bond-street at a pressure of as much as 10,000 volts. This the plaintiffs considered highly dangerous, and, as a fact, they had a good reason for thinking so, because several accidents had happened on the premises, and there had been more than one fire of a serious description, one which occurred in November, 1890, almost gutting the defendants' works. Excuses would be made for this fire, and it would be contended that the man who was in charge of the machinery lost his head, and might have prevented the catastrophe. Be that as it might, however, the fire did occur, and the plaintiffs were anxious that there should be no repetition of the accident. With this view the present action was brought, and he (Mr. Warmington) thought the evidence he should call would prove that the defendants' works as they at present existed were a source of considerable danger to the plaintiffs' property.

Witnesses were then called whose evidence went to show that accidents had happened on the defendant Corporation's premises, and that fires had occurred which had only been put out with considerable difficulty.

On the suggestion of his Lordship, Mr. Moulton, Q.C., reserved the speech which he was entitled to deliver in opening the defendants' case, until after he had called his witnesses.

Mr. S. Ferranti, Dr. John Hopkinson, and other experts were then called, and they stated that now, at all events, there was no danger what-

Digitized by Google

ever of any fire arising from the distributing room used by the defendants. That room had been made thoroughly fireproof, and, as a fact, there was nothing whatever in it that could burn. The "converters" themselves could not possibly take fire, whatever happened.

The evidence having been concluded,

His LORDSHIP said he should direct that the action should stand over for three months, to give the defendants an opportunity of seeing whether they could take extra precautions to prevent any danger from fire arising from their works. He thought that something might be done to the floors above the basement, in which, he was informed, the converters were placed. He should adjourn the further hearing of the case in order that the defendants might take such steps as would render the upper stories of their building fireproof.

### The Attorney-General v. the Boy Messengers Company (Limited); the Attorney-General v. the District Messenger Service and News Company (Limited).

These cases, which were heard on Tuesday before Mr. Justice A. L. Smith and Mr. Justice Grantham, raised the question, on informations by the Attorney-General on behalf of the Crown, whether the business of these Companies was carried on in contravention of the exclusive rights of the Postmaster-General under the Post Office Acts. The information alleged that the Boy Messengers (Limited) was a joint-stock company, the objects of which, as registered, are to carry on the business of messengers and carriers in the metropolis and other places in the United Kingdom. Further, the information charged that in July, 1890, the Company instituted a system of telegraphs. The solicitor to the Post Office had written to the Company that their delivery of letters was a contravention of the exclusive privileges of the Postmaster-General, and a correspondence ensued. It was then stated that the Company had had interviews with the solicitor to the Postmaster-General with respect to an intention on the part of the Company to introduce, as a new feature in their business, a system of electric calls, and in July last the Postmaster-General offered to grant a licence to the Company to work the system of calls provided that a stringent clause was inserted in the licence to the effect that the Company should not undertake the delivery of letters. But the Company refused to accept any licence containing such a clause. In March last the solicitor to the Postmaster-General wrote to the Company that he could not entertain their proposals; that if not assured that they would abstain from violating the law he was instructed to commence proceedings against them, and this information was accordingly filed. The Attorney-General waived penalties but asked that "it may be declared that any message or communication, written or printed, sent by one person addressed or directed to another, for the purpose of being sent and delivered by post or other means, is a letter within the meaning of the Post Office Acts, and that the receiving of letters to be so sent is the collecting of letters within those Acts and an infringement of the exclusive rights of the Postmaster-General;" and he prayed that the Company should be restrained from continuing these acts, and that an account be taken of all moneys received by them for so sending letters, &c.

Mr. Finlay, Q.C., and Mr. Ernest Pollock appeared for the Boy Messengers Company: and Mr. Bremner appeared for the District Messengers Company.

When the case first came on it was by consent postponed, as the parties were negotiating, and it was more than once so postponed. It came on again on Tuesday morning, but was once more put off until later in the day, when

The SOLICITOR-GENERAL stated that terms had been arrived at which, in the judgment of the Postmaster-General, gave sufficient security for the public interest, and at the same time also secured the proper maintenance of the exclusive right of the Postmaster-General, and, though an injunction was to be agreed to against any breach of that exclusive right, he hoped there would be no occasion to apply to the Court to enforce it. The terms agreed upon were not stated, but from what followed it may be inferred that the Companies are to take out licences from the Postmaster-General.

Mr. BREMNER, who appeared for the District Messengers Company, said that under the arrangement which had been entered into, the Company would be able to carry on their business as widely as they had hitherto done with the consent of the Postmaster-General.

Mr. E. POLLOCK, who appeared for the Boy Messengers Company, desired to say as much on their behalf. They had, he said, licences from the Postmaster-General under the Telegraph Acts, which would enable them to extend their telegraph business, as well as licences to carry on their previous business.

Accordingly a decree for an injunction will be entered against any infringement of the exclusive rights of the Postmaster-General (whatever they may be), and the business of the Companies will be carried on under licences from the Postmaster-General.

### B. Verity and Sons v. Terry.

This was an action, heard before Mr. Justice Charles on Monday last, to recover £593. 0s. 6d., for work done by the plaintiffs as electric lighting engineers. Mr. J. F. Moulton, Q.C., and Mr. S. O. Buckmaster appeared for the plaintiffs; and Mr. Cyril Dodd, Q.C., and Mr. T. J. Bullen for the defendant.

The plaintiffs' claim was for the installation of the electric light in the theatre, and various other sums for goods supplied in connection with the work. The defendant pleaded that the plaintiffs had agreed to improve and repair the existing electric lighting at his theatre, and supply the whole of the materials for the sum of £125, and to supply 15 additional lights in the defendant's offices, and an electrolier in the saloon bar of the theatre for the sum of £22. 15s. The defendent alleged, further, that any work done or goods supplied other than the 15 additional lights and the electrolier was done or were supplied without his authority or knowledge, and paid £27. 15s. into court (having already paid plaintiffs the sum of £120) as sufficient to answer the plaintiffs' claim.

Mr. G. H. VERITY, one of the plaintiff firm, in his evidence, said all the orders came from Mr. Bricknell, the defendant's agent. He went over the place and pointed out where all lights were to be put. They worked night and day to have the installation ready before a piece called *New Lamps for Old* was produced. Nothing had been done without orders from Mr. Bricknell.

Mr. CUNNINGTON, Mr. Verity's engineer, corroborated this evidence.

Mr. EDWARD O'CONNOR TERRY stated that he was the proprietor of Terry's Theatre. He let his theatre at the time in question to somebody on behalf of Miss Graham (who was bringing out "New Lamps for Old"). He left London for India in January, 1890. Up to this time he had spent some hundreds of pounds in electric lighting at his theatre with satisfactory results. When he let the theatre he communicated with the plaintiffs about improving the electric lighting. The plaintiffs' estimate or report was brought to him before he left England, and he accepted it. He never gave Mr. Bricknell any authority to vary this estimate in any way.

At this stage of the case, by suggestion of the learned Judge, the counsel engaged conferred with him in his private room, and his Lordship, on their return, intimated that he was pleased to say that the parties had come to an arrangement, whereby the defendant was to pay to the plaintiffs £375 (including the amount paid into court and paid to plaintiffs already).

The learned JUDGE said he thought the plaintiffs were not to blame in any way for what had occurred; but as the work had been done while Mr. Terry was absent his surprise at the amount of the bill was natural. The work had been well done and the prices were fair, and under all the circumstances the learned Judge thought the defendant ought to pay the costs of the action.

Judgment accordingly.

## TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891.**

The new edition of our well-known Directory and Handbook is now ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division of this Directory will be found extensive and reliable. *Orders should be forwarded at once.*

ACCEPTED TENDER.—Mr. G. Jennings, the well-known sanitary engineer of Lambeth, has secured the contract for providing and fixing patent electro-mechanical apparatus for indicating and recording in pumping station the level of water in reservoir, for the Sutton-in-Ashfield Local Board.

MESSRS. MERRYWEATHER AND SONS.—This firm send us their illustrated price list, and particulars of their improved patent sphincter grip armoured india-rubber hose, and notify that they have materially improved both the materials employed and the process of manufacturing same. Messrs. Merryweather and Sons refer with pardonable pride to the numerous awards which have been received for this hose, and caution purchasers against buying inferior makes. Amongst the list of users will be found quite a number of electrical and engineering firms. The list also includes prices and particulars of several other manufactures of the firm.

MESSRS. WOODHOUSE AND RAWSON UNITED (LIMITED).—We are informed that this Company have now opened their show-rooms at 34, Cannon-street, facing the Mansion House Station, and invite inspection. The Company intend exhibiting in these rooms samples of all the appliances and fittings in connection with electric lighting, telephone, bell, and other electrical installations, and will keep a stock ready for immediate delivery. Apart from the Company's own manufactures, a great number of appliances of other makers will be kept, including Silvertown, Henley, and okonite wires, and cables. Messrs. Woodhouse and Rawson United (Limited) also announce that in view of the large number of orders

Digitized by Google

in hand for steam and electric launches, tugs, &c., they have resolved to extend their riverside premises, and have purchased a piece of ground, situated close to Kew Railway Bridge, on the Surrey side, with a frontage to the river of between 600ft. and 700ft., where the Company will also have good dock accommodation. The new works will be nearly opposite the two existing yards of the Company, and will, it is expected, be in working order in the course of the next two months.

MESSRS. CATHCART AND PETO.—Messrs. Cathcart and Peto notify us that they have taken into partnership Mr. F. W. A. Radford, and the firm will in future be known under the title of Cathcart, Peto, and Radford. The premises occupied by the firm at 57B, Hatton-garden, E.C., will shortly be greatly enlarged to admit increased business.

MESSRS. CUTTRISS AND CO.—We are able to announce that the business of Messrs. Cuttriss and Co., electrical engineers and manufacturing electricians, of Elmwood Electrical Works, Camp-road, Leeds, is about to be transferred to a limited company, which will be registered in a few days.

BOULT'S COMPREHENSIVE WIRING TABLE.—We have received from Mr. Boult some copies of figures calculated from Mr. Kennelly's well-known formula, showing the current allowable in insulated wires laid in wood casings. The sheet is issued as a supplement to the book, and is accompanied by a number of very flattering testimonials. Purchasers of Mr. Boult's book from *The Electrician* Company can obtain a copy of these calculations post free on application to the Publisher.

ELECTRIC LIGHT INSTALLATION AT DUNSTON FLOUR MILL.—The Co-operative Wholesale Society's flour mill at Dunston-on-Tyne has just been lighted throughout by Messrs. Ernest Scott and Mountain, The Close Works, Newcastle-on-Tyne. This installation is the largest in a flour mill in the United Kingdom, and consists of about 600 16-c.p. incandescent lamps. A very complete system of electric bells has also been fitted by the same firm.

# PATENT RECORD.

## APPLICATIONS FOR PATENTS.

**NOTE.**—***The undermentioned applications are not open to pub inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.***

March 16, 1891.

4,643. P. H. WILLIAMS. Egham. Improvements in and connected with chains, cables, and couplings for electrical mains and other purposes, or for insulating, protecting, carrying or conveying electrical mains and other elements, and in preliminary preparation or insulation of such mains for being so carried, conveyed, and protected.

4,669. V. HIRBEC. London. Apparatus on the principle of utilising heat as a source of electricity.

4,678. J. PILKIN. London. Improvements in terminals for electrical purposes.

4,682. S. Z. DE FERRANTI. London. Improved means for securing safety in electrical supply systems.

4,684. W. MAYES. London. Improvements in instruments for measuring and adjusting magnetic force.

4,689. C. E. CHALLIS. London. Electric switches.

March 17, 1891.

4,715. N. S. AMSTUTZ. London. Improvements in a process of and apparatus for electrically reproducing uneven, irregular, or undulating surfaces.

4,840. G. F. ATTREE. London. Improvements in and connected with electric signalling for railways.

4,751. O. IMRAY. London. Improvements in electrical transportation systems (S. S. Wheeler, and C. S. Bradley, United States).

4,757. T. L. WILLSON. London. Improvements in the electric reduction of aluminium and other metals, and in the production of alloys thereof.

4,758. A. M. CLARK. London. Improvements in electric railways (the Waddell-Entz Electric Company, United States).

4,767. P. M. TURQUAND. London. New or improved wall fittings or plugs for portable electric lamps, also applicable to suspended electric lamps and other electric apparatus.

4,781. W. J. ENGLEDUE. London. A new or improved solution or electrolytic fluid for galvanic batteries.

4,792. E. J. SILKMAN. London. Electric type-writers.

4,794. J. E. KINGSBURY. London. Improvements in signalling and telephonic systems (the Western Electric Company, United States).

March 18, 1891.

4,812. H. A. MILLER. Forest Hill. Improvements in the construction of incandescent lamps.

4,831. W. McGEOCH, Jun., and A. J. McGEOCH. Glasgow. Improvements in holders for incandescent lamps.

4,838. M. BAILEY and J. WARNER. London. Improvements in incandescent electric lamps.

## SPECIFICATIONS PUBLISHED.

1890.

3,900. PYKE AND BARNETT. Electrical inductoria. (Price 6d.)

5,409. CAPPILLERI AND OTHERS. Electric arc lamps. (Price 8d.)

5,562. EMMOTT AND RIDER. Dynamo-electric machines. (Price 8d.)

6,802. WALLER AND MANVILLE. Electrical traction. (Price 1s. 1d.)

6,223. ANCIZAR (Zerda-Bayon). Galvanic batteries. (Price 6d.)

6,623. WARDEN AND SMITH. Electric switches. (Price 6d.)

6,924. EAGER AND MILBURN. Electric batteries. (Price 4d.)

7,422. BRYAN. Electric circuit regulator. (Price 6d.)

7,520. JOHNSON AND PHILLIPS. Signalling on electric circuits. (Price 4d.

7,624. KINGDON. Electrical transformers. (Price 8d.)

7,725. CHALLIS AND GRAHAM. Electric switches. (Price 6d.)

14,844. APPLETON AND JOSEPH. Electrical connector. (Price 8d.)

19,272A. CARPENTER. Electric soldering irons. (Price 8d.)

1891.

657. LAKE (Lord). Electric conductors. (Price 6d.)

2,297. HAZELTINE. Electric arc lamps. (Price 8d.)

# COMPANIES' MEETINGS & REPORTS.

## Oriental Telephone Company (Limited).

The eleventh ordinary annual general meeting of this Company was held on Wednesday at the City Terminus Hotel, Cannon-street, under the presidency of Mr. William Addison.

The SECRETARY (Mr. Alex. B. Chalmers) having read the notice calling the meeting, the report of the Directors was taken as read.

The CHAIRMAN then said:—In moving the adoption of the report and balance-sheet, it is again my pleasure to announce a continued progress in the business of the Company. It is true such progress is not so rapid as could be wished, owing to the difficulties we have to contend with in extending our operations. This is especially the case in India, the telegraph department of the Indian Government being most unwilling to allow the facilities which are necessary to the success of our subsidiary companies in that country. However, notwithstanding the restrictions against which those companies have to contend, I am glad that we are able to report an increase in their dividends this year, amounting to ½ per cent. on the Bengal Company's shares, and to 1 per cent. on the Bombay shares. This result is attributable in some measure to economy in management. Our exchanges in Singapore and Rangoon also show an improvement in their revenues, as, in a smaller degree, do those also at Colombo, Madras, and Mauritius. The Directors of the Telephone Company of Egypt, after paying the interest on their Debentures, amounting to £345, have declared a dividend of 6 per cent. The amount of the dividend has been brought into our balance-sheet, which you have in your hands. It is with great regret I have to announce to you the loss we have sustained since the issue of the report, by the death of our colleague, the Right Hon. G. Cavendish Bentinck, who has sat with us on your Board for five or six years. To comply with the Articles of Association, Mr. Lloyd retires in the place of Mr Bentinck, and offers himself for re-election. You will no doubt expect me to refer to the alteration in the mode of distributing the dividend. As you are aware, we have been in negotiation with a large holder of vendors' shares, with the view of some arrangement being come to for placing all the Capital on a common footing. In the course of this negotiation, an actuary, who was called in to advise upon the relative positions of the shareholders, raised an important question as to the mode in which the profits were divisible—whether or not, in fact, the deficiency of dividend due to the holders of ordinary shares for the first five years should be made up by application of the entire subsequent profits, or solely by means of the dividends upon the vendors' shares. Counsel's opinion was taken upon the point. I think it undesirable to state the nature of the opinions obtained further than to say that after due consideration of them the Directors have decided to prepare the accounts in the form in which they are now laid before you, and under which, as you will see, it is proposed that the deficiency referred to should be made up solely by the application of the dividends upon the vendors' shares. Since the issue of the report, proceedings have been taken by a holder of vendors' shares which our solicitor will explain to you.

The SOLICITOR (Mr. Joseph Addison): Before the report is considered you may like to know exactly what has been the object of the alteration in the mode of declaring the dividend. Until this question was raised, and until, as happened last year, some new ordinary shares—although only a small amount—were issued which were not entitled to the benefit of the vendors' guarantee, the question did not become of importance; but when, with the view of putting the capital of the Company on a satisfactory basis to all parties, an opinion was obtained that possibly it was only the dividend upon the vendors' shares which should go to make up this deficiency, then that fact, coupled with the issue of these new shares, has made it absolutely necessary, in the judgment of the Directors, that they should declare a dividend upon all the shares, and that they should intimate plainly the opinion which they had obtained, that it was only the dividends on the vendors' shares that should go to make up the

Digitized by Google

deficiency in the first five years to the ordinary shareholders. You quite see that if that contention is upheld it will make a very large difference in favour of the holders of the ordinary shares as against the holders of the vendors' shares, because that deficiency, which is of considerable amount, would in that view have to be made up solely out of the dividend declared upon the Vendors' shares, instead of by the adding together of the dividends on the ordinary shares with the dividends on the vendors' shares, Then, with respect to these legal proceedings, naturally the view which is taken is not one that is very agreeable to the holders of the vendors' shares, and a gentleman who is a very large holder of vendors' shares has thought fit to challenge this construction which the Board have put on the agreement, and he is now taking proceedings in one of the Courts which will come on on Friday, not with the view of stopping the payment of the dividends, but with the view, if he can, of getting the Court to decide at once which is the right construction—that is, whether the holders of the ordinary shares are to bring into account in making up the deficiency of dividends on their own shares as well as on the vendors' shares. Nothing will be done which will stop the payment of the dividend. The notices will be sent out in the ordinary way, and it will be seen whether the Court on Friday morning will give directions that the sending them out be without prejudice to the question raised by the vendors, which is a very important one. The Directors will not express any opinion on this question, although they have adopted this course. They feel that they represent the whole of the Company. The question will be duly and properly considered, and the rights of the holders of the vendors' and the ordinary shares will be fully protected.

The CHAIRMAN: I now beg to move the adoption of the report, and if any gentleman has any questions to ask before it is put to the meeting I shall be happy to answer them.

Mr. W. S. CUFF asked if there was any reason why the Directors should not tell the meeting the amount of the deficiency referred to which had to be made up. He was still not clear about the question between the holders of the ordinary and the vendors' shares. It seemed to him that by what was proposed the Directors gave the dividend to the vendors' shares, but took it back with the same hand. He did not, however, see how the position of the vendors was altered.

The SOLICITOR: I do not know that there is any objection to say that the deficiency existing at February 4, 1886, at which the five years came to an end, was £20,000. I think I had better refer shortly to the clause in the agreement. The agreement, which the vendors signed stated that "during the five years from February 4, 1881, the holders of the vendors' shares would not participate in the profits of these years until the ordinary shares received 6 per cent. in each year," which they did not do. Then the agreement went on to say, "and if in any such five years the dividend at the rate of 6 per cent. per annum upon the amount paid up, or credited as paid up, on the ordinary shares shall not be paid to the holders, the deficiency shall be made up to the holders of the ordinary shares out of the profits of the Oriental Company applicable to the payment of dividends in future years in priority to the rights of the holders of vendors' shares to participate." You see the question raised there is whether the holders of the ordinary shares are entitled to receive their share of the profits of subsequent years without counting these profits towards the £20,000.

Mr. CUFF stated that the matter was perfectly clear now.

Mr. W. M. HIBBERT thought a whole year was a long time to elapse before the shareholders heard anything with regard to the progress of the Company. Their shares, therefore, remained neglected by investors. They now paid 3½ per cent. on the shares, but when they considered that the shares were quoted at 7s. or 7s. 6d. each, this dividend really represented about 5½ per cent. Including, however, the amount written off in reduction of capital expenditure, the sum added to reserve fund and carried forward, they were earning a dividend of 10 per cent. on the present price of the shares.

Mr. CHESTON stated that he had no idea of embarrassing their proceedings that day, but as a holder of vendors' shares he could not allow the dividends to be declared in the way proposed by the Board without a protest.

The CHAIRMAN then proposed the resolution as follows:—

"*That the Directors' report, together with the balance-sheet to December* 31, 1890, *be approved and adopted, and that a dividend at the rate of* 2½ *per cent., free of income tax, for the year ended December* 31, 1890, *be declared on the paid-up capital of the Company.*"

Mr. B. ST. JOHN ACKERS seconded the resolution, which was carried unanimously.

On the motion of the Chairman, seconded by Mr. Henry Grewing, Mr. Ackers was re-elected a Director, as was also Mr. Thomas Lloyd, on the motion of the Chairman, seconded by Mr. G. B. Frost.

Mr. HICKS then proposed and Mr. Cuff seconded the following resolution, which was carried unanimously:—

"*That Messrs. Deloitte, Devers, Griffiths, and Co. be re-elected Auditors of the Company for the current year, and that their remuneration as such Auditors be the sum of fifty guineas.*"

The CHAIRMAN then said: I have now to bring before you the question of altering the Memorandum of Association of the Company, which, under a recent Act, can now be done at a moderate expense, provided such enlargement has some relation to the kind of business at present carried on. Your Directors propose taking advantage of these facilities to enable them to supply such electric apparatus or force as they may have application for.

They have no intention of departing from the business which they now carry on, but they have been asked to supply electric lighting apparatus, &c., from their different agencies, which they have been obliged to decline owing to the Company's Memorandum of Association not including such business.

Of course it will be for you gentlemen to sanction or decline such enlargement of the objects of the Company, but your Board considers it to the advantage of the Company that they should be able to execute orders for electrical apparatus other than telephones that might be offered to its agencies abroad.

Mr. FROST, in seconding the motion, stated that from time to time they received applications from the agents of the Company abroad for the supply of electrical apparatus—not that the Company was required to work it, but that they should supply it; and he thought it was quite necessary that they should take the powers in question, even if they did not use them.

The SOLICITOR then explained the nature of the alteration, after which

The CHAIRMAN proposed the following resolution:—

"*That the Company's Memorandum of Association be altered as follows: —By adding at the end of paragraph (b) of clause 3 the words 'or generation, employment or utilisation of electricity or magnetism.' By inserting after the said paragraph (b) the following additional paragraph (b 1.)— 'To carry on any business or manufacture relating to the generation, employment or utilisation of electricity or magnetism or the apparatus connected therewith.'*"

Mr. GREWING seconded the motion.

Mr. HIBBERT inquired whether any more capital would be needed in connection with what was now proposed, as they were really opening out a new business entirely.

The CHAIRMAN: We have no idea of raising any fresh capital.

Mr. HIBBERT: There is no necessity for it.

The CHAIRMAN: Not at all.

The SOLICITOR stated that the alteration proposed by the resolution would enable the Directors to do what they could not do now. Some time ago the question was raised whether the Company could take shares in companies abroad if the objects of those companies included objects beyond those contained in the Memorandum of Association of the Oriental Company. It was, therefore, very important, when the Company might be desirous of supporting the formation of companies abroad, that they should have the power of doing so, even though the Memorandum in the case of those companies might be wider than that of their own Company. In reply to a question, the Solicitor added that the alteration would not necessitate the re-registration of the Company.

The CHAIRMAN then put the motion, which was carried unanimously.

The SOLICITOR then stated that it would be necessary for the resolution to be confirmed at a subsequent meeting, of which due notice would be given.

A vote of thanks to the Chairman and the Directors was then proposed, seconded, and carried unanimously.

The CHAIRMAN briefly acknowledged the compliment, and the proceedings then terminated.

## South of England Telephone Company (Limited).

An extraordinary general meeting of this Company was held at Winchester House, Old Broad-street, on the 13th inst., Mr. D. O. Bateson in the chair, when the resolutions passed at the meeting on the 16th ult., as reported in *The Electrician* of the 20th ult., were confirmed. They were for approving an agreement expressed to be made between the Company and the National Telephone Company for amalgamating the two companies by transferring the business of the former to the latter Company.

The CHAIRMAN afterwards proposed and Mr. J. F. BROWN seconded a resolution (which was unanimously agreed to) fixing the remuneration of the Directors for the past year at £200.

On the motion of the CHAIRMAN, seconded by Mr. BILLETT, the following resolution was afterwards passed unanimously:—

"*That the purchase consideration to be received by the Liquidator under the above agreement be distributed among the members as follows;*—

"(a) *As to the cash portion of such consideration, (1) in repayment of* £2,992, *the amount of money paid in advance of calls on the Preference Shares, (2) of interest on the same sum at the rate of* 5 *per cent. per annum, from November* 1, 1890, *to the time of such repayment, and (3) the balance in payment of a sum equal to* 6 *per cent. per annum on the amount paid up on the Preference Shares from November* 1, 1890, *to the date when the Debenture Stock hereinafter mentioned commences to carry interest.*

"(b) *As to* £70,000 *Four and a-Half per Cent. Debenture Stock of the National Company by distributing the same among the holders of the Preference Shares, according to the amounts paid up on such shares otherwise than in advance of calls.*

"(c) *As to the* 12,000 *fully paid Ordinary Shares of the National Company, by distributing the same among the holders of the Ordinary Shares of this Company, according to the number of shares held by them respectively.*"

## The Eastern Extension, Australasia, and China Telegraph Company.

The following is the report of the Directors for the half-year ended 31st December last, to be submitted to the thirty-fifth ordinary general meeting of the Company, to be held at Winchester House, E.C., on Wednesday, the 22nd inst., at 2 o'clock:—

The gross receipts, including Government subsidies, have amounted during that period to £279,095. 1s. 0d., against £264,103. 12s. 11d. for the corresponding half-year of 1889. The working and other expenses, including £23,118. 6s. 6d. for cost of repairs to cables and expenses of ships, absorb £74,090. 3s. 2d. against £73,498. 19s. 3d for the corresponding

Digitized by Google

period of 1889, leaving a balance of £205,004. 17s. 10d. From this is deducted £2 915. 9s. 1d. for Income Tax, and £35,281. 9s. 10d. for interest on debentures, debenture stock, and contribution to sinking fund, leaving as the net profit for the half-year £166,807. 18s. 11d. Against this £1,120. 19s. 6d. has been charged for cost of new land line at Banjoewangie, and additions to staff quarters, and £100,000 on account of the cost of duplicating the Madras-Penang Cable, which is referred to below, leaving a balance of £65,686. 19s. 5d., which with £71,820. 7s. 5d. brought forward, shows an available balance of £137,507. 6s. 10d.

One quarterly interim dividend of 1¼ per cent. has been paid for the half-year, and it is now proposed to distribute another of like amount, making, with the interim dividends paid for the first half-year, a total dividend of 5 per cent. It is also proposed to pay a bonus of 4s. per share or 2 per cent., making a total distribution of 7 per cent. for the year 1890. The balance of £25,007. 6s. 10d. has been carried to the general reserve fund, which, after being credited with interest and profit on sale of investments, and debited with £10,722. 13s. 1d. on account of the cable renewals, &c., now stands at £495,239. 6s. 7d.

Your Directors have the satisfaction to report that, notwithstanding the financial depression existing at the time, the recent conversion of the Company's 6 per cent. debentures into 4 per cent. mortgage debenture stock, was attended with marked success, the whole of the issue having been subscribed by the shareholders at par. By this operation a saving in revenue of £6,400 per annum has been effected. Since the close of the year, nearly the whole of the 6 per cent. debentures have been paid off.

In accordance with the provisions of the trust deed, dated May 15, 1879, 320 of the Company's 5 per cent. Australian Government subsidy debentures were drawn by lot on the 7th inst. for payment at par on the 1st July next.

The negotiations with the Governments of Australasia, referred to in the last report, have resulted in an agreement being concluded between the Company and the Governments of New South Wales, Victoria, South Australia, Tasmania and Western Australia, for reduction of the tariffs to those Colonies from the 1st May proximo, as follows :—

| | | | |
|---|---|---|---|
| From 9s. 4d. | to 4s. 0d. | per word for | public telegrams. |
| „ 7s. 1d. | „ 3s. 6d. | „ | Government telegrams. |
| „ 2s. 8d. | „ 1s. 10d. | „ | press telegrams, |

for a tentative period of one year, to be extended if found to work satisfactorily. The contracting Colonies guarantee the Company against one-half the risk of any loss should the receipts at the reduced rates fall short of the present earnings from the Australasian traffic, and the Company takes the other half. It was hoped that Queensland and New Zealand would have agreed to take part in the experiment, but after considerable negotiations between the various Governments, those Colonies declined to join in the guarantee ; consequently the tariffs to Queensland and New Zealand will remain unchanged.

The Contract with the Telegraph Construction and Maintenance Company for the manufacture and laying of the Madras-Penang duplicate cable has been satisfactorily carried out, and the service is now in a thoroughly efficient condition to meet any requirements that may arise in connection with the reduced rates to Australia

The Company's maintenance ships have, as usual, been employed on various repairs, but with the exception of the interruption of the Saigon-Tonquin cable from the 20th to the 27th October, and of the cables between Java and Australia referred to in the last report, there have been no interruptions materially affecting the Company's revenue during the half-year under review.

In accordance with the Articles of Association the Right Honorable Viscount Monck and George Garden Nicol, Esq., retire by rotation, and being eligible, offer themselves for re-election. The retiring auditors, Mr. Henry Dever and Messrs. Welton, Jones and Co., also offer themselves for re-election.

## The Indo-European Telegraph Company (Limited).

The following is the Directors' report for the year 1890 :—

The Directors have to regret the death of one of the foreign members of the Board, Mr. A. Delbrück, Banker, of Berlin.

The Company's revenue from all sources for 1890 amounted to £113,807. 3s. 11d., as compared with £108,288. 15s. 5d. for 1889, showing an increase of £5,518. 8s. 6d. The expenses were: on commercial and general account, £29,728. 18s. 1d. ; on maintenance account, £28,173. 1s. 6d. ; total, £57,901. 19s. 7d., as against £59,240. 6s. 9d. for 1889, a decrease of £1,338. 7s. 2d. Deducting the above expenses, taking credit for £2,035. 10s. 3d. brought over from 1889, and debiting income tax, there remains the sum of £56,668. 16s. 7d. From this amount, £10,000 has been placed to reserve ; and that sum, together with £10,625, amount of interim dividend, have to be deducted, leaving a balance of £36,043. 16s. 7d.

The Directors now propose the declaration of a dividend for the six months ending December 31st, of 17s. 6d. per share, making, with the dividend already paid, 6 per cent. for the year and a bonus of 20s. per share, both free of income tax, making in all 10 per cent., carrying forward £4,168. 16. 7d. to the credit of 1891.

As the shareholders are aware, the Telegraph Conference was held last year in Paris ; nothing occurred to materially affect the interests of this Company. The Directors in association with some of the Australian Colonies and the Eastern Extension Telegraph Company, as well as the Indian Government and the Eastern Telegraph Company, subject to the consent of certain Governments interested, have arranged as an experiment to introduce a 4s. per word rate, for messages exchanged with the Australian Colonies. This is made practicable owing to the guarantee of the Colonies to bear half of the loss sustained by the application of the reduced rates. Queensland and New Zealand, which have declined to join in the above guarantee, will not participate in the benefit of the reduction. Should the trial thus proposed to be given to very low rates prove a failure, the tariffs will be again raised. Duplex apparatus have been applied, and are working very satisfactorily, upon both of the Company's land and cable wires, between London and Germany.

It will be observed that notice is given of a special resolution which the Board consider advisable in the interests of the Company.

The following Directors retire by rotation, and offer themselves for re-election :—J. Herbert Tritton, Esq., and Major-General Tremenheere, R.E. The transfer books will be closed from the 14th to the 28th instants, both inclusive. The auditors, Messrs. C. F. Kemp, Ford and Co., public accountants, retire, and offer themselves for re-election.

## New York Belting and Packing Company (Limited).

The adjourned statutory general meeting of this Company was held on Tuesday, at the offices, 98 and 100, Queen Victoria-street, under the presidency of Mr. H. B. Henyon.

The SECRETARY (Mr. J. C. Wylde) having read the minutes of the meeting held on the 7th inst.,

The CHAIRMAN said : Our first duty is to put before you, "That the adjournment from the Cannon-street Hotel to this office be acknowledged."

Mr. J. H. TOD said : I saw Mr. Stevens on Saturday. He had just come back from America, and unfortunately, through a domestic bereavement happening since his departure from this country, and through business in Liverpool, he had to go off at once. We have, therefore, no written statement, but only his verbal statement to Mr. Pope, which was very satisfactory. Mr. Stevens is perfectly satisfied as to the nature and extent of the business. One question I put to him was to be perfectly certain when in America that the valuation of the machinery, which is always a ticklish matter, was absolutely cor-

rect. He is fully satisfied himself that it is under-estimated. Some changes have been made there, and I think Mr. Pope told you of that last week. Mr. Belmont has joined the Board. The business is going on thoroughly well, and Mr. Stevens is satisfied that we shall be able to increase it very materially within the next year or two. There will be a meeting somewhat later on, on account of some verbal alterations being required in the Articles of Association for Stock Exchange purposes.

After a few remarks from shareholders present, the meeting, which was purely formal, terminated.

## NEW COMPANIES REGISTERED.

**BRITISH HYDRAULIC FOUNDRY COMPANY (LIMITED).**—This Company has been registered in Edinburgh with a capital of £200,000, in £10 shares, to acquire patents relating to machine-moulding and metal-casting granted to Stephen Alley and John Alex. MacLellan, Glasgow; to carry out an agreement with Alley and MacLellan, engineers, Polmadie, Glasgow; to carry on the business of metal founders, engineers, steelmakers, iron-masters, &c.

**BROWN'S METALLIC PACKING COMPANY (LIMITED).**—This Company has been registered in Edinburgh with a capital of £11,000, in £10 shares, to purchase from Alex. Francis Garden Brown, Swindrigemuir, Dalry, his invention for metallic packing applicable to bearings and the patent applied for, and to carry on the business of mechanical engineers, iron-founders, &c. The registered office is at 51, West Regent-street, Glasgow.

**A. EARNSHAW AND SONS (LIMITED).**—Registered with a capital of £30,000 in £10 shares, to acquire the business of A. Earnshaw and Sons, Crown Works, Booth Town, near Halifax, Yorkshire, and to carry on generally the business of iron-founders, machine and tool makers.

**ROBERT HINDLE AND CO. (LIMITED).**—Registered with a capital of £15,000, in £50 shares, to (*inter alia*) acquire, construct, and maintain tramways, railways, manufactories, electric works, &c. Office, Sabden, Lancashire.

**JOHNSON, MATTHEY AND COMPANY (LIMITED).**—Messrs. Johnson, Matthey and Company, the well-known assayers, announce that on the occasion of admitting to partnership three of the sons of their seniors, they have considered it advisable for family reasons, and with the view of assuring to the business for the future a normal capital, to register it as a Joint Stock Company under the title of "Johnson, Matthey and Company, Limited," incorporated under the Companies' Acts. The nominal capital (ordinary and preference shares in equal moieties) is £900,000, of which £750,000 is now issued, and £600,000 paid up, leaving an uncalled liability on the ordinary shares of £150,000. The whole of the issued capital is taken up by the members of the firm, who will continue to manage the business as Directors, and no change is contemplated in the character of its operations. The Company acquires the business as from January 1st last.

**MOSS BAY HEMATITE IRON AND STEEL COMPANY (LIMITED).**—Registered with a capital of £308,196, in 17,122 6 per cent. Preference shares of £8 each, and 17,122 ordinary shares of £10 each. Objects: To carry on the business of ironmasters, miners, mechanical engineers, metal workers, tool makers, electricians, suppliers of electricity, boiler makers, and manufacturing chemists, to buy and sell, manufacture and repair machinery, electrical implements, tools, and utensils.

**STAFFORDSHIRE CHEMICAL COMPANY (LIMITED).**—Registered with a capital of £50,000, in £10 shares, to carry on the business of manufacturers of chemicals, or any business connected therewith.

**UNION ENGINEERING COMPANY (LIMITED).**—Registered with a capital of £19,000, in 1,000 Preference Shares of £10 each and 300 Ordinary Shares of £30 each. Object:—To acquire the business of the Union Engineering Company, carried on at Holt Town, and 2, Clarence-buildings, Booth-street, Manchester, and to develop and extend the same.

## CITY NOTES, &c.

**ANGLO-AMERICAN TELEGRAPH COMPANY.**—At a meeting of the Board of Directors of this Company on Friday last, it was resolved to declare an interim dividend for the quarter ended March 31st last of 12s. per cent on the ordinary Stock, and 24s. per cent. on the Preferred Stock, less income-tax, payable on the 1st May to the stockholders registered on the books of the Company on the 7th inst.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the past week amounted to £5,918.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The traffic receipts of this Company for the week ended April 12th amounted to £827.

**DIRECT UNITED STATES CABLE COMPANY.**—The Board of this Company have resolved upon the payment of an interim dividend of 3s. 6d. per share, free of income-tax, being at the rate of 3½ per cent. per annum for the quarter ended March 31, 1891, such dividend to be payable on and after the 24th inst.

**GREAT NORTHERN TELEGRAPH COMPANY OF COPENHAGEN.**—The accounts of this Company for the year 1890 have just been issued, from which it appears that, after providing for the interim dividend of 5 per cent. per annum, and an extra dividend of 7s. 2d. per share, and adding £66,666 to the reserve fund, a balance of £48,216 will remain to be carried forward.

**INDIA RUBBER ESTATES COMPANY (LIMITED).**—On a petition of Martin's Bank (Limited), judgment creditors on a dishonoured acceptance, but who have not issued execution, Mr. Justice Chitty on Saturday made an order for winding up the Company.

**NEW SHANGHAI ELECTRIC COMPANY (LIMITED).**—The report of the Directors of this Company states that after paying all expenses, the working account for the 14 months (from October 31, 1889, to December 31, 1890), shows a total profit of Tls. 7,705.22, which the Directors recommend should be dealt with as follows:—Plant account for depreciation, Tls. 3,690.08; dividend of 7 per cent. to all shareholders for the period ended December 31, 1890, Tls. 3,339.00; carrying forward, Tls.676.14; total, Tls.7,705.22. The Company have contracted to light the China Merchants' Kinlee-yuen Wharves, with six lamps for three years from April 1st next, at the same rate per lamp now charged to the municipality. Owing to the delay caused by strikes, &c. in England, the incandescent lighting plant was not ready until May 1, 1890, and its actual working only covers eight months, and not at full power during that time. With this short period of probation, the Directors are not yet prepared to give any definite opinion as to the future prospects of this branch. The increase in the price of coal during 1890 has further added to the expenditure, as was the case in 1889. Mr. R. M. Campbell having resigned on leaving Shanghai, Dr. Neil Macleod was invited to join the Board. Mr. F. E. Haskell, on his return to Shanghai, was also asked to re-join. These appointments require confirmation by the shareholders. In accordance with the deed of settlement, Mr. J. Beattie retires from the Board, but offers himself for re-election. The auditor, Mr. C. J. Dudgeon, resigned on leaving Shanghai, and Mr. R. F. Eastlack was temporarily appointed in his place. The latter now retires, but offers himself for re-election.

**PETZOLD AND CO., ENGINEERS (LIMITED).**—The transfer books of this Company will be closed from April 15th to May 1st, inclusive.

**REUTER'S TELEGRAM COMPANY (LIMITED).**—Mr. Justice Chitty on Saturday confirmed a special resolution of this Company to alter the Articles of Association by adding to the objects of the Company the telephoning of news, the construction and purchase of telephones, and the business of advertising agents, and contractors in all its branches in all parts of the world.——The twenty-seventh ordinary general meeting of the Company will be held at the Company's offices, 24, Old Jewry, London, E.C., on Wednesday, the 29th inst., at noon, and the transfer books will be closed from the 14th until the 28th inst., inclusive.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended April 10, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,777.

# THE NON-CONDUCTOR OF ELECTRICITY.

**VULCANISED FIBRE,**
PATENTED.

WAREHOUSE.

This new material is supplied in two qualities, Flexible and Hard.

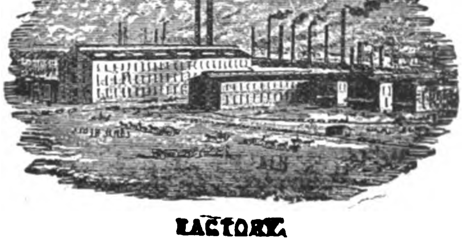
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

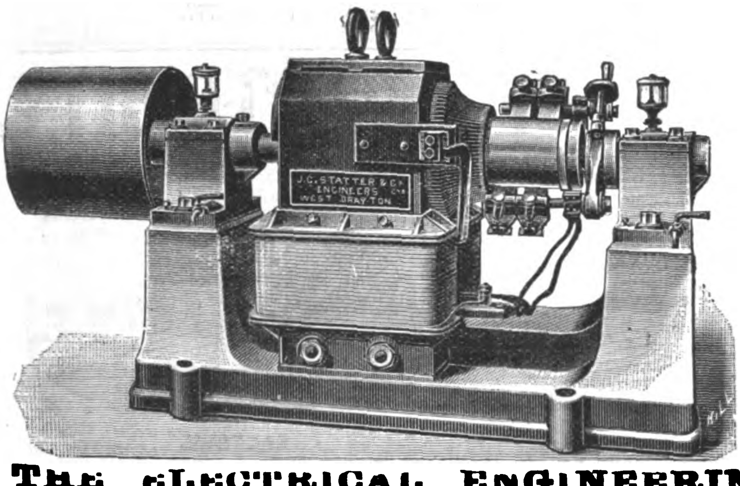
IMPROVEMENTS IN DYNAMOS



STATTER - BRUNTON
DYNAMO.

**The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.**

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

**STOCK SIZES UP TO 77 KILOWATTS.**
MACHINES BUILT TO 500 KILOWATTS.

THE ELECTRICAL ENGINEERING CORPORATION, LIMITED,
[STATTER'S] [UNITED.]
68, Victoria Street, London, S.W. WORKS:—ALLIANCE ENGINEERING WORKS, WEST DRAYTON, NEAR LONDON.

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

## ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 675.—Vol. XXVI. FRIDAY, APRIL 24, 1891. Price Fourpence.

## NOTES.

The debate initiated by Earl Compton in the House of Commons last Friday did not give rise to any serious complaints against the Postal Telegraph administration. Telegraph clerks have still some grievances to be redressed; but they may think themselves lucky in belonging to a service which is able and generally willing to listen to them. As to the public, it seems that they have little or nothing to complain about. Mr. Henniker-Heaton's contribution to this branch of the discussion did not go beyond deprecating the charge made for addresses and ridiculing the rules for counting certain double-barrelled compounded words. As to the former, Mr. Heaton will have to shout himself dumb before he induces any Government to relax the present regulation, which is both fair and logical. He is on surer ground when criticising the unmeaning restrictions and contradictory rules laid down for the counting of words whether in the addresses or the texts. Everybody has experienced the vexation of these arbitrary regulations, which are unintelligible apparently even to the post-office clerks themselves, who often spend five minutes on a matter which ought to be perfectly clear without any references whatever. When one attempts to settle the point by throwing down an extra halfpenny, it is declined with thanks, the clerks seeming quite as much afraid of taking too much as of accepting too little. We once took the trouble to look up the "Postal Guide" in order to account for some eccentricity of this kind. To our amazement we found that if the word in dispute was *A*, it counted as one word; but if *B* it is counted as two; and that we might learn to which of the two categories it belonged by referring to another part of the Guide, or, failing that, to a list of places somewhere else. We did not pursue the subject, and have ever since felt a sort of sneaking respect even for the member for Canterbury.

It is difficult to give comforting advice to the firm whose letter on the wiring of their works will be found in our present issue. There are numerous rules for wiring, and the subject has been frequently dealt with in our columns. The rule about 1,000 amperes to the square inch was made in the early days when the heating of conductors was not understood. The Paper by Prof. Forbes, in 1884, ought to have exploded the idea, and the experiments of Mr. Kennelly, in 1888, have set the matter on a practical footing; while the Board of Trade, in their latest rules, abandon altogether current density, and specify a limit of temperature. According to Mr. Kennelly, and no one has as yet disputed his figures, a No. 18 wire will carry 11 amperes at a density of 5850 amperes per square inch, without raising the temperature more than 15°C. However, the thousand ampere rule is on the safe side for all ordinary work. Our correspondents appear to put forward the fact that they run their lamps 5 per cent. under their proper voltage as though this were a precaution or matter of safety. They lose just about 20 per cent. of their light by doing this, and without any possible advantage other than prolonging the life of the lamps. For every penny thus saved many times that sum is wasted in power. The use of wire of so large a gauge as No. 8 is universally condemned by electrical engineers, and all conductors whose area is greater than that of No. 14 should be stranded.

It is true that small switch connections and lamp terminals are rarely soldered, but we strongly approve of soldering the conductors at switch-board instruments and switches and at the dynamos, not to the terminals, but to suitable thimbles or sockets which may be firmly attached to the terminals. The only really unsightly detail in the engine-room of the City and South London Railway was the connection of the conductors to the dynamos, the ends being squashed out in a flat bunch and jammed against the terminal by screws. We should like to see the end of every conductor larger than $\frac{7}{22}$ sweated into a thimble.

Cut-outs are very much overdone. Mr. Preece pointed out some years ago that an enormous number of dry joints offering resistance and chance of difficulty are introduced by the lavish use of fuses, but our correspondents are mistaken in supposing that a loss of 20 per cent. could thus be produced. The proper place for a cut-out is at the branch as close as possible to the joint. They are to protect the wire, not the lamp. The remaining point in the letter is a very difficult one. The electrical advisers to insurance companies are very fond of setting up rules drawn from their general experience, and are quite at sea when a peculiar case is put before them. The conditions of a dye works are very peculiar, and have sorely puzzled many electrical engineers. This particular case cannot be so bad as many, as it appears that iron staples are used; in many dye works copper would have to be employed. Metal staples in any case are bad, and sheet copper saddles would be but little better. Where there is merely steam and no acid vapour, the

Digitized by Google

use of well varnished teak casing should suffice, if carefully put up, as in ship work, with a cement filling. Creosoted wood cleats, fastened with copper screws, would probably stand the peculiar atmosphere of dye works better than anything else, a first-rate insulation varnished with the new flexible acid-proof varnish that is now used for accumulator work being employed.

MR. TOLVER PRESTON's article on "The Ether as a Source of Motion," which we print in another column, touches a subject of the greatest possible interest, as it really raises the whole theory of the circumstances under which we may expect to obtain energy available for useful purposes. The first law of thermodynamics, that of the conservation of energy, is consoling for our descendants because it asserts that, in spite of all the work which has been done in the world, the amount of energy in it is now as great as ever. The second law of thermodynamics, or the law of available energy, is of quite a different character. It asserts that there is a natural tendency for all available energy to dissipate itself and become useless, and, when very roughly interpreted, is equivalent to the assertion that the industries of the world will come to a standstill when our coal supplies become exhausted. While, however, the first of these laws is quite unalterable, it has been shown by Maxwell that the second is only strictly true of inanimate bodies, and that it is possible to imagine processes by means of which the tendency can be checked or even reversed in any particular case, although these methods may be as yet quite impracticable. It is to processes of this character that Mr. TOLVER PRESTON is alluding when he refers to his screens.

THE existence of such screens is not contradictory to any law of nature, and it is, therefore, theoretically possible to find them. Moreover, there is no doubt about the correctness of his assertion that the ether is an inexhaustible source of energy, and that, if a means could be found of making this energy available, engines could be continuously worked by it as from a new kind of coal. The perpetual motion so obtained would, after all, be quite analogous to that shown in a mill wheel urged round continuously by water power. But such screens, and such methods, are none the easier to find on this account. No one has any right on scientific grounds to say that it is impossible to find a metal with conducting powers so good that its specific resistance would be represented by a cipher. There is no doubt of the warm welcome such a metal would receive among electricians; but the question naturally arises whether the probability of finding such a substance makes it worth while looking for it in spite of the many great advantages it would undoubtedly possess.

IN connection with the screening of magnetic force, which Mr. TOLVER PRESTON alludes to, it is quite possible that the screen he suggests the search of is simply a sheet of metal of infinite conductivity. If a magnet is moved about in the neighbourhood of such a sheet, currents are induced in it which exactly counteract the effect of the magnet, as far as the side of the sheet opposite the magnet is concerned. The currents so induced do not die away, because the sheet, having no resistance. does not absorb any energy in heat. The strength of the currents alter according to the position of the magnet, and they are always so arranged that the lines of force due to them are equal and opposite to the lines of force due to the magnet. The effect is exactly as if none of the lines of force due to the magnet penetrated the sheet, which accordingly acts as a perfect magnetic screen. A line of force cannot cut a piece of metal whose conductivity is infinite, so that if the field magnets of a dynamo were once excited, and the limbs surrounded by two or three rings of this metal, the magnetising current could be removed altogether, for the lines of force would be, as it were, tied in place.

A METHOD, by means of which a system of electrical supply at constant potential may be utilised to supply electrical energy at constant current, is of considerable interest, even although it may be quite impracticable at present. A device with this object in view has been suggested in *L'Electricien*, by M. P. BOUCHEROT, and its action depends on the curious properties of choking coils and condensers. Several Papers recently appearing in our columns have made our readers familiar with the fact that, when an alternating current is passed through an inductive coil and condenser connected in series, the voltages on coil and condenser may each exceed the voltage which is driving the current through the combination. This action is due to resonance, and may become very marked under certain conditions. If, now, the condenser or coil is shunted with a resistance, the voltage falls, and the smaller the resistance the lower the voltage. This is the state of things needed for a constant-current system of supply, and M. BOUCHEROT has succeeded in showing that, under certain circumstances, the current through the shunt is independent of the resistance. Such a combination placed across the mains of a constant potential system will therefore supply a constant current to a circuit connected with the terminals of either the coil or condenser.

THE suggestion is highly ingenious, but is far too theoretical to be of service at present. In the first place it is necessary to procure choking coils and condensers which do not absorb any appreciable energy when alternating currents pass through them, since M. BOUCHEROT assumes that the resistance of the coil is nothing, and makes a similar assumption with regard to the condenser. It is also needful that the resonance condition should be fulfilled, and, if the choking coil is to take any appreciable current, this condition implies that the condensers will require to be of enormous capacity, unless alternating currents of high frequency, such as Mr. TESLA advocates, come into use. All such devices are unworkable at present owing to the great expense of condensers of suitable capacity, and the difficulty of getting them to stand high alternating potentials. The idea of M. BOUCHEROT can only be carried out in practice when condensers are obtainable which compare as favourably with those in use at present as the accumulators of to-day compare with the original cells of PLANTÉ. Of course it does not necessarily follow that the improvements will take as long to bring about.

**Birmingham.**—Electric lighting at Birmingham was formally inaugurated on Wednesday by the Mayor at the Birmingham Electric Supply Company's central station in Dale End.

**Leeds.**—At the last meeting of the Town Council assent was given to the application of the Yorkshire House-to-House Electricity Company for a Provisional Order.

**King's College, London.**—A special course of practical work in Light and Spectrum Analysis will be given in the Wheatstone Laboratory on Wednesday evenings from 7 to 9 p.m.

**Fire at Siemens and Halske's St. Petersburg Factory.**—On the night of the 13th inst. a fire occurred at Messrs. Siemens and Halske's lamp factory in St. Petersburg, by which damage to the amount of 250,000 roubles was done.

**Electrical Bills in Parliament.**—In the House of Commons on Friday last, the London Overhead Wires Bill was read a third time.—The Central London Railway Bill was read a third time and passed in the House of Commons on Monday.

**The Chicago Exhibition.**—The construction department for intramural transit in Jackson Park for the World's Fair, has decided to adopt the Adams system of single track elevated railway. The stations will be about 1,000 feet apart. Each car will be supplied with an electric motor and will hold 30 passengers. The track will be three miles continuous loop.

**The South African Correspondent of** ***Machinery*** understands that the executive have decided to declare the letters of incorporation of the Johannesburg Electricity Company of no value, as they have not been published in the *Staatscourant* in terms of the law. There is some probability of the Transvaal Government buildings in Pretoria and Johannesburg being lighted by electricity.

**Oxford.**—Under the Provisional Order granted to the Electric Installation and Maintenance Company, works are now in progress for the supply of electricity to the whole of this city. The system of distribution adopted is the "Chelsea" system of battery sub-stations. The works are being pushed forward with great rapidity, and it is expected that the supply to the public will be commenced about the end of October.

**Provisional Orders.**—The Board of Trade has granted Provisional Orders relating to Bolton, Canterbury, Dewsbury, Hanley, Harrogate, Sunderland, Ealing, Norwich, Southport, Stockport, Surbiton, Tynemouth, Bishops Stortford, Croydon, Heckmondwike, Londonderry, Southend, Weston-super-Mare, Acton, Chiswick, Coventry, Kidderminster, Llanelly, and South Shields. These Orders have been embodied in Bills which are to be submitted to Parliament for confirmation.

**The Elmore Copper Process.**—The troublesome method of giving the iron mandrils a preliminary coating of copper by the cyanide process has been discontinued, and copper rollers are now employed. The deposited copper adheres with just sufficient strength to withstand the friction of the burnisher, and is easily removed by a few light blows. Some large cylinders about 13ft. 6in. long by 3ft. 4in. in diameter have been turned out. These are for use in the wire-making department.

**A Curious Cause of Increased Coal Consumption.**—According to the *Revue Industrielle*, M. Cornut, chief engineer to the Association des Proprietaires à Vapeur du Nord, having been called in to investigate the cause of a considerable augmentation in the consumption of fuel by a large battery of boilers, discovered that this phenomenon was due to the presence of water in the smoke shafts. The measures which were taken to exclude the water have resulted in a saving of 16 per cent. in the annual coal bill.

**Lundy Cable Company.**—Mr. G. F. Rogers informs us that some time ago the liquidator of this Company offered this cable for sale, and he purchased it. He found the cable in perfect condition, except in one or two places where it had been chafed by the rocks, and also found a break, caused probably by some wreck having driven over it, the cable on both sides being in absolutely perfect condition. He thinks that if the cable be relaid to the Devonshire coast at Braunton there would be no further trouble in maintaining it, as it would be lying upon sand for the whole distance.

**Electricity in Mines.**—Mining engineers, says the *Mining Journal*, cannot afford to overlook the fact that electricity now occupies a position of ascertained value among the resources of their profession. Messrs. Atkinson's Paper and the discussion at the Institution of Civil Engineers show that both its capabilities and limitations have been carefully determined in actual practice, and that it has long since passed beyond the experimental stage as a means of transmitting power through the workings of a mine.

**Electric Traction Statistics.**—The statistics of the electric railways of Massachusetts for the year ended September 30, 1890, are as follows:—

| | |
|---|---|
| Number of companies having electric lines in operation | 17 |
| Overhead trolley system, total miles | 157·77 |
| Storage battery system, total miles | 3·09 |
| Total miles electric railway in State | 160·86 |
| Number of companies having electric lines under construction | 7 |
| Overhead trolley system, total miles | 28·45 |
| Storage battery system, total miles | 6 |

**The James Accumulator.**—In this accumulator the positive plates consist of lead alloyed with 1 per cent. of cadmium, whilst the negative consist of lead alloyed with 2 per cent. of antimony. The plates are pierced with circular holes, in which the active material is placed. Those on the positive plates are filled with a mixture of 8·5 parts of minium, 1 part of litharge, ·4 part of carded asbestos, and ·1 part of powdered carbon. The holes in the negative plates are filled with a mixture of 9·4 parts of litharge, ·1 part of sulphur, with ·4 part of asbestos, and ·1 part of powdered carbon.

**The Boy Messengers Company.**—The terms of the arrangement between the Postmaster-General and this Company are as follows: The Postmaster-General grants license for the "Electric Call System" in the County of London, including the City, and any other place not within the county but within five miles of the General Post Office. The Postmaster-General will connect the Company's offices with fire and police stations by telephones. Terms of the license 12 years. Royalty £25 per annum and 2s. 6d. per instrument (call box). The Company to act as agents of the Postmaster-General, delivering letters stamped with 1d. royalty.

**A Peculiar Accident.**—A peculiar accident recently occurred at Lynn, Mass. The central station caught fire, and the wires from the dynamos were burnt, breaking the circuit. Relieved of its load, the 700 H.P. engine became unmanageable, and started off at such a rate of speed that the large fly-wheel was broken into fragments, and flew in all directions, causing much damage to the building. An excellent illustration of the principle of the transformation of energy, as the power produced by the engine, instead of being transformed into electrical energy, was, on account of the breaking of the circuit, able to devote itself to wrecking the fly-wheel.

**Austrian Telegraph Statistics.**—The statistics of the Austrian Post Telegraph Department for 1889 have just been published. The receipts were, including international telegrams, 4,181,087fl., against 3,899,628 in 1888, an increase of 7 per cent. The total number of messages was 25,192,235, as against 23,839,620 in 1888, an increase of nearly 6 per cent. The Government now owns 26,677 kilometres of trunk lines, comprising 73,003 kilometres of wires. During 1889, 42 central telephone stations were opened, including those belonging to private companies, and 96,322 telegrams were transmitted by telephone to telegraph offices, and 128,094 telegrams were transmitted by telephone to subscribers.

**Utilisation of the Water-Power of the Rhone.**—As is well-known, the water-power of the Rhone is being largely utilised for industrial purposes in the neighbourhood of Geneva. Colonel Turettini (head engineer of the St. Gotthard Tunnel), who carried out the works, has just issued a report as to the state of the work. The canal on the left bank is provided with 20 turbines, working up to 4,400 H.P., of which only half is at present in use. During the past year 216 motors, totalling 1,565 H.P., have been driven from the works. The smallest, of ⅓ H.P., have been used to run sewing machines, whilst the largest (625 H.P.) has driven the electric light

Digitized by Google

installation for the town of Geneva. The total cost of the works was £227,200, and the year's receipts reached £82,600.

**Exports of Telegraph Apparatus.**—The value of the exports of telegraph wires and apparatus connected therewith during March was, according to the Board of Trade returns, exceptionally large, the total value having amounted to nearly £400,000, as compared with a little over £51,000 in the corresponding month of last year. As the January exports were also exceptionally heavy, the aggregate exports for the first quarter of the current year compare very favourably indeed with the corresponding figures for the two previous years. The following are the details for the three months, and for the quarter, in comparison with the corresponding figures of the two previous years :

| | 1889. | 1890. | 1891. |
|---|---|---|---|
| January ............ | £113,230 | ... £71,686 | ... £238,223 |
| February ............ | 32,086 | ... 201,594 | ... 22,306 |
| March ............... | 285,993 | ... 51,390 | ... 392,552 |
| First quarter ...... | £431,309 | ... £324,670 | ... £653,081 |

**Leamington.**—At the last meeting of the Town Council, the Town Clerk stated that the Board of Trade suggested several courses with regard to the rival applications for Provisional Orders made by the Corporation and the Midland Electric Light and Power Company. (i.) Both Orders might be granted ; (ii.) the Corporation Order might be granted with a purchase proviso ; (iii.) the Company might be granted an Order. The Corporation, the Board of Trade said, had allowed the Company to come into the town and spend a very large sum of money, and they thought it only fair that it should be allowed to compete in the supply of electric light with the Corporation or be bought out. The Mayor thought the Corporation would be wanting in common sense if they were to think of supplying electric light in a town where gas could be obtained at 2s. 6d. per 1,000. It was then moved that the Town Clerk have full power to drop the application. The proposition was carried unanimously.

**The Telephone Service of the Metropolis.**—Referring to the formation of the Association for the protection of the subscribers to the National Telephone Company's Metropolitan system, the *Economist* remarks in its last issue :—"This is a step which is perfectly justified by the circumstances of the case. In the matter of charges for telephonic service, the Metropolis is not only behind Continental and American cities, but also behind provincial towns. . . . The Company has, to some extent, been compelled to move with the spirit of the times in the provinces, and has recently made very considerable reduction in the charges to its subscribers ; but in the Metropolis, every effort to induce the Directors to improve their service, or reduce their charges—both steps are required—has been futile, and telephony has remained at a standstill. . . . The only explanation which can be found for the defiant attitude assumed by the Company towards the public in London is that, in the Metropolis, the Company thinks it has not much reason to fear competition. . . . Fortunately, the public are not without the possibility of a remedy. The telephone service is merely a branch of the telegraph service, and it is not only the duty of the Post Office to see that the public is sufficiently served, but it has all the machinery at hand with which to undertake the service. The difficulties in the way of a new private competition to the National Telephone Company, therefore, do not apply in the case of the Post Office. . . ."

**Cambridge.**—At the last meeting of the Town Council, Alderman Finch said that it would be in the recollection of the Council that a resolution was passed instructing the Electric Lighting Committee to prepare contracts for the electric lighting of Cambridge, and submit them for the approval of the Council. The Committee proceeded to prepare contracts in accordance with the instructions they had received. The Committee invited tenders for the erection of a station, and when they came to examine the tenders they found that instead of the sum being £4,900, as was put down in the report of the probable expenditure, the lowest tender was £11,260. That result surprised the Committee. It then occurred to the Committee that there might, perhaps, be a scheme that was not quite so costly as the one recommended by Dr. Fleming. They therefore appointed a Sub-Committee to proceed to other stations to study some of the schemes. The system the Sub-Committee recommended was remarkable for its mechanism, and for the small amount of labour that was required. Dr. Fleming, they believed, would be unwilling to take upon himself the responsibility of carring out a scheme which he did not recommend, and as the Committee were not electrical engineers, they would like to be in a position to ask for information from an authoritative and responsible person. They had ascertained there were already persons in different parts of the town prepared to take the light to the extent of 2,700 lights. He proposed : "That the Committee prepare the contracts they were directed to prepare, with liberty, if necessary, to consult another expert." The proposition was carried.

**Telephones on Shipboard.**—The Société Génerale des Téléphones, have, says *Engineering*, erected a considerable number of installations on board ship to enable communication to be maintained between the various parts with greater facility than by the use of speaking tubes. Among the more important ships fitted are the ironclads "Devastation," "Redoubtable," "Admiral Duperre," "Courbet," "Admiral Baudin," the crusier "Cecille," the torpedo cruiser "Sfax," and the Spanish ironclad "Pelayo." In these, all the circuits radiate from the conning tower. Care has been taken to make every part as strong as possible, and to avoid all chances of breakdown. To this end the conductors are made of copper ribbon and efficiently insulated. In those cases in which an officer or a man has two lines through which he can speak, each line is provided with its own complete apparatus for sending and receiving, and no attempt is made to make one apparatus serve for both lines. The telephonic apparatus consists of "Berthon" microphone transmitters and "Ader" receivers. Experiments on board the "Devastation" proved that with this apparatus a conversation was not interrupted between the conning tower and the central battery, even during the firing of the heavy guns. The "Berthon" microphone is so constructed that damp has no influence upon it. This is also the case with the "Ader" receiver, the coils of which are let into a bituminous block. On board the "Devastation," an apparatus has been used after having been immersed in a pailful of sea water. The cells employed are Léclanché Agar-Agar cells (dry.) The call-bells have different sounds, so as to distinguish them from one another.

**Bath.**—At the last fortnightly meeting of the Surveying Committee of the Bath Urban Sanitary Authority, Prof. Forbes' report was laid upon the table, but its consideration was postponed for a fortnight. Prof. Forbes states in his report that Mr. Massingham has at the central station ample power and plant for supplying the present requirements of Bath. The defects are (*a*) that proper arrangements have not been made for cutting off the steam pipe from any single engine ; (*b*) that there is no automatic device for regulating the electric pressure on the incandescent circuits ; and (*c*) there is no compensated voltmeter for indicating the pressure which ought to be maintained at the station, in order to keep the pressure at the consumers' lamps fairly constant. In the contract, lamps of 1,200 c.p. were specified, but the total quantity of light given out by each of the street lamps is, Prof. Forbes thinks, certainly not more than 300 or 400 candles. The arrangements for the private lighting appear to Prof. Forbes to be good on nearly every point, the chief defect being the inadequate arrangements for keeping the pressure constant. Appended to the report is a correspondence between Mr. Massingham and The Laing Wharton and Down Construction Syndicate who supplied the plant, and between the Clerk to the Urban Authority and Prof. Forbes, more particularly with reference to the great discrepancy in the candle-power of the lamps. The contractors state that although the 6·8 ampere Thomson-Houston arcs are called nominal 1,200 c.p., they actually give, when measured, without a globe, at an angle of from 40 deg. to 60 deg. below the horizontal, even more candle-power than this ; but with opal globes it is possible to reduce the candle-power even more than 50 per cent. They add that they have never had complaints before. Prof. Forbes admits that the arc lamps do emit 1,200 c.p. at their greatest intensity, and offers to carry out photometric tests.

## LIGHTNING CONDUCTORS.

BY DR. OLIVER LODGE.

### Experiments with Leyden Jar Discharges.

It may be remembered that in 1888-89* I began describing a series of experiments which I had made in connection with lightning conductors, especially a series of experiments on "the alternative path." These consisted in arranging that a couple of Leyden jars, charged up to a known potential determined by the length of their spark—which I called the spark A, should discharge round various circuits, and that specific portions of these circuits should be tapped off by an air-gap shunt, at which a spark might occur if it were able—this shunting or short-circuiting spark being called B; and the portion of the conductor thus tapped off or shunted out was called the alternative path. It was shown that the length of the B spark was a measure of the E.M.F. needed to send the given discharge through this conductor, and the ratio which the length of the B spark bore to the length of the A spark was shown to be calculable from theoretical considerations; being indeed this:—

$$\frac{B}{A} = \frac{\text{(total impedance of alternative path)}}{\text{(inertia portion of impedance of entire circuit)}} \times \text{(damping,}$$

or reduction of amplitude, during a quarter swing.)

There remain, however, a good many other experiments which have not yet been described, some of them of the same nature, and some on a different plan, and I propose to continue the description of the more interesting of them.

I take first some more experiments on the alternative path plan, made with the object of verifying still more certainly the effect of different metals, and of ascertaining more completely the effect of iron, especially of iron cores introduced into a coil of wire included in the discharge circuit.

### Effect of Iron introduced into Alternative Path Spirals.

§ **58.** Referring back to § 18, where iron inside a circuit is reported as having no effect on the length of the B spark, I proceeded to test the matter further.

*September* 28, 1888.—Wound a spiral of uncovered No. 12 copper wire on a long glass tube, with interspaces of between ⅛in. and ¼in., and made a long paraffined bundle of fine iron wires, say 2ft. long and ¾in. diameter, to fit the tube. Used this spiral as alternative path both with and without the iron core. A spark between machine knobs 4·1 centimetres long.

| — | B spark with spiral as alternative path. | — |
|---|---|---|
| Without iron core...... | 2·27 | Centim. length at which B sparks just fail. |
| With iron core inserted | 2·27 | They still just fail. |
| Ditto ................ | 2·12 | They occur and fail about equally often. |
| Remove iron core ...... | 2·12 | They do just the same. |

But this is noticeable, that whenever the B spark fails, so that the discharge has to go round the spiral, *the noise of the A spark is distinctly less when the iron core is in the spiral than when it is withdrawn.* Repeated this many times, and made quite sure of the observation. The difference is very marked: without the iron core the discharge is much noisier. Compare this with the effect of an iron wire as alternative path as reported in § 55.

### Magnetisation Observations.

§ **59.** Tried whether the iron bundle was magnetised after this treatment. It was. It lost some on tapping, but not much. Inserted it the other way into helix, and passed a spark: no change in the magnetism. Passed three sparks: magnetism destroyed. Passed more sparks: magnetism put back in old direction. Passed still more: magnetism reversed.

* The paper began in Vol. XXI., page 815, and ended temporarily in Vol. XXIII., page 269.

Put the core in now the original way, and sent sparks: magnetism not destroyed till after several sparks, then it became reversed again. On the whole it appears that the magnetisation caused by discharge current is somewhat accidental, but that there is a tendency in one direction.

*October* 1.—Tried this further with a set of 4 steel knitting needles, kept well separate by corks and inserted inside spiral.

Whenever the B spark failed, so that the whole discharge had to pass round the spiral, the magnetisation produced was feeble but in the correct direction. It took several sparks to produce much effect.

Wherever the B spark occurred, so that probably all the oscillations after the first were short-circuited through the air gap, the magnetisation excited was much more vigorous, but it was almost a toss-up which polarity it had; a preponderance was found for the same direction as before. Often, however, it was suddenly and violently reversed.

Lengthening the B gap so that all the flash had to go by the helix again, the magnetism was gradually set right even if it had been started wrong, but the residual magnetism was now only feeble.

To sum up:—The entire discharge gave feeble magnetism definite in direction; while, when partially shunted by a B spark, it gave strong magnetisation uncertain in direction.

### Further Alternative Path Experiments comparing Iron, Copper, and Lead.

§ **60.** *October* 13, 1888.—Having found that the effect of iron wire used as alternative path was to shorten the B spark, and to diminish the noise of the discharge altogether, I proceeded to examine and make sure of this; and for this purpose had had the new wires rigged up round the room as reported in § 54. Six wires altogether, of iron, of copper, and of lead, a pair of each metal, one thick and one thin, their particulars being given above (Vol. XXIII., p. 268).

Gallon jars standing on table connected up with short wires to machine, their outer coats connected to knobs of spark micrometer (where the B spark occurs).

Distance between the A knobs (those of the machine) 4·0 centimetres.

| Alternative Path. | Length of B spark in cms. | Remarks. |
|---|---|---|
| None .................... | 5·354 | .................................... |
| No. 12 Copper Wire ... | 5·20 | B spark occurred sometimes. } Copper is always less definite than iron in fixing a B spark-length. |
| Ditto .................... | 4·425 | Spark still often fails. } |
| No. 12 Iron .......... | 3·074 | Pretty definite. Spark on the verge of failing altogether. |
| No. 12 Lead .......... | 3·925 | Spark fails to pass 4 times out of 5. |
| No. 12 Copper again ... | 4·075 | Fails 3 times out of 4. |
| No. 12 Lead .......... | No perceptible | difference in noise, or anything between lead and copper. |
| No. 12 Iron .......... | 2·975 | Fails 9 times out of 10. Noise of spark much less. |
| No. 12 Lead ........ .. | 4·074 | Fails 5 times out of 6. |
| Thin Lead ........... ... | 3·250 | Fails 3 times out of 4. Nearly as quiet as iron. |
| Thin Iron .............. | 3·250 | Fails 4 times out of 5. |
| Thin Copper ............ | 3·600 | Fails 1 out of 2, but pretty definite. Noisier than either iron or thin lead. |
| To compare with some old altern | ative paths. | |
| Old circle of No. 5 Copper (see § 42) ... | 0·952 | Fails 3 times out of 4. |
| Ditto, No. 2 Iron ...... | ·915 | Fails 7 times out of 9. |
| Same length of No. 12 Lead ................. | 1·00 | Fails 3 times out of 4. |

### Summary of Table.

§ **61.** It is here to be noticed that the B spark with iron as its alternative path is shorter than with either of the other metals, as if it formed an easier path for the discharge; the real reason being its enormous resistance or throttling to an alternating current. Thereby the vibrations are rapidly damped out, and the difference of potential considerably reduced even

Digitized by Google

in the time of a quarter-period, *i.e.*,the time which elapses after an A spark before the B spark occurs. This same resistance it is which so markedly reduces the noise and violence of the A spark, *i.e.*, of the discharge altogether, when iron forms part of the circuit. A thin lead wire has something of the same effect, but a thick lead wire permits nearly as noisy a discharge as does copper. The throttling effect of even a thick iron wire is very marked.

It is noteworthy also that the adjustment for the critical B spark-length is decidedly sharper and more definite for iron or thin lead than it is for copper, especially for thick copper.

### Singular Effect of Iron Cores.

§ 62. It is further to be noticed that the introduction of iron into a helix, through which the discharge has to pass, although it does not affect the difference of potential required to propel the discharge through that helix, yet exerts a very marked effect in quieting the discharge. It may be understood as increasing the radiating power of the circuit, and thus aiding the quiet dissipation of energy. But if it did this alone it ought to shorten the B spark, as iron does when forming part of the circuit. It does not affect the B spark at all, so far as I have been able to ascertain, when inserted into helices; hence it would appear that it must increase the impedance of the alternate path, as well as the damping factor, and that the two effects, the one tending to lengthen the B spark, the other to shorten it, just neutralise each other.

I see no theoretical reason why these two different effects should just balance each other, and hence was at first disposed to explain the constancy of the B spark, when iron cores were introduced or removed, by supposing that they produced no effect whatever. But they do produce some effect, as is evidenced by their quieting of the noise of the discharge.

It is therefore singular that the E.M.F. needed to drive a discharge through a coil should be independent of the presence of iron in its core.

Referring back to § 34, theory gives for the ratio of the B spark potential to the A spark potential

$$\frac{\mathrm{B}}{\mathrm{A}}=\frac{\sqrt{(p_o^2+\mathrm{R}_o^2)}}{p+p_o}\,e^{-\frac{\pi(\mathrm{R}+\mathrm{R}_o)}{4\,(p+p_o)}}$$

where $p_o$ is the inertia part of the impedance of the alternative path, and $p$ the same thing for the rest of the circuit; and where $\mathrm{R}_o$ is the resistance or dissipation of energy constant for the alternative path (inclusive of its radiating power), and R the same thing for the rest of the circuit. Now an increase of $p_o$ alone would almost always increase the ratio B/A, but an increase of $\mathrm{R}_o$ alone need not. The effect of an iron core may naturally be supposed to consist in an increase of both $p_o$ and $\mathrm{R}_o$; and experiment suggests that while $\mathrm{R}_o$ is largely increased by the insertion of iron cores, there is also a corresponding increase in $p_o$ of such magnitude that the above ratio $\frac{\mathrm{B}}{\mathrm{A}}$ remains appreciably constant.

(*To be continued.*)

## THE ETHER AS A SOURCE OF MOTION.

BY S. TOLVER PRESTON.

The recent discoveries of Prof. Hertz having experimentally proved that all electric and magnetic "attractions" and "repulsions" are *ether thrusts*, additional confidence must be excited in the view that molecular "attractions" and "repulsions" are also *ether thrusts*. For "action at a distance" is now being generally discarded, and if so, what else can influence or act on molecules but the ether in which they are immersed? Besides, Faraday thought that molecular "attraction" (chemical action) was electric. Now, it is proved by Hertz's experiments (which confirm Maxwell's theory) that light and heat waves are *electric*; if so, Faraday's view that molecular actions are electric in their nature, must be true. Indeed it appears highly probable, if not certain, that molecular "attractions" are at least partly electric, if not wholly so. Such being the case, coal must be regarded (assuming the above highly probable view to be true) as a new *machine* for deriving motion from the ether; coal "combination" with oxygen being effected by ether thrusts.

It appears to me highly important at once, without waiting for this view to be *absolutely* proved, to ask ourselves now what we are doing, if this view be true. In our way of using coal (in the steam engine), we let the machinery—coal and oxygen—be thrown away after having made one stroke,* so to speak. The question is, is it necessary in deriving power from the ether, to *waste machinery* in proportion to the power derived? Can we not use our machinery in the same way as we employ all normal machinery for deriving power from *subsidiary* sources, winds, waterfalls, &c., *i.e*, can we not employ the machinery permanently, and not throw it away after having made one stroke, which is a very expensive process?

Would cooling down by suitable mechanism, the products of combustion to a point far lower than that yet reached, so weaken the molecular attractions by weakening the assumed cause of stress (viz., vibration), that by some imagined chemical process (?) the work required to separate out the carbon would be† notably reduced; and so the carbon could be used again as a normal machine for deriving motion from a source?

It must be so far true (on the above view) that—contrary to preconceived ideas—the energy expended in separating the carbon from the oxygen is not "stored up" so as to be available again for the approach of these molecules. It is no more necessarily "stored up" than the energy expended in separating a keeper from a magnet is necessarily "stored up," for, as far as we know, this expended energy is dissipated in the ether, and is not available for the return of the keeper. The keeper can return by an ether thrust or stress, and the ether can have inexhaustible energy to draw upon for effecting the return of the keeper; even if we expended no energy on the ether in separating the keeper. As a somewhat parallel instance—if the kinetic theory of gravity be true it is *certain* that in lifting a weight, the energy is *not* stored up for the fall of the weight, but dissipated beyond recovery in the ether.

"Why, then, expend energy in‡ lifting a weight or in separating a keeper at all?" it may be asked; or rather, "What is the *theoretic* necessity for this?" Obviously there is none, if the energy expended be not available for approach. If, then, a "screen" could be invented which reduced magnetic "attraction," we could separate the keeper with reduced work, and so the keeper could return again under the action of the ether, and we should have a second example of a *machine* for deriving motion from a source in a normal way. The same applies to electric "attractions." Surely it is important to recognise the theory of this.

It may be observed, too, that the ether gets at any rate all the energy back ultimately (although doubtless it does not want it, as its own store of energy is inexhaustible). For suppose we could invent a "screen" for nullifying or reducing the work expended in separating electric and magnetic bodies, and so derive energy continuously from the ether for industrial purposes, we should not cheat the ether of this energy. For, obviously, we cannot accelerate matter infinitely; if not, then, *whatever form the work takes*, the energy must return to the ether ultimately. Take the case of the locomotive, for instance. Suppose we drive it by coal; the same coal being employed as a normal machine (*i.e.*,

* I pointed out this (to be a consequence of rejecting "action at a distance") in the "Physics of the Ether," pp. 94—97. But now from the recent discoveries, this theoretic view is strongly confirmed by experimental means.

† Was any possibility of diminishing the force of molecular attraction contemplated in forming the second law of thermo-dynamics; and would the above hypothetical case be opposed to this law (which, however, it should be remembered, is not rigid, but self-violated on molecular scale in gases). Possibly we have not yet cooled down far enough to judge decisively what effect this has on the molecular forces.

‡ Under the old (statical) idea that the energy is "stored up," there seemed to be a theoretic necessity for expending energy; as it was argued the weight could not fall or the keeper return without. But in modern science we are concerned with dynamics, not with statics.

Digitized by Google

over and over again). Then, supposing this, for the sake of argument, to be possible; yet the ether which does the work gets all the energy back. For we know, as a fact, that all the energy expended on the locomotive and train, passes continuously to the ether, in the form of waves of heat. The products of combustion in cooling down (by radiation) give their energy—*back*, we may say, on our view—to the ether. The disturbed air in cooling down does the same, also the warmed axle-boxes, rails, &c. Not a particle of energy can be abstracted permanently from the ether; it must return to it. Why, then, it may be asked, waste energy, by giving energy (superfluously) to the ether which it does not want, when we separate (electrically charged?) molecules, electrically charged masses, and magnetic bodies? We have only to discover "screens," if they exist, or some other dodge or device, for avoiding performing work that serves no useful or rational object at all; and we then shall be able to utilise the ether as a source of motion in a way that is practical, and appears only normal and natural. Such is the problem, I venture to think, we should have clearly before us (and realise clearly the theoretical principles involved); since, if this problem be soluble, it can only be solved under that condition.

It may give additional confidence to note that in a Paper "On the Ultramundane Corpuscules of Le Sage" (relating to gravity), *Phil. Mag.* May, 1873, Sir William Thomson makes the remark incidentally, that if a crystal were permeable by the gravitation particles more easily in the direction of one axis than in the direction of another (as the crystal is in regard to light), then such a crystal would be slightly heavier according to which axis is vertical. So that we could derive work from the ether by employing such a crystal as a permanent machine (in the way I have elucidated); we could let the crystal fall when in a position of *maximum* weight and lift it up again when in a position of *minimum* weight. This would be deriving work from the ether by a machine, which (unlike coal), is not used *once* only, can be retained in permanent employ like a normal machine. So that Thomson admits that the principle *is not opposed to theory*, as we see. I may mention, as a fact, that I saw this Paper of Thomson's on Le Sage's theory of gravity, in 1877, when working on gravity at that time, my first Paper on that subject having been published in September, 1877. I had evolved the principle, however (from a somewhat different and more general point of view from that of Thomson), independently, as I need scarcely mention, in the "Physics of the Ether," pp. 94-97.

It may be remarked, perhaps, that I tried some experiments with very large tuning-forks in the late Prof. Guthrie's laboratory some seven years ago, and found it possible with a fork weighing, perhaps, some four to six pounds, to suspend floating in the air below the vibrating prong, pieces of carboard some 4in. long, ¾in. wide, and about $\frac{1}{16}$in. thick. Now, although I did not actually make the following experiment, there is no doubt that by suspending a strip of cardboard vertically by two threads, it could be deflected from the perpendicular by a vibrating fork placed at some distance. It would be easy then to introduce a "screen," such as a thin plate of metal between the cardboard and the fork, when the threads would resume their vertical position, owing to the "attraction" being neutralised by the screen. On taking away the screen, the cardboard will be attracted a second time, and the procedure may be repeated as often as wished.* So that this seems to be an illustration (experimental) of the possibility of deriving work through vibrating matter, with the co-operation of the medium in which this vibrating matter is immersed, and by means of a machine (here the fork) which is constantly used, and not only *once* used and then thrown away, like coal. This case would seem, therefore, to have considerable theoretic interest in regard to the problem of deriving work from the ether.†

* If the tuning fork be kept in vibration by an electromagnet, this would be comparable to a molecule kept in vibration by the sun (as we know it is).

† Of course, it is not of the slightest consequence how feeble the "attraction" of the fork for the cardboard is (if the effect be only visible), since we are not concerned with quantitative effects here, but with a principle. In the *Phil. Mag.* for November, 1870, and June, 1871, it is stated that attractive actions with forks were visible at the distance of a metre.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Continued from page 725.*)

§ 69. To return to condensers. Imagine a simple conducting circuit of no resistance (Fig. 22). Suppose that at some time or other a current C was started in it. Some work was done in starting C—work stored in the surrounding medium as magnetic induction—but once having arrived at a steady value no more work is required and C will remain constant for ever. The total induction threading the circuit under these conditions may be called B. Now, what will happen if we suddenly put the condenser S into the circuit? Will the current stop instantly? Evidently not, for the moment that it began to do so, B would diminish, and so set up an electromotive force equal to $\frac{dB}{dt}$, driving the current on. If it does *not* stop it will begin charging the condenser, and creating a potential difference between its terminals in a direction tending to stop itself. It will therefore decrease, and while decreasing there will be the corresponding decrease in B, acting as a forward electromotive force against the back electromotive force due to the charging of the condenser. But the current does not want either a forward or a back E.M.F.; there being no resistance it needs exactly no E.M.F. Clearly then, the current will diminish just sufficiently fast to allow $\frac{dB}{dt}$ to be exactly equal at every instant but opposite in direction to the growing potential difference V at the condenser terminals. Now V is equal to

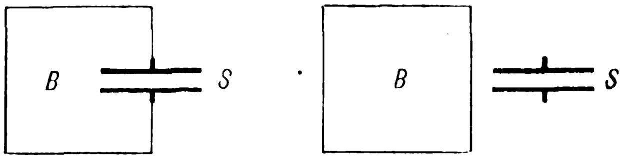

FIG. 22. -Electric Circuit of no Resistance, and Condenser.

the ratio of the quantity of electricity stored in the condenser to its capacity, K, or

$$V_t = -\frac{q_t}{K};$$

the minus sign is used because the charge would reverse the current if it could, and the current is considered to be positive. The E.M.F. due to the decreasing induction is $\frac{dB}{dt}$, and if we assume, for simplicity, that the magnetic medium is air or other non-magnetic substance, we know that B is directly proportional to C, so that we may write

$$B = LC,$$

where L is the induction due to unit current multiplied by the number of times it threads the circuit. L is usually called the coefficient of self-induction; it does not matter what it is called so long as it is clearly understood what it is. In the present case the induction is only linked once, there being only one turn of wire, so that L is simply the induction due to unit current.

§ 70. Now, $$\frac{dB}{dt} = L\frac{dC}{dt},$$

and this must at every instant exactly balance V;

therefore $$L\frac{dC}{dt} + V = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

or $$L\frac{dC}{dt} = -\frac{q}{K}.$$

If this is differentiated with respect to $t$, we have

$$L\frac{d^2C}{dt^2} = -\frac{1}{K}\frac{dq}{dt} = -\frac{1}{K}C.$$

Digitized by Google

Each side may now be made a perfect differential by multiplying by $2\frac{dC}{dt}$; thus we have

$$2\frac{dC}{dt}\frac{d^2C}{dt^2} = -\frac{1}{LK}2\,C\frac{dC}{dt}.$$

Both sides being integrated, we arrive at

$$\left(\frac{dC}{dt}\right)^2 = -\frac{1}{LK}C^2 + A \quad . \quad . \quad . \quad . \quad . \quad (2)$$

A being the necessary constant of integration, the variables $c$ and $t$ can now be separated, preparatory to the final integration, thus:—

$$\frac{dC}{dt} = \frac{1}{\sqrt{LK}}\sqrt{ALK - C^2};$$

or

$$\frac{dC}{\sqrt{ALK - C^2}} = \frac{1}{\sqrt{LK}}dt.$$

The integral of the left-hand side is $\sin^{-1}\frac{C}{\sqrt{ALK}}$, so that

$$\sin^{-1}\frac{C}{\sqrt{ALK}} = \frac{t}{\sqrt{LK}} + \theta$$

and

$$C_t = \sqrt{ALK}\sin\left(\frac{t}{\sqrt{LK}} + \theta\right) \quad . \quad . \quad . \quad . \quad (3)$$

§ 71. This may be simplified, for we reckon time from the instant when $q = o$, that is to say, from the instant when the condenser was put into the circuit, and the current was then at its maximum, namely C′. But the above sine function is at its maximum when $\frac{t}{\sqrt{LK}} + \theta = 90°$, so that $\theta = 90°$ since $t = o$, and

$$C_o = C' = \sqrt{ALK}\sin\theta = \sqrt{ALK},$$

also $\sin\left(\frac{t}{\sqrt{LK}} + \theta\right)$ is equal to $\cos\frac{t}{\sqrt{LK}}$, so that (3) is reduced to

$$C_t = C'\cos\frac{t}{\sqrt{LK}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

The current then varies according to a simple periodic law. When $t = 0$ the current is at its maximum, and when $\frac{t}{\sqrt{LK}} = \frac{\pi}{2}$ the current is zero, so that the value of $t$ given by the equation

$$t = \frac{\pi}{2}\sqrt{LK},$$

corresponds with one-fourth of the complete period T, consequently

$$T = 2\pi\sqrt{LK},$$

or

$$F = \frac{1}{2\pi\sqrt{LK}}.$$

§ 72. The proof just given that the current becomes oscillatory when the condenser is inserted in the circuit has a somewhat fraudulent air of wisdom about it. It is either unreal or clumsy, according as it is seen from the point of view of the practical man or the mathematician. The latter may be referred to Sir W. Thomson's original Paper on the subject, or to Dr. Fleming's exhaustive discussion of condenser discharge ("Alternate Current Transformer," Vol. I., page 368). To the practical man we may be permitted to remark that the so-called solution of such a differential equation as (1) is in its very nature only guess-work, and the result is consequently no proof in the strict sense of the term. All we have really done is to find a function to express the relation between current and time, such that its rate of change at any instant is directly proportional to its integral from 0 up to that instant. For the electromotive force due to changing induction is proportional to the rate of change of current, and the potential difference at the condenser terminals is proportional to the quantity in it at any instant, that is to the integral of the current. Now in hunting for some function which fulfils this condition we soon discover the Cosine; its differential coefficient is a sine, its integral is a sine therefore if the current varies according to the Cosine of the time $\frac{dB}{dt}$ will vary directly as V, and consequently by using proper constants, we can make the induction E.M.F. always equal to V. The proof then, merely points to the Cosine as *a* function which fulfils the conditions, but it does not tell us that it is the only one. However having found a suitable function, the application of a little common-sense soon convinces us that it is the only possible one. The diagram given in Fig. 23 will serve as an aid to thought in arriving at orthodox convictions. The current C is shown as constant up to the time 0, when the condenser is put into the circuit. The current immediately falls off, and after a time $\frac{1}{4}$ T, reaches zero. At first sight it might seem the more rational course for the current to remain zero; but imagine it to do so and it is at once recognised that $\frac{dB}{dt}$ would immediately fall to zero also, leaving V to drive an *infinite* current back through the circuit, there being no resistance.

§ 73. Having thus started an alternating current in a condenser circuit, will it ever stop? Only a short time ago one would have said no, with a light heart. We are now, however, compelled to admit that the current waves do really produce radiation waves in the ether, or rather the two things are part and parcel of the same phenomenon. At all events light waves—very long ones—emanate from the circuit as a centre, and a little energy goes flying off into the uttermost parts of the universe, doing some good there let us hope, but, so far as our circuit and condenser are concerned, the available store of energy put into the circuit when we started the current C is gradually frittered away, and becomes lost to us. Consequently the alternate current would slowly die away, even if the resistance of the circuit were really zero as we have assumed.

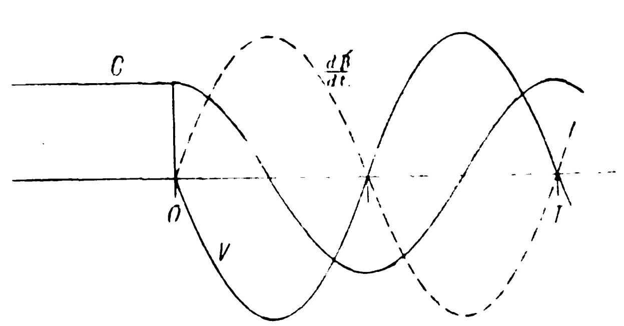

FIG. 23.—Diagram of Electromotive Forces and Current in the circuit shown in Fig. 22. C is the steady current. The condenser is put in the circuit at the epoch O. The full line V is the potential difference at the condenser terminals. The dotted line $\frac{dB}{dt}$ is the counter E.M.F. due to the changing induction in the circuit.

§ 74. Fig. 23 shows that the oscillatory current in a condenser circuit is necessarily an idle current, and therefore exactly what is wanted to supply the idle part of the exciting current of an open transformer. But real circuits have a tangible resistance, and this leads to a rapid diminution of the amplitude of the current waves, unless we can devise a method by which the energy thus lost by the circuit may be continuously replaced by a fresh supply. Suppose the circuit in Fig. 22 has a finite resistance R, then we might imagine a magnet to be spun round anywhere in the circuit so that its induction threaded it alternately in reverse directions. If the magnet is rotated so that the impressed E.M.F due to it has the same frequency as the current, and if we further arrange that its E.M.F. is cophasal with the current and at every instant exactly equal to C R (plus something very small for the power supplied to the universe as extra-double-infra-red-light), the state of things shown in Fig. 23 becomes possible and stable, although it is not exactly what is wanted and does not represent what Mr.

Digitized by Google

Swinburne is trying to achieve. Given a circuit and condenser like that in Fig. 22, can the necessary power be supplied in any other way? Yes. The condenser may be shunted by a branch circuit G. (Fig. 24).

§ 75. The current will want to divide itself between P and G, and as it is all required to traverse P which represents a transformer primary, we will have an alternator A in the G circuit running at the same frequency as the alternating condenser current in P, and impressing an E.M.F. cophasal with V and $\frac{dB}{dt}$, and of the same magnitude and shape. This will prevent any current flowing through A, so that the condenser current will alternate through P exactly as though the G circuit were absent. Now let us put another alternator *a* into the G circuit, running at the same frequency but a quarter period ahead of A, so as to have its E.M.F. cophasal with the alternating condenser current. The E.M.F. of the little alternator, being adjusted to the right value, will supply the $C^2R$ loss in the transformer primary circuit P in precisely the same way as the spinning magnet was supposed to do. Of course in practice the alternator A not only supplies the E required to keep the current out of G, but by being run slightly out of step with the phase of V and $\frac{dB}{dt}$, it can be made to have a component E a quarter period ahead, and of the right value to provide for $C^2R$ lost in P. All this sounds very alarming but in reality there are no adjustments. The condenser settles everything without human aid, for when connected across the mains it immediately monopolises just so much of the idle

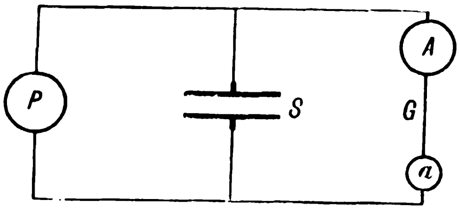

FIG. 24.

current in P as will make its potential difference equal at every instant to that on the mains, and it is a simple matter to calculate what capacity the condenser ought to have to deal with the whole of the idle current in P and no more. Of course the switching on of the condenser tends to lighten the load on the alternator by the equivalent of the waste of power as $C^2R$ in its armature coils due to the idle current. We say tends to lighten—it is by no means certain that condensers can be made to absorb no power, and the $C^2R$ loss saved in the armature may possibly be balanced by a different kind of $C^2R$ loss in the dielectric of the condenser.

§ 76. The condenser capacity required to supply an idle current of given value is readily found from the following considerations. Assume the idle current C is really sinoidal, so that

$$C = C' \cos \frac{2\pi}{T} t.$$

Suppose the system is working at an effective pressure E on the transformer primaries, then at the instant at which $C = 0$, that is when $t = \frac{T}{4}$, the potential difference between the mains is a maximum, and approximately equal to $\sqrt{2}$ E. The quantity of electricity available for the condenser during the quarter period is

$$Q' = \int_0^{\frac{T}{4}} C\,dt,$$

and the capacity of the condenser must be such that this quantity Q′ raises V to exactly $\sqrt{2}$ E; but

$$Q' = \int_0^{\frac{T}{4}} C\,dt = \int_0^{\frac{T}{4}} C' \cos \frac{2\pi}{T} t\,dt = C' \frac{T}{2\pi};$$

and therefore since $V' = \frac{Q'}{K}$,

$$V' = \frac{C'T}{2\pi K} = \sqrt{2}\,E;$$

or remembering that $C' = \sqrt{2}\,C$,

$$K = \frac{CT}{2\pi E}; \quad \text{or } K = \frac{C}{2\pi E F},$$

an equation which gives the capacity K in farads when E and C are effective volts and amperes, and T is the periodic time in seconds, or F the frequency. But how if the idle current is not sinoidal? We have seen that in order to keep it out of the alternator it must follow a sine law, otherwise V cannot be made equal to E at each instant, and if these two variables are not always equal and opposite, some current will succeed in passing beyond the condenser terminals and traverse the armature of the alternator. If the current is not a simple sine function of the time the condenser cannot possibly be made to take the whole of it; it will only absorb what may be called the sine component of the current, leaving all irregularities in the current-wave—*ripples* as they are poetically called—to be supplied by the alternator. But for all practical purposes the formula just given is perfectly reliable, as only a comparatively rough guide is wanted to enable a condenser of suitable proportions to be made up, leaving the final adjustment until it is in actual use, when its capacity is readily varied until an ammeter in the main between the alternator and condenser indicates that the former is supplying the minimum current.

§ 77. A transformer circuit with a condenser across the mains presents the curious paradox of a complete metallic circuit in which the current is very much greater in one part than in the remainder. Perhaps it was this paradoxical behaviour (first described by Mr. Blakesley) which directed Mr. Swinburne's attention to condensers. One is so accustomed to consider it an axiom that the total current flow at any instant is the same at every part of a complete conducting circuit, that the condition tacitly implied in the axiom, namely that the circuit has no electrostatic capacity, is forgotten. To the eye of Maxwell and perhaps also of Faraday, the condenser itself was just as much a part of the circuit as the wires themselves, and from this point of view there is nothing anomalous in a condenser circuit. Counting the condenser as a part of the circuit the algebraic sum of the currents in the three branches P, S, and G (Fig. 24) is at every instant exactly zero.

*(To be concluded.)*

## THE ELECTRIC LIGHTING OF ST. BRIEUC.

BY GASTON ROUX.

Saturday next, the inauguration of the electric light at St. Brieuc will take place. The installation is unimportant from the point of view of mere size, but it is worthy of notice as being the first one on the Thomson-Houston system which has been erected in France. It possesses, moreover, one or two peculiar features, the power being generated eight miles from the lamps to be lighted, and the alternators employed being regularly worked in parallel with compounded excitation. Having spent several days at St. Brieuc, in carrying out some experiments with alternating currents, I was able to study every detail of the installation, a brief account of which may not be without interest.

The generating station is situated at Ponts-Neufs, and the motive power is furnished by two Hercules turbines, fitted with automatic governors and running at 250 revolutions, made by Singrün, of Epinal, one being of 125 H.P., and the other of 75 H.P. They can run separately or simultaneously the same shaft on which are two active and two idle pulleys. They are fed by a 36ft. fall from a reservoir of about 33,000,000 gallons capacity, into which three small streams run.

The dynamos are two 70-unit Thomson-Houston composite-field alternators, giving from 2,100 to 2,600 volts at 1,070 revolutions. The difference of potential at the dynamo terminals varies within wide limits, since the fall of pressure on the line at full load is 20 per 100. The main excitation is furnished by

Digitized by Google

small continuous current machines as usual, but the additional excitation required to compensate for the fall on the line is supplied by a rectified current taken from the alternator itself. The manner in which this is carried out is shown by the accompanying diagrams (Fig. 1). The armature is wound in two halves, $A_1$, $A_2$. One end of each half winding-terminates at the collector ring, $C_1$ and $C_2$ respectively, and the other ends are connected, as shown, to opposite sides of the rectifying commutator, R, to the two brushes of which are joined in parallel the compensating field-magnet circuit and the adjustable resistance. This commutator R is arranged at the end of the watched, and at the moment when they burn brightly the new machine is switched into circuit. Owing to the great impedance of the reactive coil the new machine gives but little current at first. The copper is, however, now slowly swung over until it completely covers the coil, when the reactive apparatus is switched out of circuit.

At the preliminary trials at Ponts-Neufs the total load was only half the maximum output of a single alternator, yet running in parallel was easily carried out. A wattmeter was introduced into the circuit of the loaded alternator, and it was easy to see that the load was divided the moment the second machine was

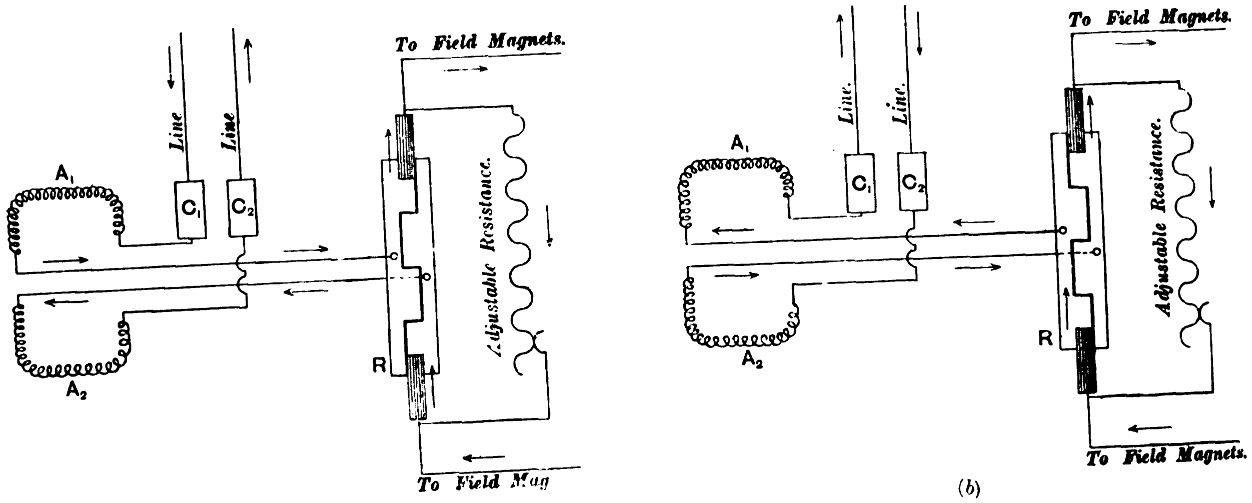

Fig. 1.—Diagram of the Connections of the Thomson-Houston Composite-Field Alternator.

dynamo spindle, and has as many divisions as the alternator has poles, with the result (*see* Fig. 1, *a* and *b*) that the current in the field-magnet circuit is kept uni-directional, and increases as the total current flowing in the armature increases, so that the increased loss on the line is compensated for by increased excitation. The low resistance of the adjustable shunt entirely prevents sparking at the brushes. Great care has been taken to insulate the alternators from earth. They are mounted on blocks of paraffined wood resting on a thick sheet of indiarubber, which in turn rests on more blocks of paraffined wood, the holding-down bolts being cased in indiarubber tubes. The two machines are arranged to run in parallel as soon as one is

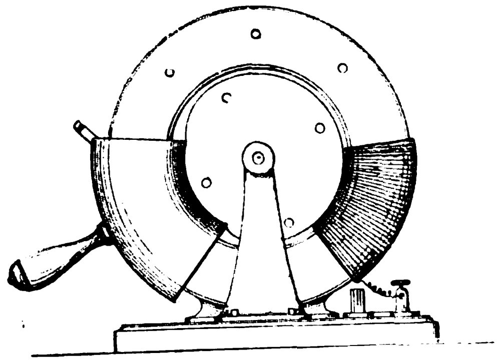

Fig. 2.—Reactive Coil or Dimmer.

working at maximum load. As the switching over has to be carried out without fluctuation of the lights, a reactive coil (Fig. 2)* is first of all brought into circuit with the new machine and its inductance slowly diminished until the new machine is giving the required current.

The exact *modus operandi* is as follows:—The additional machine is first of all speeded up and excited, and the reactive coil thrown into circuit, the copper sheath being well away from the primary coil. Two pilot phase lamps, which are connected in series to the secondaries of a double transformer, the primaries of which are in series with the two machines, are then

* For description see *The Electrician*, January 2, 1891, p. 256.

switched in. At each passage of the seam of the belt over the pulleys, however, there was a small transfer of energy.

The switchboard, it should be mentioned, is provided with the ingenious Thomson-Houston lightning arresters* and earth detectors. A sketch of the earth detector is given in Fig. 3, by which it can be seen that if the switch L is connected to the + main, the existence of an earth on the − main will be shown by the lamp lighting up, provided the fault is of fairly low resistance.

The wires are run overhead, 18in. apart, on double-bell porcelain insulators, supported on wooden posts 20ft. high.

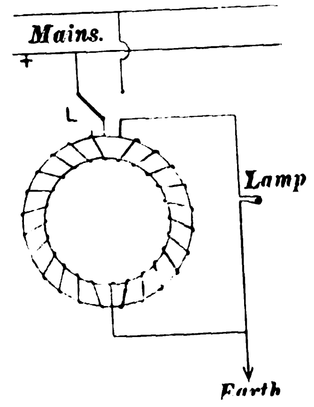

Fig. 3.—Thomson-Houston Earth Detector.

The conductor is of stranded Mouchel copper. It has a cross-section of ·075 sq. in., and is lightly insulated. The resistance of the line is 8·9 ohms. Near the town the line runs under the railway, and here Berthoud-Borel concentric cables are used.

The fuses which are fitted on the primary circuits of the transformers are of a somewhat peculiar kind. Unlike Mr. Ferranti's, these fuses are very short, being only 1¼in. long; and as they are bent into the arc of a circle the distance between terminal and terminal is barely ¾in. The lead strips are, however, enclosed in a loose indiarubber tubing. Several tests were made to see if a permanent arc would not form

* See *The Electrician*, January 9, 1891.

Digitized by Google

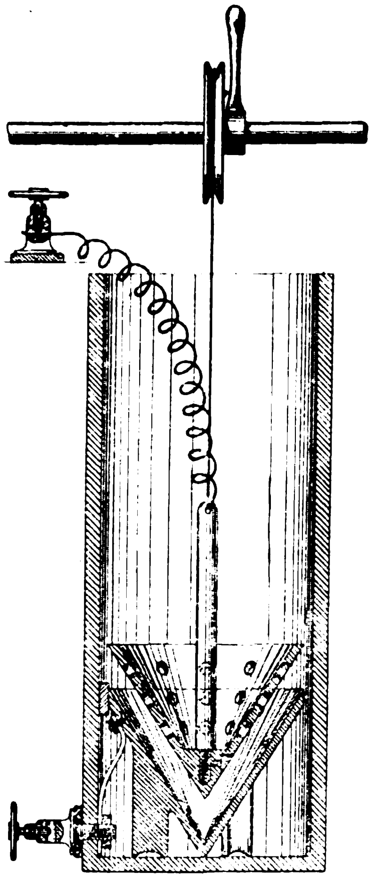
across this short break whenever a fuse melted. So long as the indiarubber tube was retained, nothing happened on melting the fuse, but an arc invariably formed (even with a much longer break) when the experiment was tried without the protective tube.

The charge is by meter, or on a three years' agreement, the lamps being replaced by the Company. The price of a Board of Trade unit is 7d.

## LYON'S LIQUID RESISTANCE.

The stage lighting of the Lyric Theatre is controlled by resistances invented and patented by Mr. H. Lyon, and, after being used at every performance for nearly six months, they have proved to be very well adapted for the purpose.

Provision is made for the control of 21 separate circuits, and for each of these a resistance is provided. The apparatus consists of a stoneware jar or cylinder two feet deep by nine inches



diameter. An inverted cone of lead, having three feet cast on it, stands on the bottom of the jar, and is connected to one of the conductors by a bolt passing through a hole near the bottom, a water-tight joint being made of india-rubber washers. This cone is fixed in place by wooden wedges. A second cone is attached by a flexible conductor to a terminal fixed near the top of the jar, and is suspended by a cord, so that it can be raised or lowered by means of a pulley. The jar contains a suitable electrolytic solution of metallic salts, and the movable cone is provided with holes to allow it to move more readily through the liquid. The cones are turned in a lathe so that they may make a good fit when in contact. The column of liquid for 50 amperes is about 10in. deep. It is found that when the cones are in contact, the resistance is quite negligible, there being only a very small fraction of a volt fall when 30 amperes are passing. On slowly moving the handle attached to the pulley, the cone rises and resistance is gradually introduced, the motion being perfectly smooth. It is, indeed, impossible to jerk it owing to the dash-pot action of the cone in the liquid.

Resistances of this kind are particularly suitable for stage effects since the illumination may be changed insensibly, and coloured lamps may be very gradually substituted for white, by allowing one resistance to increase and another to decrease simultaneously. Not only is the resistance introduced by the separation of the cones, but when the movable one begins to emerge from the liquid, the area of contact diminishes until, just before breaking contact, the current is reduced so much that there is no visible spark. The effervescence is very trifling, and, owing to the depth of the jar, no spray whatever is given off. The temperature of the liquid under ordinary daily work does not appreciably vary. The resistances at the Lyric Theatre are arranged in two sets, each separate circuit being provided with an independent lever, but each half can be worked simultaneously by a worm gear.

It is evident that a resistance which is capable of such smooth working affords great facility for accuracy of adjustment to any desired value, and cannot inflict the serious shocks on dynamos supplying the current, which nearly always happen when ordinary switches are used. Mr. Lyon, therefore, has designed special forms of his resistance for use in electroplating and electrotyping, and in connection with an important plant for transmission of power.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, April 24th** (To-Night).

Institution of Civil Engineers.

*7.30 p.m.* Students' Meeting. Papers to be read: (1) "A New Type of Water-Motor." By A. Sealy-Allin, Stud. Inst. C.E. (2) "Hydraulic Power as applied to Pressing-Machinery." By H. Evington, Stud. Inst. C.E.

Old Students' Association.

*7.30 p.m.* Smoking Concert at Mason's Hall Tavern.

Royal Institution.

*9 p.m.* Evening Discourse. "Euphuism—Past and Present." By Rev. Canon Ainger, LL.D.

**SATURDAY, April 25th.**

Royal Institution.

*3 p.m.* Afternoon Lecture. "The Dynamo." By Prof. Silvanus P. Thompson, D.Sc.

**TUESDAY, April 28th.**

Institution of Civil Engineers.

*8 p.m.* Ordinary Meeting. Paper to be further discussed: "The Cost of the Generation and Distribution of Electrical Energy." By R. E. B. Crompton, M. Inst. C.E.

**WEDNESDAY, April 29th.**

Society of Arts.

*8 p.m.* Ordinary Meeting. "The Use of Petroleum in Prime Motors." By Prof. William Robinson.

**THURSDAY, April 30th.**

Royal Institution.

*3 p.m.* Afternoon Lecture: "Recent Spectroscopic Investigations." By Prof. Dewar, F.R.S.

Institution of Mechanical Engineers.

*7.30 p.m.* Ordinary General Meeting. Papers to be read and discussed, as far as time permits: "Research Committee on Marine-Engine Trials: Report upon Trial of the steamer 'Iona.'" By Prof. Alexander B. W. Kennedy, F.R.S. "On some details in the Construction of modern Lacashire Boilers." By Samuel Boswell.

**FRIDAY, May 1st.**

Royal Institution.

*5 p.m.* Annual Meeting.
*9 p.m.* Evening Discourse. "Hawks and Hawking." By J. E. Harting, F.L.S.

Institution of Mechanical Engineers.

*7.30 p.m.* Ordinary General Meeting.

**SATURDAY, May 2nd.**

Royal Institution.

*3 p.m.* Afternoon Lecture. "The Dynamo." By Prof. Silvanus P. Thompson, D.Sc.

*** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

# The Electrician.

**Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny**
**Editorial, Publishing, and Printing Offices:**
**SALISBURY COURT, FLEET ST., LONDON, E.C.**
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher,* "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "*Coutts and Co*" *All other letters to be addressed to the Editor.*
*All letters intended for insertion in* "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*
"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*
*New Volumes of* "THE ELECTRICIAN" *commence in May and November.*

## SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**
*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*
TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*
SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued* "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*
*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## STEEL-PLATE PORTRAITS

*Of W. H. Preece, F.R.S.; Michael Faraday; Sir John Pender, K.C.M.G.; Sir William Thomson, F.R.S. (Past-President of the Institution of Electrical Engineers); C. H. B. Patey, C.B. (Late Secretary of Telegraphs, G.P.O.); Dr. John Hopkinson, F.R.S. (Past-President of the Institution of Electrical Engineers); Dr. Oliver J. Lodge, F.R.S., and Prof. William Crookes, F.R.S. (President of the Institution of Electrical Engineers), have been issued as Supplements to* "THE ELECTRICIAN." *A few Copies of these admirably-executed Steel Engravings can be supplied, price 1s. each, post free on roller, 1s. 2d. Or framed in neat Black Pillar or Brown Ornamental Frames, price, post free, 4s. 6d.*

## ECONOMY IN THE USE OF GLOW LAMPS.

An advance proof of an article on the highest economy in the use of glow lamps has been forwarded to us by Mr. H. WARD LEONARD, of the Edison General Electric Company of New York. Unfortunately, the conclusions which he draws, and the data by which they are arrived at differ so widely from the practice of this country, that in its present form the article would be of little interest to our readers. The subject, however, is one that concerns every user of electric light, and every supply company, though it affects them in different ways. In the United States the lamp renewals are often undertaken by the supply companies, and it is not unusual, we believe, for contracts to be made for the supply of so much candle power. Nothing of the kind is to be found with us, nor will be until street lighting is undertaken by supply companies. There is little indication of any extension in this direction at present, since it is well known that street lighting is generally done at a contract price which does not pay the gas companies. While there are a few examples of street lighting by glow lamps as at Weybridge and Fareham, it is probable that in the larger towns this will only be undertaken when the local authorities themselves supply the current. The interests will then be identical, as

Digitized by Google

both coal bill and lamp renewals will be paid for from the same purse.

At present, the consumer naturally tries to keep down his meter readings, and at the same time, his lamp bill; all he wants is light, and for the minimum cost. The supply company, on the other hand, wants to induce the customer to take as much electrical energy as possible. The efficiency of lamps affects the company in two ways, while the cost of lamp renewals does not concern them in the slightest degree. If wasteful lamps at five watts per candle are fashionable, the meters will run round, and the earnings will be increased, but as Mr. F. Bailey pointed out at the Society of Arts in December last, "an improved lamp efficiency will benefit the supply companies by enabling them to increase their lamp connection." Given a house wired for a number of lamps, the majority being eight candle-power nominal, and the pressure being fairly constant at 100 volts; given also the price of a lamp at 3s. 9d., and the cost of electrical energy at 7d. per unit, what is the best efficiency at which to run the lamps, or with the ordinary Edison-Swan make, what nominal voltage should be chosen? The lamp makers reply that their lamps should be run at four watts per candle—that is to say, 100 volt lamps are to be used, and the consumer gets about 36 candle-power hours for one penny. If he uses 95 volt lamps, they will give about 20 per cent. more light, and will consume about 4½ per cent. more current, giving at about 3½ watts per candle some 41 candle-power hours for a penny. But the life will be shortened. On the other hand, if he uses 105 volt lamps, there will be more than 20 per cent. decrease in the light, which will be of a dull quality; he will save about 3 per cent. of current, the lamp will run at about 5 watts per candle, giving 29 candle-power-hours for one penny, but the cost of renewals will be very considerably decreased. From the consumer's point of view it should not be difficult to arrive at the best possible point at which the cost of current and of lamp renewals is a minimum. In a Paper before the Physical Society in 1885 this was shown, but the lamps were of foreign manufacture, and not comparable with those of the present day. Our information as to the life of glow lamps is very meagre, and it is not likely that any very important contribution will be made to our knowledge of the subject, until the present master patents expire. We shall then have a flood of promises, but shall be unable to judge of their accuracy until the new lamps have run their thousand hours or so. Even before the first batch have had their day, the makers will have probably gained such further experience that a second edition of their prospectuses may be nearer the mark as to the durability of their goods. At present, we have a general notion that lamps last from 1,000 to 2,000 hours, if run steadily at their marked voltage. It is customary to accept the recommendation of the manufacturer, and to use the lamps at the pressure marked upon them. Of course, everybody grumbles at a monopoly except those within the ring, but almost every English electrical engineer has reason to be thankful that the lamps to which we are restricted in this country are as good as they are, and it is generally felt that the extravagant price at which they are sold contributes in some measure towards the careful and scientific development of the very important work which is done at Ponder's End.

The life of the lamps could possibly be arrived at by instituting extensive observations in large concerns, but such statistics are always rendered uncertain owing to a want of perfect uniformity in the pressure. A given variation in the pressure undoubtedly produces a much greater variation in the life of a lamp. For this reason the mean voltage is not to be relied upon. A *short* spell of high pressure will tell on the duration of a filament, but a similar spell of low pressure will not materially prolong its life. If the pressure be 105 volts for four hours and 99 volts for the remaining twenty hours of the day, the mean will be one hundred, but the life of the lamps will be shorter than if the voltage had remained constant at this mean value. But there must be some well defined and probably some simple relation between the life of ordinary glow lamps and the pressure, this pressure being constant—we are only concerned at present with the single make of lamps commonly used in this country. This relation is perhaps buried in the bosoms of the directors, or, more likely, of the manager and scientific adviser of the Company, and it is jealously guarded, not, we are sure, because they are ashamed of it, but because any statement might "be used against them" as a guarantee. At present, then, it is not possible to decide in this country, as is done by Mr. Ward Leonard, at what strain it is desirable to run any given lamp. He arrives at 3·1 watts per candle with 600 hours' life, but bases his calculations on 1·7 cents per horse-power hour, and 44 cents as the cost of a lamp. The lamps to which he refers have a life of 300 hours at 2·77 watts, 900 hours at 3·6, and 1,500 at 4 watts. He finds that these last conditions are the most economical when fuel costs nothing, and ·1007 cent per hour is charged for labour, insurance, taxes, &c.

Accepting as we do the nominal volts of a lamp, we assent to the recommendation of the lamp makers, that four watts per candle is a desirable strain to apply to the filament. Having already disclaimed any hostile disposition towards them, we venture to raise the question as to whether they are altogether the proper authorities from which such a recommendation should come. That it is generally accepted is an unmistakable proof of the confidence which is felt both in their honesty and in their intimate scientific knowledge of the physics of the glow-lamp, for it is to their immediate interest to advocate a short life and a merry one. Has, then, the "co-efficient of involuntary mendacity" anything to do with this four watts per candle as far as the consumer is concerned? and does the life of the filament at four watts per candle give best possible economy when the electrical energy costs 7d. per unit? We have not any intention of attempting to pry into trade secrets, but there are several matters of great interest to the electric lighting industry which might be revealed in the form of percentages or factors without disclosing any actual statistics. Mr. Bailey, for example, in the paper to which we have already alluded, gave some information as to the candle power of lamps mostly used. He gave statistics comprising several thousand lamps. The makers could easily give the relative numbers without alluding in any way to the actual numbers. They might also recommend that lamps should be run at, say, their nominal voltage when energy costs 7d. per unit, and may with economy be overrun to a certain amount when 9d. is charged. From such a recommendation the life of the lamps might perhaps be calculated by some inquisitive person, but the result would have to be arrived at by so roundabout a method that there would not be much danger to the makers of any confrontation with the figure as constituting a guarantee. Of course there is another argument in support of their reticence, and that is, that they do not want to teach their trade to those who will soon begin to compete with them.

The matter is one which concerns large users of electric light, but which hardly touches the supply companies, cutting as it does in two directions as far as they are concerned. In America they have a great advantage, and the Paper by Mr. Ward Leonard, coming as it does with such authority, places at the disposal of consumers of electric light in that country some very valuable information.

## REVIEWS.

**Wiring Slide Rule.** (Crompton and Co., Limited.)

Most engineers are so familiar with the slide rule which is usually placed in the ordinary two-foot rule, that the contempt they frequently show by not using it is remarkable; it is, in fact, more generally employed for taking dimensions of small holes than for arithmetical work. Slide rules have also been designed for calculating the strength of girders and for similar work; but no slide rule has hitherto been introduced which shows greater promise of utility than the Wiring Slide Rule invented by Mr. A. P. Trotter, and now being issued by Messrs. Crompton and Co. (Limited). Electrical Engineers can now obtain all the information they require for wiring purposes from a small card provided with two slides. The range covered by the card includes any number of lamps up to 100, from 5 c.p to 40 c.p., and taking from 20 watts to 150 watts supplied at any distance up to 500 yards with any given fall of potential from one to 25 volts.

Easy manipulation of the slides gives the size of cable required, the current density, the maximum current for cased conductors for a limiting rise of temperature of 35° Fahr., and other information. The sizes of cables are given in both S.W.G. and B.W.G., and for solid and stranded conductors; a most instructive line being devoted to the amperes per square inch for two volts fall. When so many price lists and catalogues issued by the manufacturers of covered conductors are disfigured by a column professing to give the "capacity (!) in amperes" or "working current," mostly calculated not only at 1,000 amperes per square inch, but even at 2,000 amperes per square inch, the advent of this wiring slide rule comes at an appropriate time, and cannot fail to be appreciated. Wiring contractors will find it invaluable, and as five minutes' practice will enable anyone in charge of wiring work to understand its use, it may reasonably be hoped that users of the electric light will never have to say, "We get a good light in the basement, but the lamps are very dull upstairs."

The slide rule is at present constructed on a card, which might well be glazed or varnished; and it is to be hoped that it will be produced as an ivory rule, with, say, bevelled edges, one marked off in inches and the other in millimetres.

F. B.

## THE EFFECT OF A CONDENSER INTRODUCED INTO AN ALTERNATING-CURRENT CIRCUIT.

BY DR. OLIVER LODGE.

The history of the reaction of a condenser on alternating currents, which has recently excited some interest in connection with the Deptford mains, and has been called by the undesirable name of "the Ferranti effect," seems to be as follows:—

In March, 1868, Sir W. R. Grove described in the *Phil. Mag.* an observation he had made as to the increased power of a magneto-electric machine to excite an induction coil when a condenser was interposed in the circuit: not as a lateral expansion as usual, but directly in the circuit.

In May of the same year, Clerk Maxwell explained the effect entirely, expressing it both mathematically and popularly (*see Phil. Mag.*, 1868, or *Scientific Papers*, Vol. II., page 121).

Then Dr. Alexander Muirhead re-discovered the effect, and told Dr. Hopkinson of it; and the latter, in November, 1884 (*Journal*, Society of Telegraph Engineers, XIII., p. 513), explained it on the same lines as Clerk Maxwell. Then Mr. Ferranti re-observed it, this time on a commercial scale, and the matter has become well known.

The shortest statement of the theory is, perhaps, as follows:—

The equation to the current of a condenser connected to an alternating dynamo is

$$L\frac{dC}{dt}+RC+\frac{1}{S}\int C\,dt=E\sin pt$$

instead of $=0$ as usual.

The solution of this equation is, writing $\frac{pRS}{1-p^2LS}=\tan\epsilon$,

$$C=\frac{pSE\cos(pt-\epsilon)}{\sqrt{\{(1-p^2LS)^2+p^2R^2S^2\}}},$$

or, for the difference of potential between the terminals of the condenser,

$$V=\frac{E\sin(pt-\epsilon)}{\sqrt{\{(1-p^2LS)^2+p^2R^2S^2\}}}$$

Everything depends therefore on the value of this denominator; and, according as it is less or greater than unity, the amplitude of the reverberations of potential V is greater or less than the exciting amplitude E.

The maximum possible effect is obtained when the natural period of the condenser-circuit agrees with the period of the impressed E.M.F., and when resistance is small; *i.e*, when $p^2LS=1$; and in that case we have for the amplitude of V simply

$$\frac{V_0}{E}=\frac{1}{pRS}=\frac{\sqrt{(LS)}}{R}=\frac{\text{impedance of circuit}}{\text{resistance of circuit}},$$

a ratio always greater than unity, and sometimes much greater.

Clerk Maxwell's popular mode of putting the matter is something like this:—

Capacity acts as a spring,
Self-induction acts as inertia.

Now, if you want to wag a massive load to and fro you will find it much easier to wag if it be mounted on a spring, so as to have a natural period, than if it were perfectly free on rollers; especially if you are willing to accommodate your pushes and pulls to its natural period of vibration under the circumstances; and you can thus get up in it pretty big swings. The resilience of the spring exerts most of the force, and very small impulses accumulate. Resistance acts as treacle, and opposes the motion anyhow. If resistance formed the greater part of the obstruction, as it would if the body were light (*i.e.*, a circuit of small self-induction), then the special advantage of the spring (*i.e.*, the condenser) would not be felt.

One might put the Deptford case like this: Two massive pendulums are connected by a long rod. One of the pendulums is then swung to and fro regularly over a given arc by hand, in the direction of the length of the rod; the other must of course swing equally, if the rod is rigid. This represents two transformers connected by an aërial line without appreciable capacity, and one of them excited by an alternating dynamo.

But let the rod be elastic, and proceed to swing one pendulum as before. It is now possible to have a different extent of swing in the second pendulum: it may be less; but it may, by proper timing, be made considerably more. This represents two transformers connected by a cable with capacity.

Anyone can try attaching a spiral spring to a heavy pendulum bob, and getting up swing by means of it. An almost imperceptible motion of the hand at one end is sufficient.

In recently writing out the notes of my Leyden jar experiments on "overflow" and "recoil kick," briefly and hastily mentioned in my lectures on Lightning Conductors, I find they fall into the same category as these effects; and this it is which has directed my attention to the subject. Mr. Preece was good enough some months ago to send me particulars of the occurrences in the Deptford mains, under the impression that the phenomenon must be allied to what I had been interested in; but at that time I did not see the connection between what was observed there and my Leyden jar surgings. I saw, moreover, that the matter was in competent hands, and did not occupy myself with it. This article comes, therefore, rather late in the day.

**Physical Society.**—The meeting of the Physical Society of London advertised for May 8th will not be held, but a meeting will take place at Cambridge on May 9th. Members proposing to attend this meeting are requested to communicate with the Hon. Secs., Prof. J. Perry and Mr. T. H. Blakesley.

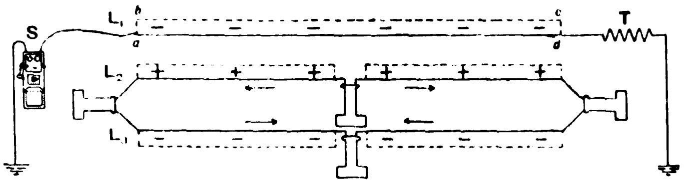
## NOTE ON THE RELATIVE DEGREE OF DISTURBANCE CAUSED BY ELECTROSTATIC AND ELECTRO-MAGNETIC INDUCTION BETWEEN TELEPHONE CIRCUITS.*

BY A. E. KENNELLY.

Referring to Fig. 2 of Mr. Carty's Paper† let $L_1$ be a primary line, $L_2$ and $L_3$ the lines of a secondary circuit. Suppose also, to simplify the conditions, that $L_3$ is so far remote from $L_1$ and $L_2$, by comparision with the half-inch of distance separating these latter, that all inductive influence on or from $L_3$ may be omitted from consideration. The most convenient way of dealing with $L_3$ is to replace it by the ground, and we have then only to consider the two circuits, $L_1$ and $L_2$, each as taken negligibly small for the case under discussion.



By considering, first, the amount of disturbance that would be statically set up in $L_1$, if electro-magnetic action did not exist, and, second, the magnetic disturbance on the hypothesis that no static induction took place, it is possible to form a comparative estimate of the relative proportions of these disturbances, when, as in practice, both influences act together. The result will not be accurate, because the influence of each not only combines with, but also to a certain extent modifies, the action of the other; but the discrepancy due to so elementary a treatment will not, in all probability, invalidate the results of a first approximation.

Let $k$ be the mutual electrostatic capacity of $L_1$ and $L_2$ per centimetre length of each, in absolute electro-magnetic units

Let $\mu$ be the mutual electro-magnetic capacity, or mutual inductance, of $L_1$ and $L_2$ per centimetre of each in absolute electro-magnetic units.

Let $l$ be the length of each of the wires in centimetres.

Let $e$ be the primary circuit electromotive force, which is periodic in value.

Let $n$ be the number of periods completed by $e$ per second.

Let $\omega_1$ be the impedance in the circuit of $L_1$ in absolute electro-magnetic units.

Let $\omega_2$ be the impedance in the circuit of $L_2$ in absolute electro-magnetic units.

Let $\gamma_e$ be the current in each of the two end telephones of the secondary circuit owing to electrostatic induction when electro-magnetic induction is supposed to be absent.

Let $\gamma_m$ be the current in each of three telephones in the secondary circuit (one at the centre of $L_2$ and the others at its ends), when electro-magnetic action is supposed to exist between the circuits to the exclusion of static induction.

Let $q$ be the total electrostatic charge induced on $L_2$ at any moment by static induction.

Let $r$ be the radius of each wire (copper) in centimetres.

Let the wires be parallel and the distance between their axes be $d$ centimetres in the horizontal plane elevated $h$ centimetres above the ground.

Then if the end of $L_1$ distant from the transmitter be disconnected from the ground and electrostatic influence only be supposed to act upon the secondary circuit, the potential of $L_1$ at any moment will be $e$, the value of the periodic electromotive force, while the induced charge upon $L_2$ will be expressed by

$$q = -e\,l\,k.$$

The flow of current from $L_2$ to ground will at any moment be the time rate of change in $q$, or numerically

$$\frac{dq}{dt} = l\,k\,\frac{de}{dt};$$

and since this by symmetry will divide equally between the two end telephones in $L_2$, the current in each is numerically

$$\gamma_e = \frac{l\,k}{2}\,\frac{de}{dt}.$$

Now, with electro-magnetic induction active, and static action suspended, the distant end of $L_1$ is connected to ground through a certain impedance. The current then existing in the primary circuit at any moment is

$$\frac{e}{\omega_1},$$

and in the secondary circuit $\frac{l\mu}{\omega_1}\frac{de}{dt}\cdot\frac{1}{\omega_2} = \gamma_m$ since this affects all three telephones alike.

Since $\gamma_e$ and $\gamma_m$ are periodic currents of the same frequency, they will produce equally loud sounds in the telephones when of equal numerical value, and the ratio of static to magnetic disturbance in the two cases will be

$$\frac{\gamma_e}{\gamma_m} = \frac{k}{\mu}\,\frac{\omega_1\,\omega_2}{2}$$

Provided, then, that the impedance of the primary circuit at the receiving end is always large, the ratio of static to magnetic disturbance will be approximately expressed by this equation. In order to apply it to the case of Fig. 2, we have to determine from the geometrical relations of the wires their mutual capacities $k$ and $\mu$.

The value of $k$ in absolute electrostatic units has been given by Mr. Oliver Heaviside in the *Journal of the Society of Telegraph Engineers* for April, 1881 (with a misprint in the formula here avoided) —

$$k = \frac{\frac{1}{2}\log_\epsilon \frac{\sqrt{d^2+4h^2}}{d}}{\left\{\log_\epsilon \frac{2h}{r}\right\}^2 - \left\{\log_\epsilon \frac{\sqrt{d^2+4h^2}}{d}\right\}^2}$$

Substituting for $d$ 1·25 centimetres or half an-inch.
,, for $h$ 1,000 centimetres or about 33ft.
,, for $r$ 0·1 centimetres or ·04 inch about representing No. 12 B. and S. gauge.

$k = 0·0794$ absolute electrostatic units $= 7·94 \times 10^{-23}$ absolute electro-magnetic units, or 0·0128 microfarads per mile.

The value for $\mu$ can also be found from another formula first published by Mr. Heaviside in the *Journal* of the above-mentioned Society for May, 1878, namely :—

$$\mu = \log_\epsilon \frac{d^2+4h^2}{d^2}$$

from which $\mu = 14·75$ absolute electro-magnetic units or 2·37 millihenrys per mile.

Thus for equality between $\gamma_e$ and $\gamma_m$ we must have with these values of $k$ and $\mu$.

$\omega_1\,\omega_2 = 3·717 \times 10^{23}$ absolute electro-magnetic units.

Three telephones of 75 $\omega$ and 90 $h$ each would to a frequency of $n = 435$ corresponding to the note $a_1$ offer an impedance of $7·72 \times 10^{11}$ or 772 ohms, the impedance of the three telephones to this frequency being more than three times their resistance.

For $\gamma_e \div \gamma_m = 1$, $\omega_1$ must now be $3·717 \times 10^{23} \div 7·72 \times 10^{11}$ or $4·816 \times 10^{11}$ or 481·6 in round numbers 500 ohms, while with the primary circuit of Fig. 2 having a transmitter of 165 $\omega$ and 730 $h$ with a call-bell at the distant end of 550 $\omega$ and 2·7 $h$, the total resistance would be 715 $\omega$, the total inductance 3·43 $h$, and the impedance to the same frequency of $n = 435$ would be $9·40 \times 10^{12} = 9400$ ohms or about 13 times greater than the total resistance. The impedance $\omega_1$ is thus nearly 20 times greater than that needed by the formula for equality between $\gamma_e$ and $\gamma_m$ and roughly the static disturbance in Fig. 2 may be estimated as 20 times greater than the magnetic.

## TANNING BY THE AID OF ELECTRICITY.*

The slow rate at which hide is converted into leather has induced many inventors to devise methods by which the chemical change might be accelerated, but the want of any definite knowledge as to the precise action between the gelatin and tannin has been a serious obstacle to the development of new processes. The authors described a number of methods for bringing the tanning liquor into intimate contact with the hides both by hydrostatic pressure and by mechanical agitation, the first one dating as far back as 1823. Various electrical processes for accelerating tanning were described, but little information could be given as to their success. The authors described the process of Worms and Balé and that of Groth, the latter being explained at considerable length, with full dimensions of the vats employed, of the electrodes within the vats and of the other details, mechanical, electrical and chemical. During the recent winter,

* Abstract of a Paper read by Dr. S. Rideal and Mr. A. P. Trotter before the Society of Chemical Industry on Monday, 20th April.

Digitized by Google

a very extensive series of experiments has been carried out at Bermondsey. The process (see *Electrician*, Jan 16 and 23, 1891) consists in stretching the hides upon frames, which are rotated in a circular vat resembling a brewers' mash tun. The current density upon the electrodes was about ½ ampere per square foot, and the density in the liquor was about $\frac{1}{20}$ of an ampere per square foot of the transverse sectional area of the vat. Currents of 1¼ to 4 amperes were used, and the mean resistance of the vat was from 8 to 10 ohms. while at work. The tanning liquor was in all cases of the ordinary character, consisting chiefly of mimosa bark and gambier. The strongest solution used contained 4¼ per cent. of tannin. It was found by first measuring the resistance of the liquor, and then putting in the hides and withdrawing the liquor until it stood at the former level, that the resistance of the green hides was practically that of the liquor, confirming the observations of Arrhenius, that the resistance of solidified gelatin does not differ materially from that of the liquefied substance.

From experiments on a small scale, made by Mr. W. Fox Bourne at Mr. Swinburne's laboratory it was found by the authors that the resistance of the strongest liquor was given by the empirical formula,

$$\text{Ohms per cubic inch} = 82 - 11\,d.$$

Where $d$ is the density of the current in amperes per square foot of electrode. The polarisation was found to be practically represented by the following empirical formula,

$$\text{Volts} = 1{\cdot}4 + {\cdot}194\,d + 8\,d^2.$$

Where $d$ is again the density in amperes per square foot of electrode. The resistance of the liquor was found to rise when diluted and proved to be inversely proportional to the strength of the liquor + the resistance of a saturated solution. The power spent in the liquor was only 36·8 watts. Thus only about $\frac{15}{1000000}$ of the whole body of the liquor was electrolysed. A very elaborate series of observations embracing the many quantitative tests by the Kjeldahl process were made to determine the nitrogen of the leather, and thus to ascertain the exact rate of absorption by the hides, during rest, during motion and during the combination of electricity and motion. The results of these tests were plotted upon diagrams, which gave a very clear idea of the rate at which the tanning proceeded, under the different circumstances. The general result was that leather is produced in eight to ten days instead of eight to ten months.

The Paper concluded with a *resumé* of the present knowledge of electrolysis and of the migration of the ions, as far as they appear to bear upon the subject of the Paper. The acceleration of the tanning does not appear to be due to osmosis any more than to electrolysis. Dr. Oliver Lodge has found, for example, that the migration of the ions in electrolysis of sulphuric acid is at the rate of $\frac{1}{385}$ centimetre per second for hydrogen and $\frac{1}{500}$ centimetre per second for $SO_4$ with a slope of potential of about one volt per centimetre. In these experiments it was about $\frac{1}{10}$ of this slope, but the progress of tanning was only about $\frac{1}{1300000}$ centimetre per second or 7½ inches per annum.

## PHYSICAL SOCIETY.

At the meeting of the Physical Society on April 17th, the following communications were made:—

### "On a Property of Magnetic Shunts,"

by Prof. S. P. Thompson. After referring to a few instances in which magnetic shunts are employed, as for example, the ordi-

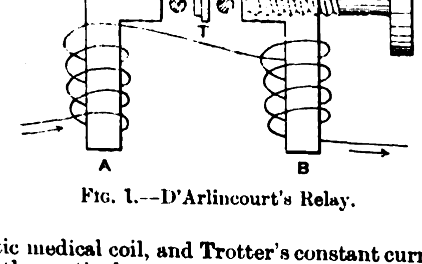

Fig. 1.—D'Arlincourt's Relay.

nary magnetic medical coil, and Trotter's constant current dynamos, he said that the particular property he wished to speak of was the time taken for such a shunt to lose its magnetism as compared with the other branch of the magnetic circuit. If these times were very pifferent, unexpected results might be produced, and these might be regarded as being due to a kind of magnetic time constants. Short pieces, as was well known, demagnetise much more rapidly than long ones, particularly if the latter form, or be part of, a closed magnetic circuit. Hence in alternators, such as Kingdon's Keeper Dynamo, in which both magnets and armature are stationary, it was important that the revolving keepers should be short. The most important application of a magnetic shunt occurred, he said, in d'Arlincourt's Relay, described in Vol. IV., *Journal* of the Society of Telegraph Engineers and Electricians, and shown diagrammatically in Fig. 1. In this relay the polarised tongue T plays between two projections $a$ and $b$, near the yoke Y, and it is claimed to have a quicker action than ordinary kinds. The reason of this the author explained was as follows (Figs. 2 and 3).

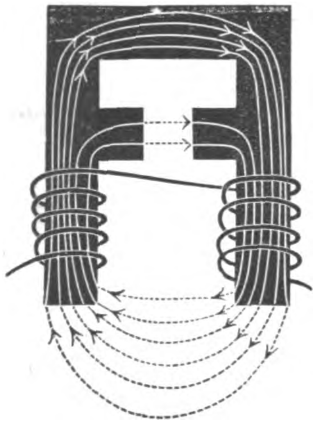

Fig. 2.

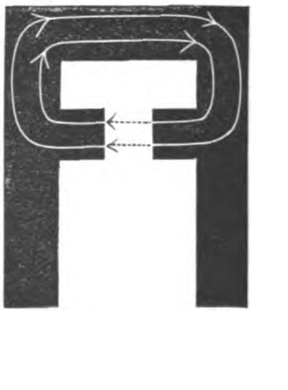

Fig. 3.

Diagrams showing the path of the lines of force through the relay when excited (Fig. 2), and the path of the lines of force when dying away after the magnetising current is broken (Fig. 3).

When a current flows through the coils the greater part of the magnetic lines pass through the yoke, but a few leak across from $a$ to $b$, and move the tongue against the contact P. On stopping the current, the magnetism in the extremities A and B dies away much more rapidly than in the yoke, consequently the direction of the field between $a$ and $b$ is reversed, and the tongue T thrown back against the stop Q.

DISCUSSION.

Prof. PERRY asked if any experiments had been made to test whether the throwing back actually occurred. He also inquired whether such action would be augmented or otherwise by having a thick copper tube round the yoke, or by laminating the iron.

Mr. BLAKESLEY asked if placing a yoke across A B instead of the present one would not improve the action.

Prof. AYRTON said he would be glad to know whether the relay was any more sensitive than an ordinary one as regards the ampere-turns, or the watts required to actuate the instrument. In India, he remembered that they used inductive coils, shunting the ordinary relays, in order to expedite the action and to avoid confused signals arising from the electrostatic capacity of long lines.

In reply, Prof. THOMPSON said he had tried an experiment on a horseshoe electro-magnet, and found evidence of throwing back when working near the bend or yoke. Putting a yoke across A B would, he thought, tend to neutralise the effect desired.

### "An Alternating Current Influence Machine,"

by James Wimshurst. This machine consists of a varnished glass disc, with or without metallic sectors, mounted on an axis, and rotating within a square wooden frame fixed in the plane of the disc. The frame carries four square glass plates, each of which has one corner cut away, so as to clear the box of the disc. These plates are placed one at each corner of the frame, alternately on the two sides, and the disc revolves between them. There are thus two plates on one side of the disc situated at opposite ends of a diagonal of the frame, and two on the other side of the disc, at opposite ends of the other diagonal. Tin-foil sectors fixed to the outer sides of the plates act as inductors, and wire brushes connected with them touch the disc about 90deg. behind the centre of the inductors. The peculiarity of the machine is that, although sparks can be readily obtained from it, a Leyden jar cannot be charged by bringing it to one of the terminals. From this the author concluded that the electricity produced was alternately of positive and negative sign, and this he showed to be the case by means of an electroscope. The alternations, he said, occurred about every three-quarters of a revolution, the suspended paper discs which he used as an electroscope remaining apart for that period and collapsing during the next quarter of a turn. Using discs with various numbers and sizes of sectors the author finds that the smaller sectors and the

Digitized by Google

the fewer the number the greater the quantity of electricity produced. Plain varnished glass is the best in this respect. Such a disc, however, does not excite itself quite so freely as one having numerous metallic sectors. By removing two of the inductors and placing an insulating rod carrying collecting brushes at its ends, across a diameter of the disc, the machine was used to produce direct currents. Numerous discs and various-shaped inductors accompanied the machine, by means of which a Holtz, Voss, or ordinary influence machine could be imitated.

DISCUSSION.

Prof. S. P. THOMPSON congratulated the author on the most interesting and puzzling machine he had brought before the Society. He inquired if the machine would work if the direction of rotation was reversed, or if two of the inductors were removed, and also whether all the four inductors are electrically of the same sign at the same instant.

In reply, Mr. WIMSHURST said the machine would not excite if the direction of rotation be changed without also changing the direction of the brush-arms; but it would work as a direct-current machine, when two inductors were removed.

## REPORT OF HIGH-SPEED ELECTRIC RAILWAY WORK.*

BY O. T. CROSBY.

The experiments here reported were the first serious efforts ever made to at once double railway speeds, and as such should, I think, be systematically recorded They were made for the Electro-Automatic Railway Company, of Baltimore, Md.

For the purpose of demonstration, a circular track nearly two miles in circumference was laid at Laurel, Md.; gauge, 28in.; weight of rail 16lbs., shape T. To the ties was built up a vertical frame-work on both sides of the track, this carrying from cross-pieces a 2 × 6in. wooden stringer, suspended above the middle of the track, while to the lower surface of the stringer was attached a small T rail, head down. This upper rail was intended to serve as an electric conductor, and also, in connection with upward pressing wheels, as a guide. The latter function was not successfully performed, the lateral oscillation of the car, on so slight a track, being too great. Part of the track was on trestle work crossing a swamp, the overflow of which caused frequent washouts.

The locomotive was very simple. Three axles carried 28in. wheels; on these were hung a steel box 16ft. long × 14in. high × 30in. wide. A slight vertical play of the box was provided for by springs, but, horizontally, the three axles were in rigid connection. On each of these axles it was designed to place a motor. The head was pyramidal; the weight of the car with three motors was about three tons. A second similar box of steel was made to be drawn by the motor-car, the two to be connected by a ball-and-socket arrangement, the interval between the cars to be flanged over, so that only one surface should be presented to meet atmospheric resistance. The tail was pyramidal. The second car was not in use more than once.

The track work and cars were completed as above outlined, when the matter was brought to the Sprague Electric Railway and Motor Company, with the request that they design motors of which the armatures should be placed directly on the three driving axles of the car, the construction of which was already nearly finished. It was further conditioned that the motors should do 20 H.P. of work each, at a normal speed of about 3,000 revolutions per minute. This corresponds to a car speed of about 250 miles per hour. Needless to say that on so light a track, none of which was straight, and with a car weighing three tons, and with only 60 H.P. available for work, no such speed was attained. The motors were carefully designed by Mr. H. F. Parshall, of the Sprague Company, for a normal impressed E.M.F. of 500 volts, and thoroughly filled the specifications. They were to be connected in multiple across the 500-volt circuit supplied with current from a dynamo made by the Edison Machine Works. When the motors were finally mounted and ready for action it was found almost impossible to start the car, due probably to stiff bearings, and when several trials of speed had been made the results were disappointing.

Work having been resumed, it was soon found that a given speed could be attained with less current if two motors were in service than with three, and consequently the motor on the middle axle was removed. The two motors were able to produce a greater speed than the track could stand. These machines were of the U type. The armature was wound with 100 sections of No. 12 B.W.G. wire, each section of two turns. This armature, with its commutator, was rigidly mounted on the axle. The pole-pieces were attached to brackets centred on the axle; the keeper was spring-supported on a cross-piece carried by the steel casing. Bearings were of phosphor-bronze, and lubrication was by oil from an ordinary cup. No trouble on this score was experienced. Each magnet core was wound with 120 turns of No. 4 B.W.G. wire. At 30 amperes, the armature induction was about 80,000 lines per square inch. These motors, since wound according to specification for the 500-volt circuit, were originally connected in multiple arc. This connection was changed, they being placed in series, thus diminishing the potential control required at the station, by reason of the fact that the machines were run at a speed so much below that for which they had been calculated. To supply the current, contact was made between the upper rail and brushes of sheet copper set against the rail by springs. These served their purpose well. The return circuit was through the wheels and rails, the steel casing being insulated from the axle by fibre plates and washers at joints and bolts. Rail bonds were used throughout: the resistance of the external circuit from the feeder junction to a point diametrically opposite was about 0·25 ohm. The station was placed inside the circle, about 200ft. from the track. The generator was a 70 H.P. Edison machine, not compounded originally, and was driven by a 90 H.P. high-speed Ball engine.

The usual course of a run was this: Speed-observers were stationed around the circle, distance apart being known. Watches of these observers and of recorders who read current and potential were compared. Potential readings were taken at station and at one or two points on the line, permitting easy reduction to horse-power. Mr. Dashiell, my assistant, then took the engine, and I managed the dynamo. A current of from 20 to 40 amperes usually started the car. When the car had attained a speed of 75 to 100 miles per hour, the line potential was about 450 volts. The time limitation of the runs was invariably caused by failure of the track to serve its purpose. On three occasions the car left the track; once at 45 miles per hour, once at 80 miles per hour, and once, the last time, at about 115 miles per hour. Curiously enough, on the two former occasions, the derailment was to the inside of the circle, super-elevation being about four inches. It was easy to tell in the station when a derailment was imminent, as the ammater was most violently agitated by the make and break of the circuit caused by the particularly bad spots in the track. The agitation increased with each trip round the circle, and ended in a run-off, or, after some experience had been gained, in a cessation of the trial. As the track limited the length of run in time, so also it limited the speed obtainable. Each trial the longest being about 22 minutes consecutive running--was followed by an overhauling of the track, requiring from a few hours' to a week's work by four or five men. Could the experiments have been made on a road-bed and track, deemed even second-class according to steam railway standards of rail-weight, &c., there can be no question that, without any other change, the car could have maintained for several hours a speed of 120 miles per hour.

The speed obtained in the first round—that is, in the first 9,240 feet—varied from 30 to 75 miles per hour; this determined by the management of the rheostat. The rate of acceleration from point to point in going round the circle was irregular, due to the grades, which, going in the direction usually followed, varied from 2 0 to 2·5 per cent. The fact that the track—always bad—went rapidly from bad to worse during each run, made it difficult to analyse the records with a view to determining the true coefficient of traction. Moreover, the coefficient for such a track, even in its best condition, would be greater than for the track that would necessarily be built for actual service. The figures obtained were of little worth as far as fixing absolute values at very high speed, but at least served to show the error of many train resistance formulæ found in the text-books. Some of these formulæ give good enough results when used for the low speeds on which they are based, but their algebraic form is such as to give rise to great error when higher speeds—say 80 to 120 miles per hour—enter. This whole matter of train resistance has been more fully treated in a Paper, "Limitations of Steam and Electricity," read by me before this Institute on May 21, 1890. The particular element of atmospheric resistance, for which special experiments were made at Laurel, was fully treated in a Paper read by me before the West Point branch of the Military Service Institute. The using for atmospheric resistance figures resulting from the experiment, we obtained the values, 46·0, 42·5, 50·0, 58·7, and 48·0 pounds horizontal effect per ton should be corrected for curvature, making them 30·7, 28·4, 33·4, 39·1, and 32 pounds respectively. Other and lower values were obtained when the track, as at first, was in better condition.

The maximum speed—that of the final derailment, could not be absolutely determined, since the car left the track at some distance from the last two observers, whose time record gave the speed attained between the points of observation. It was clear, however, that final speed was between 110 and 112 miles per hour. A length of 1,000 feet of track was injured, about 300 feet of the upper framework wrecked, and the car itself was landed about 30 feet from the track. It seemed clear that the Laurel plant had passed its days of usefulness.

* Abstract of a Paper read before the American Institute of Electrical Engineers, New York, February, 1891.

Digitized by Google

For purposes of demonstration I now proposed to the Company that they should build a track about four miles in circumference, and should run a train of two or three cars drawn by one locomotive. Calculations were based on the following data:—1. Speed, 150 miles per hour. 2. Cross-section of car, minimum, consistent with the seating of passengers. 3. Gauge of track, 4ft. 8·5in. 4. Character of track, the best. 5. Electromotive force, as high as possible. 6. Cars to be connected so as to present a continuous exterior. 7. Atmospheric resistance at 150 miles per hour, taken at 15lbs. per square foot of cross-section (wedge or parabolic locomotive head being used). 8. Traction coefficient (exclusive of air resistance), at 150 miles per hour, taken at 25lbs. per ton.

From the two resistance coefficients just given, it followed that for every square foot of cross-section, regardless of weight, 6 H.P. would be required, and for every ton of weight, regardless of cross-section, 10 H.P. must be supplied. For a locomotive of about 600 H.P. having 30ft. cross-section, the dead weight was calculated to be about 18 tons. Steel cars of equal cross-section were designed weighing, empty, about five tons, with carrying capacity of about five tons. The important question as to power required could then be thus tabulated:—

| | 150 miles per hour. | 120 miles per hour. |
|---|---|---|
| Locomotive alone | 360 H.P. | 288 H.P. |
| Locomotive and one car loaded | 460 " | 369 " |
| Locomotive and two cars loaded | 560 " | 446 " |
| Locomotive and three cars loaded | 660 " | 528 " |

To perform the work here indicated, two motors of the Manchester type were provided, one armature directly on each of the two axles of the locomotive cars. They were supposed to be at first connected in arc across a 1,500-volt circuit, each taking about 130 to 150 amperes, and delivering about 250 to 300 H.P. The armature conductors were to be of about 40,000 circular mils, cross-section. The cross-section of the core was to be 110 square inches net. Through this armature it was desired to force 22,000,000 lines, or 15,200 per square centimetre. The hysteresis loss in such an armature revolving at 1,200 revolutions per minute was calculated to be about 3,000 watts. The $C^2R$ loss ($C=135$ amperes, $R=0·26$ ohms when $T=75$deg. C.) $=4,740$ watts—or about 8,000 watts for the two losses. The number of armature conductors was to be 340, divided into 170 sections, wound in one layer, each conductor to lie in a slot. The magnets were to have a cross-section of 164 square inches, through which 14,300,000 lines of force were to be passed ($B=13,500$). The magnet coils of the two armatures were calculated to be in series with each other, but in shunt with respect to the two armatures. The commutator was designed to be 23in. in diameter.

The problem of brakes for a mass of, say, 40 tons, running at 150 miles per hour, is a serious one. The Galton and Westinghouse tests indicate a very low value for the coefficient of friction between brakeshoe and wheel, at high speeds; they report it in some cases at 60 miles per hour as low as 0·04. As, however, it rapidly increases at lower speeds, an average of 0·1 may be taken. The total retarding effort, *i.e.*, brake resistance and track and atmospheric resistance, must be kept below that which will just produce sliding of the wheels, and the coefficient of sliding may be taken on an average at 0·08 of the weight of the wheels. If, then, we represent by P the maximum allowable brake pressure on the wheels, by R resistances other than brake friction, and by W the weight on braked wheels, we may write the following inequality:

$$0·1\,P+R<0·08\,W.$$

The value of P should be determined as that which, with a small margin, will satisfy this condition of inequality. Following this calculation, it was found that a brake pressure of about 5,000lbs. should be applied to each wheel. This was designed to be produced by magnetic brakes similar to those used by Mr. Daft on the New York Elevated Railway. A mass of 80,000lbs. moving at 150 miles per hour represents 64,000,000 foot-pounds of energy. Average resistance due to brakes $=0·1\times60,000=6,000$lbs. Average resistance from track and atmosphere for average speed of 75 miles $=400$lbs. In addition, the motors may be required to generate a current which shall be wasted over the rheostat. Since the field circuit in the case of shunt-motors is independent, magnetisation may remain constant, and average E.M.F. of 1,500-volt motors (*i.e.*, motors generating 1,500 volts E.M.F. at 1,100 revolutions per minute, or, with 42in. wheels, at 150 miles per hour), would be, while the train was coming to rest, 750 volts. Make the external resistance such that, the two armatures being in series, an average current of 200 amperes shall flow. Then average dynamo resistance in pounds $=2,000$. Total retarding effort $=6,000+400+2,000=8,400$lbs. Dividing 64,000,000 by this last quantity, we have 7,620ft. (about $1\frac{1}{2}$ miles) as the length of run to come to a stop, and the time of stopping about 100 seconds.

For the mechanical construction of the locomotive, two plans were contemplated. The preferred has a 7ft. wheel base for the drivers and a pony axle in front, free to move laterally over a certain distance, dragging the drivers in the same direction. In this particular case the total weight of the locomotive is about 18 tons, each motor being six tons. Of the total, 15 tons rest on the drivers. If, then, the adhesion coefficient, while running, be taken at only 0·1, a circumferential effort of 3,000lbs. may be exerted without slipping the wheels. This is safe, since if 600 H.P. of work be required at 150 miles per hour $=13,200$ft. per minute, the horizontal effort $=\frac{600\times33,000}{13,200}=1,500$lbs. For starting the load the adhesion coefficient may be taken at ·25, giving 7,500lbs. possible pull, this being much in excess of the value required. The locomotive construction is such as to put the entire weight of the armature directly on the axle. In designing this, I did not overlook the fact that the armature must thus be subjected to much jarring. But I believe the difficulty should be met by excellent mechanical construction, rather than that spring movement should in any way be attempted.

As to the supply of current, it is proposed to use the double metallic system. This departure from the ground return so commonly employed in street railway work, seems justified mainly by considerations of the convenience of high voltages. The conductors will be placed in an inverted wooden trough, about 5·5 feet above the ground. The conductors for each side of the circuit to be two—one insulated and continuous: the other a bare, flat strip, broken into sections, these being normally out of circuit; the locomotive trolley-arm operating a switch which shall throw out the rear section and throw into circuit the section ahead. As to what the line voltage should be, progress in the arc of insulation can alone determine.

In the important matter of limiting curvatures, calculations were made in the ordinary way, using the particular values for weight and height of centre of gravity. A safe speed was then tabulated as that which is just one-half the speed that causes the resultant of weight and centrifugal force to pass through the outer rail of a curve. The beneficial effect of super-elevation, neglected in the calculation, would, of course, practically increase the factor of safety. The following table resulted from the method described:—

| Radius in feet. | Safe speed, by rule above, in miles per hour. |
|---|---|
| 1,000 | 71 |
| 2,000 | 93 |
| 3,000 | 120 |
| 4,000 | 140 |
| 5,000 | 158 |
| 6,000 | 172 |
| 7,000 | 187 |
| 8,000 | 198 |

Copper calculations were made, based on a station potential of 3,000, and also of 6,000 volts, stations being 50 miles apart (thus supplying current 25 miles on each side), and on a service requiring one train on each 25 mile section, the drop on the line being 35 per cent. of station potential. Then for a line of 1,000 miles, as from New York to Chicago, with copper at 15 cents per pound, and for 3,000 volts initial, total cost per mile works out at $66,000.

To arrive at operating expenses, suppose twenty trains each way each day, and a schedule of 125 miles an hour, I arrive at a total of $394.42 per trip. Income per trip, with 15 passengers, and 15,000 pounds of freight, $500. The total daily load of freight each way required to justify the service above treated is 300,000 pounds, or if 200 through passengers be carried (*i.e.*, 10 trains for passengers each way each day), then only 150,000 pounds of freight. The *present* movement between New York and Chicago, in mail and express, is not far from this figure.

To demonstrate all or nearly all that has been outlined in this Paper, will cost about $300,000, covering the construction and operation for a reasonable time of the four-mile circular line proposed above. Last year the Baltimore Company met unexpected difficulty in efforts to raise the needed money; their operations were suspended, and my connection with them ceased just at the time when plans were completed—even to working drawings. I have been much pleased to learn, within the last few days, that far from being discouraged, they are now confidently hoping that they may push on, in the near future, the great work to which they have laid their hands.

## SOME REMARKS ON HERR H. LUGGIN'S WORK ON THE MODE OF CONDUCTION IN ARC LIGHTS.*

BY F. UPPENBORN.

From the observation that the total difference of potential between a pair of electrodes does not undergo any great change when the current strength suddenly increases, H. Luggin arrives at the conclusion that the abrupt difference in potential between the anode and the arc does not increase proportionately to the current density. The author does not consider this deduction to be justifiable; the non-appearance of any increased difference of potential with increased current density may be due to a decrease in that part of the voltage dependent on the length of the arc when the current density is raised. If Δ represents the total potential difference between a pair of electrodes, then for any strength of current we have pretty approximately

$$\Delta = a + b\,L,$$

where $a$ and $b$ are constants and L is the distance between the electrodes. The author has drawn up a series of results of measurements he has taken, which clearly show the above-mentioned influence of current strength on $a$ and $b$. The increase in sectional area of the arc as the current strength rises, which is very difficult to observe and to measure, is not the only cause of the diminution in the value of $b$. As the current strength rises the temperature of the arc increases, which gives another reason for a decrease in the total voltage.

## PARLIAMENTARY INTELLIGENCE.

HOUSE OF COMMONS.—THURSDAY, APRIL 16TH.

### Central London Railway Bill.

On the order for the consideration of this Bill,

Mr. STUART rose to move the first of a series of amendments with reference to the running of workmen's trains on the proposed railway. He moved to leave out "three" and insert "six."

Mr. HOWELL seconded the amendment. He thought it effected a very reasonable extension.

Mr. BARRAN said that if unreasonable obligations were laid upon the Company the railway would, in all probability, not be constructed at all. He hoped that the House would maintain the Committee in their decision.

Mr. GANE said that no fact had been laid before the House which justified the imposition of a heavier obligation than had been imposed by the Committee. The Committee, in what they had done in this case, had gone considerably beyond anything previously done under similar circumstances, and in all fairness, before an additional burden was placed on the Company, very strong grounds should be shown for doing so. He was in hearty sympathy with the spirit of the proposal to place all the privileges they fairly could within reach of the working classes, but there must be a reasonable limit, and in this case the proposed increase in the number of trains was, in the circumstances, unreasonable.

The amendment was negatived.

Mr. STUART then moved the second amendment, to the effect that the hour at which the trains should run in the morning should be eight o'clock, instead of seven.

Mr. O. V. MORGAN said the amendment would entail no additional expense on the company, but would confer an immense boon on a large number of persons who would use the railway. He hoped, therefore, it would be adopted.

The House divided, when the numbers were—

| | |
|---|---|
| For the amendment | 68 |
| Against | 148 |
| Majority | 80 |

The amendment was therefore rejected, and the Bill ordered for third reading.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *April* 12, 1891.

**Accumulator Cars.**—Storage battery traction has received another rebuff at the hand of its old foe, experience. For two years vigorous efforts have been made by a company in New Orleans to operate storage battery cars, but these have resulted in disaster; the cars have been taken off and the company that operated them has disappeared from public view. This, coupled with the stoppage of the few storage battery cars that were operated in New York, has had anything but a wholesome effect on the prospects of electrical storage.

**The Chicago Exhibition.**—The electrical section of the World's Columbian Exposition is starting off vigorously, and plans on a considerable scale are being drawn up. There will be active rivalry between the various electrical companies for prominent places at the Exposition, and it will take no ordinary amount of skill and tact to deal with their demands satisfactorily. Mr. Barrett, the chief of the electrical section, however, is thoroughly up to his work.

**The Rapid Transit Question in New York.**—The Rapid Transit Commissioners in New York have had under consideration during the past few months a vast number of schemes for the solution of this great problem, and have, it is stated, narrowed down the selection to about half a dozen. A premature report that went the rounds of the daily press a few days since stated that the decision reached was, for the present, extended elevated facilities and a tunnel for the New York Central Railroad from its present station at Forty-second-street down to the Battery; and, for the future, the Greathead system. This is vigorously and authoritatively denied. The Greathed system, however, has been rather a favourite without any very good reason. As a large proportion of the work on Manhattan Island would have to be done through rock, the Greathead plan of excavation loses much of its characteristic advantages. It is at its very best when pushing through soft material, but is certainly not particularly well adapted for driving a tunnel through hard rock. The feature of a tight iron tube is good, but as the principal difficulty as regards percolation of water through the sides of a tunnel comes from tunnelling too deep, the precautions necessary in London would hardly be needed New York, unless the cutting was deliberately made far below the surface and through the solid rock.

**Alternate Current Distribution Patents.**—A decision recently arrived at by the Commissioner of Patents has an important bearing on alternating current work in this country. The question involved was that of priority in the parallel system of distribution as developed in this country. The first application was by Mr. M. M. Slattery, of Fort Wayne, Indiana. Mr. Wm. Stanley, jun., had sometime previously had such a system in operation, and immediately presented an unfiled specification dating back to 1885. As important interests were at stake, the contest in the Patent Office has been a bitter one, and finally has come up to its ultimate decision before the Commissioner of Patents, being appealed from the Commissioners-in-Chief to him. The decision was unhesitatingly in behalf of Mr. Stanley, who had a plant in operation in Great Barrington, Mass., in March, 1886, antedating Mr. Slattery beyond a reasonable doubt. The Westinghouse Company conducts its operations largely on the basis of the Stanley patents, and this decision has an important bearing on its rights in the alternating current field that were rendered decidedly shaky by its being beaten in the Gaulard-Gibbs controversy. As it stands now, the Westinghouse Company has a strong case against other alternating current companies in this country.

## CORRESPONDENCE.

### THE SPLIT-DYNAMOMETER FOR DETERMINING DIFFERENCES OF PHASE BETWEEN TWO ALTERNATING CURRENTS OF EQUAL PERIOD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I just happen to notice your remark in the number of Feb. 25, 1891, of your paper, *The Electrician*, about a note on the determination of differences of phase between two alternating currents of equal period, which I published a short time ago in the *Electrical Engineer*, New York.

You say there that I describe this "split-dynamometer method" in the *Electrical Engineer* of Feb. 4th without any reference to the work of Mr. Blakesley, and in apparent ignorance that the method is quite old. Indeed, I consider the method as quite old—as old as the electrodynamometer-

* Exner.'s Rep., Vol. XXVII., part 2.

Digitized by Google

wattmeter, when it was first used by an electrician who knew what he was doing. My note does not contain anything which could be construed as a claim to the invention of this method; but I merely described it, because the publication of a rather complicated method, by means of a couple of synchronous-motors and other devices, led to the discussion of this subject. I must confess myself guilty of not having explicitly mentioned Mr. Blakesley in connection with this method.

But I fear I have committed such crimes more than once, for instance, by describing Wheatstone-bridge methods or using Ohm's law, without mentioning Mr. Wheatstone or Mr. Ohm, supposing that everybody would know that I do not claim the invention of Wheatstone's bridge or Ohm's law.

In this particular case I omitted reference to Mr. Blakesley the easier, as just one or two weeks before my article "Blakesley's Split-dynamometer Method" for power measurements had been mentioned in the very same paper. Indeed, I did not know, and I do not believe that Mr. Blakesley claims the invention of this method, although I read it in Mr. Blakesley's book on "Alternating Currents of Electricity," which is just as well known on this side of the Atlantic as on the other. I thought that the very first electrician, whoever deliberately connected a dynamometer-wattmeter into an alternating electric circuit controlled by voltmeter and ammeter, was really determining the difference of phase between E.M.F. and current, and I for my part do not think so little of the European electricians, to assume that before 1885 nobody had insight enough to see that the well-known ratio of the apparent watts into the real watts, which the wattmeter gives—the plant-efficiency, as Kapp calls it—is nothing else but the cosine of the shifting of phase.

That his wattmeter method is of but little value for the determination of the difference of phase between E.M.F. and current, I cannot agree with either. In a proportionally built wattmeter, the self-induction of the fine wire coil can easily be kept so low, that it can either be neglected entirely, or introduced into the reduction as a correctional member.

In a wattmeter built by me a short time ago the self-induction of the fine-wire coil (100 turns) was found to cause a shifting of phase of $1\frac{1}{2}°$ in 200 ω resistance, so that the maximum correction for self-induction amounted to only 2·6 per cent. of the apparent number of watts, for 100 complete periods, or 200 reversals per second. The instrument gives with 13 watts still a deflexion of 9°. That the impedance of the coil, and therefore the correction of the instrument, varies with the frequency is self-evident. I use a table with the instrument, giving the angles of retardation and the percentage of correction for the different frequencies.

After a long and continuous use of electro-dynamometers as voltmeters, wattmeters and ammeters, I must say that I was always very much satisfied with them, and must consider the electro-dynamometers as the most reliable and exact instruments, if properly handled and properly understood. Therefore, I was very much astonished to read in the discussion of Mr. Swinburne's "Transformer Design" lately, that so *evidently wrong* results should have been got by the "split dynamometer method," as the "observed" decrease of the hysteresis of the converter for increasing load from 69 watts to three watts proves.

By a deviation of the current-wave or E.M.F.-wave from the sinusoidal form such an enormous difference cannot be accounted for; because even a large deviation from the sine-shape must be still of very little influence upon the correctness of wattmeter-readings. Indeed, when reducing wattmeter-readings for self-induction, it must be borne in mind that the wattmeter correction for self-induction depends not only upon the frequency of the alternating current, like in the voltmeter, but also upon the difference of current phase between fixed coil and movable coil, so that for the same frequency the wattmeter correction can have quite different values, depending upon the amount of retardation. A neglect of this latter dependence must indeed introduce a serious error into the wattmeter readings.

Under the assumption of a true sine-wave, let $\overline{OC}$ = the maximum value of the current, in length and position, in ordinary polar-co-ordinates, with $\overline{OA}$ as zero-line; let $\overline{OE}$ = the maximum value of impressed E.M.F.; let $\overline{Oe}$ = the maximum value of resulting E.M.F. in the fine wire coil, that is resulting from the impressed E.M.F. and the E.M.F. of self-induction; $\overline{Ee}$. $\omega = EOe$ is then the retardation caused by self-induction in the fine wire coil.

The reading of the wattmeter gives:

$$\overline{OC} \times \overline{Oe'} = \overline{OC} \times \overline{Oe} \times \cos \phi.$$

while the real power of the alternating circuit is:—

$$\overline{OC} \times \overline{OE} \times \cos (\phi + \omega) = \overline{OC} \times \overline{OE'}.$$

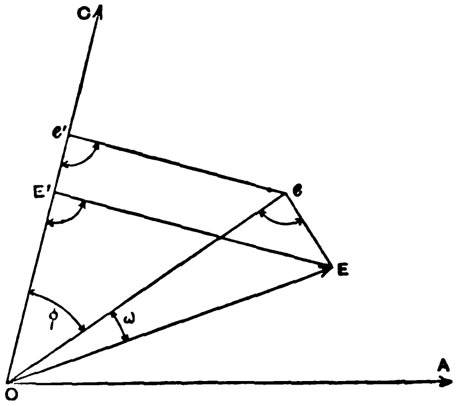
Hence the wattmeter-reading is too large by the amount:—

$$\overline{OC} \times \overline{E'e'} = OC \times \overline{OE} \times \sin \omega \sin \phi.$$

Therefore, when using a wattmeter for power-determination, &c., its readings have to be decreased by the amount:—

$$\text{Sin}\ \omega \tan \phi,$$

and this wattmeter correction is variable, depends upon the angle of retardation $(\omega + \phi)$ of the alternating circuit.



It is small only for small values of $\phi$, where it can be neglected, because $\omega$ is small too, but increases for larger retardations, and will then introduce serious errors if not properly accounted for.

For instance, in the wattmeter mentioned above is $\omega = 1·5°$. Therefore the correction is, for an angle:—

| | | |
|---|---|---|
| $\omega + \phi = 0$ (no self-induction in circuit) | + ·07 | per cent. |
| $\omega + \phi = \omega = 1·5$ degrees ................. | ·0 | |
| $\omega + \phi = 10°$ ................................ | − ·39 | " |
| $\omega + \phi = 30°$ ................................ | − 1·4 | " |
| $\omega + \phi = 60°$ ................................ | − 4·2 | " |
| $\omega + \phi = 80°$ ................................ | − 13 | " |

for 100 complete periods per second.

Chas. Steinmetz.

Yonkers, N.Y., April 2, 1891.

## INDUCTIVE DISTURBANCES IN TELEPHONE CIRCUITS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: A perusal of the article in your issue of April 10th suggests that Mr. J. J. Carty is pursuing with commendable assiduity, at a distance of some ten years, a path already, to no inconsiderable extent, explored by English telephonists.

In his Fig. 11, Mr. Carty sketches a plan from which he evidently expects important results, for reducing in a single wire the disturbing influences of neighbouring conductors. The same plan is described, figured, and claimed in my patent No. 4,428, of 1881. It has never been of much use practically, because the dividing and earthing of the wire at its centre prevented the necessary call signals being transmitted without the intervention of special apparatus. This objection has recently been overcome, but the plan can scarcely be made as efficient and simple as a metallic circuit.

Shunts, both of low and high impedance, on the plan illustrated in Mr. Carty's Fig. 10, but applied to single wires (their use with a metallic circuit is unnecessary, since that should in itself be sufficient to suppress all disturbances), I

Digitized by Google

employed as long ago as 1885. On the single trunk lines between Falkirk-Stirling, Stirling-Dunfermline, and Dunfermline-Kirkcaldy, telegraphic induction was greatly reduced by their aid without spoiling the speaking. But lines so fitted are liable to be stopped by faults that would not fatally affect an unshunted wire.

Mr. Carty's assumption that the important part played by static induction in telephonic disturbances has been hitherto overlooked, surprises me, for I was under the impression that it had been recognised years ago. Personally I had satisfied myself on the point by direct experiment. In practice, however, all problems in connection with metallic circuits can be solved by assuming the presence of current induction only, a fact which may account for the little prominence given to static induction in published discussions.—Yours, &c.,

A. R. BENNETT.

## WIRING OF CALICO PRINT WORKS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We place the following circumstances before your readers, in the hope that it may be of interest. Three years ago we put the electric light in our works, where the processes of bleaching, printing, and dyeing calico are carried on. The installation consists of about 320 glow lamps, employing a Manchester dynamo producing 200 amperes at 100 volts.

The mains and wiring complete were all done by ourselves, and are of ample capacity, being reckoned at 1,000 amperes per square inch, and the lamps are run at 95 volts. All the wires were supplied by a well-known firm, and are the best quality of insulation.

The mains are supported with wooden cleats, and the branches of 8 S.W.G and less, are fixed with iron staples to the beams of the roofs or floors.

The insurance companies not being satisfied for several reasons, got an electrician to examine this installation carefully, and he insists on many changes which we think unnecessary for a public work. Among them—all the mains and wires to be put into wood casing, every joint to be soldered, and a safety cut-out placed at every lamp.

Wood casing we strongly object to, owing to the atmosphere of steam all over the place saturating the wood, which we think would cause the insulation to decay, prevent the wires drying during the night, prevent inspection, and revarnishing the insulation when required. Also it would be difficult to carry out in our works, and involve great expense.

As to the iron staples, they are most carefully put up, of ample size, and the insulation is not abraided.

As to the soldering of "every" joint, this is something new, and we do not believe there is an installation in this country where dynamo connections, switch-board instruments, small switches, and lamp terminals are soldered. Lastly, a safety cut-out at every lamp to be effective would mean a loss of energy of perhaps 20 per cent. We would be glad to hear what your correspondents have got to say to this, remembering that public works are not like a private house, that expense is a consideration, and that the engine is fully loaded, has little surplus power, and that the amperes taken are noted every evening.—Yours very truly,

M. & Co.

April 17, 1891.

## CONTRACTORS' GRIEVANCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There is a growing evil at the present day which not only manufacturers and contractors, but users of electric lighting plant, should unite for their mutual interest to put a stop to. It is the practice of sending inquiries broadcast, and of advertising for tenders.

In the present instance I went from Leeds to Ipswich to tender for lighting the Asylum. I was informed that I was the thirty-eighth person who had thus called, whilst there, number 39 came in from Newcastle, and No. 40 telegraphed he was coming. Assuming that only 40 persons tendered at an average expense of £5 each, the electric lighting industry is burdened with an expense of two hundred pounds (probably more). The final result of all this is a polite letter stating that the committee have for the present abandoned the idea of lighting the Asylum by electricity.

The greater part of this unnecessary expense would have been avoided by calling in a competent adviser, and asking tenders of a few firms only.—Yours, &c. W. H.

# LEGAL INTELLIGENCE.

### London Electric Supply Corporation v. Friese Greene and Collings.

In the Queen's Bench Division, on Tuesday, the case of the London Electric Supply Corporation *v.* Friese Greene and Collings came before Mr. Justice Denman and a special jury. This was an action to recover £64. 11s. 7d. for the supply of electric current to the defendants' premises, 192, Piccadilly, during the years 1888 and 1889. The defendants contended that the supply was bad, and that their business suffered in consequence, and they counter-claimed for damages.

Mr. Moulton, Q.C., and Mr. S. Lynch appeared for the plaintiffs, while Mr. Dodd, Q.C., and Mr. Lewis Coward represented the defendant Collings, and Mr. Leily the defendant Mr. Friese Greene.

Mr. MOULTON, in opening the case for the plaintiffs, said that for several years past there had been a supply of electricity from works at the Grosvenor Gallery to certain premises in Bond-street, W. The defendants were photographers, and they first applied to be supplied with the current in December, 1887. At that time it was quite impossible for the plaintiffs to accede to their request, because there were a large number of prior applications from other persons for the supply of the current. On April 4, 1888, however, the defendants were joined to the plaintiffs' system, and supplied with the light. Shortly after that Messrs. Collings left the firm, and he was prepared to withdraw the claim as against them. The defendant, Mr. Friese Greene, continued to use the arc lamps for purposes of photography, and the incandescent lamps in other parts of his premises. Quarterly accounts were sent in down to March, 1889, when the plaintiffs were informed that the defendants had ceased to use arc lamps. There was a breakdown on one occasion, and the plaintiffs wrote to their clients informing them of the way in which it occurred, and making a reduction in their charge. The defendants received an allowance of £1. 16s. The defendants made no complaint with regard to the light until just before the action was commenced. Now, however, they alleged that they took their present premises relying upon the plaintiffs supplying them with a steady and constant supply; that the plaintiffs were not able to keep up a uniform and constant current during the whole of the time; that in consequence they had sustained damages to the extent of £2,000, and that the whole object of their taking the premises had failed. He (the learned counsel) submitted that there was no ground for the counter-claim.

Major CHARLES WALLER, Secretary of the plaintiff's Company, then gave evidence, and the further hearing was adjourned till Wednesday.

WEDNESDAY, APRIL 22ND.

Mr. LEILY, in opening the case for the defendant, submitted that the plaintiffs had broken their contract. Instead of supplying the defendant with a uniform steady light they gave him an irregular and unsteady light, which irritated his customers and seriously injured his business. Sometimes the light would go out altogether, and leave the studio in total darkness. The light supplied by the plaintiffs in 1888 and 1889 was as bad as it could possibly be, and when the defendant complained he was met with the story that matters would shortly improve. Even when the current was on it was miserably below the standard pressure required for the defendants' purpose. He (the learned counsel) maintained that the defendant had suffered damage in consequence of the plaintiffs' breach of contract, and that he was entitled to compensation.

Mr. FRIESE GREENE, the defendant, gave evidence in support of the statement of counsel. He said his premises in Piccadilly were of no use for photographic purposes without an artificial light. He had the premises fitted up by Messrs. Verity, and he had a lamp in his studio of 4,000 c.p. The current supplied was never sufficient to light the lamp. In consequence of the plaintiffs failing to supply him with a sufficient current he had sustained considerable damage.

Other witnesses having given corroborative evidence,

The learned counsel summed up on behalf of their respective clients.

The jury found a verdict for the plaintiffs for the amount claimed.

Judgment accordingly, with costs.

### Jablochkoff's Patent.

A motion of the Electrical Engineering Corporation (Limited), asking that the requirements as to advertisements and notices, in reference to a petition for the confirmation of the Jablochkoff patent, should be dispensed with or modified, was heard on Wednesday, before the Judicial Committee of the Privy Council. Lord Watson, Lord Hobhouse, Lord Morris, Sir Richard Couch, and Lord Shand being present.

Mr. Moulton, Q.C., and Mr. Roger Wallace appeared in support of the motion; the Attorney-General and Mr. Sutton for the Crown.

Mr. MOULTON said, that on the last occasion the hearing was adjourned in order that they might make such advertisements as they could, and present such petition for confirmation as they saw fit. On examining

Digitized by Google

into the dates they had discovered that the ordinary period for confirmation would not expire until after the end of the patent, and therefore, after considering everything, they came to the conclusion that the only course would be to apply to their Lordships to remit the ordinary rules with regard to advertisements and to allow them to give such advertisements as their Lordships thought fit and proper in the circumstances, so that both petitions (for confirmation and prolongation of the patent) should come on for hearing before May 22nd, on which day the period of the patent expired. Before presenting the petition for prolongation they gave notice to all persons who had given notice of appearance, and to all persons who had a statutable right to notice. He asked that the requirements as to advertisements and notices in reference to the petition for confirmation of a patent should be dispensed with or modified.

The ATTORNEY-GENERAL said, he had nothing in the least to say with reference to any relaxation of the rule which their Lordships thought fit. It would be his duty to contend on behalf of the public when the application came on for hearing that it was not a case in which the patent should be confirmed; but he was not dealing with that now. He submitted that their Lordships should be satisfied that sufficient notice was given, and he suggested that advertisements should be inserted in the *London Gazette*, two London newspapers, and electrical newspapers.

Lord WATSON said, their Lordships were of opinion that this was a case in which the rule with respect to notice might be relaxed without detriment to the public. They would fix Wednesday, May 13th next, for the hearing of both petitions. They would dispense with the provisions of Rule 1, and direct that the petitioner give due notice of the hearing of the petition for confirmation in the *London Gazette*, *The Times*, *The Electrician*, the *Electrical Review*, *Industries*, and *Engineering*.

### The Chatham, Rochester, and District Electric Lighting Company v. the South-Eastern Railway Company.

The Chatham, Rochester, and District Electric Lighting Company has just been joining issue with the South-Eastern Railway Company upon the question of the amount of compensation which should be paid by the railway company for the compulsory acquisition of the land upon which the central lighting station is now situated at Rochester. The Electric Lighting Company claimed £11,000, and the Railway Company offered £5,000. The case was heard at Rochester before Mr. J. Brennan, Under-Sheriff of Kent.

Mr. Bidder, Q.C., and Mr. Lewis Levy were counsel for the claimants; the Solicitor-General (Sir E. Clarke, Q.C.) and the Hon. Bernard Coleridge appeared for the Railway Company.

Mr. BIDDER said that the progress made by the Electric Light Company had been remarkably encouraging. In 1889 the Company only supplied a few hundred lights, but it now supplied over 3,000. Plant costing £7,500 had been erected, and a well sunk at a cost of £1,400. The Company had found another suitable site near the river Medway, the price of which was £1,500, but there was work necessary to be done, which would involve a certain total of £5,000, so that by the time the works were re-established £7,500 would have been expended, which they considered the Railway Company should pay. In addition the Company would forfeit a rental of £55 per annum for 12½ years certain for a rental of £350, and they would have heavy rates and taxes to pay. It was, therefore, fair that the Electric Lighting Company should be compensated for the extra annual cost, and also that it should not be turned out of its premises until everything was ready to supply customers from the new site.

The Managing Director and Secretary of the Company gave evidence, as also did Mr. S. Z. de Ferranti, who stated that he was consulting engineer to the Company, and considered its business had now reached the critical stage. The price charged for current varied from 3¾d. to 4½d. per B.T. unit, which was lower than the tariff of any other company he knew of. Dr. John Hopkinson and Prof. Henry Robinson also gave evidence on behalf of the Electric Lighting Company.

The SOLICITOR-GENERAL, on behalf of the Railway Company, agreed to give undisturbed possession of a portion of the land for a year, and offered £5,000 compensation.

The inquiry, after lasting several days, terminated in an award of £7,000 for the Electric Lighting Company.

### The Fareham Local Board and the Fareham Electric Light Company v. Smith.

This was a motion which came before Mr. Justice Chitty on Thursday, 16th inst., and was treated as the trial of the action for an injunction to restrain the defendant from removing or interfering with the electric wires and apparatus placed in Osborne-road, Fareham. The defendant was owner in fee in possession of land having a frontage in Osborne-road. The defendant had sent in a copy of plans of intended buildings on his land, and alleged that the poles and wires which were erected on his side of the road would interfere with his intended buildings.

Mr. JUSTICE CHITTY said that the defendant claimed to have a right to cut the wires of the Electric Light Company because he was the owner of the soil of half of the road, subject only to any statutory rights vested in the Local Board. That was the main ground on which the defendant justified his threat to cut the wires. He would assume that the defendant was right in his claim to the soil of the road. The Local Board, however, had a proprietary right in the zone above the surface, or, at any rate, had a possession of so much above and so much below as fell within the objects of the Public Health Act of 1875. In the present case the Local Board had contracted with the plaintiff company for the supply of electric light for public purposes. In pursuance of such contract, and, as the plaintiffs contended, by virtue of the Local Board's statutory right, posts and wires had been erected. The defendant did not complain of the work done being unnecessary for its purposes or beyond what was justified to carry out its object. It appeared to his Lordship, therefore, that the defendant must fail unless he could show that what had been done by the plaintiffs was a trespass. The question, therefore, arose whether the works were within the area of user of the street. He thought that they were within that zone which the statute had vested in the plaintiff Board. That being so, the defendant was not entitled to assume the position of Attorney-General and interfere. He therefore granted an injuction as asked, with liberty to both parties to apply, so that if any unforeseen circumstance should arise the defendant might apply to modify the injunction. The costs would follow the event.

### The Oriental Telephone Company (Limited).

A motion in connection with the above Company came before Mr. Justice Kekewich in the Chancery Division of the High Court of Justice, on Friday, Sir Horace Davy, Q.C., and Mr. Kerry appearing on behalf of Mr. G. P. Ness, while Mr. Cozens-Hardy, Q.C., and Mr. Theobald held a brief on behalf of the Company.

Sir HORACE DAVEY said his client was a vendor of the Oriental Telephone Company, and held vendors' shares therein. The question upon which the decision of the Court was asked was purely one of the construction to be placed upon an agreement dated January 25, 1881. The substance of the agreement was that under its provisions the vendors of their rights to the Company were to receive, as holders of certain Preferred shares granted to them, a minimum dividend of 6 per cent. for a period of five years, or, in other words, 30 per cent. in all. One of the clauses in the agreement went on to provide that if, after the expiration of the limited period of five years, the vendors had not received their full 30 per cent. then, that the difference between what they had received and what they ought to have received should be made up out of the surplus profits of the concern. The difficulty that was experienced was with regard to these latter words. It now turned out that holders of the Preferred shares had not received their full dividend of 6 per cent. for the period of five years, and they claimed, under the agreement of January 25, 1881, a sufficient share of the profits as would make up their interest to 30 per cent., insisting that their claim should be in priority to any of the other shareholders. This view he (Sir Horace Davey) understood was not taken by his learned friend, Mr. Cozens-Hardy, who appeared for the Company, and whose contention was, he believed, that the agreement of January, 1881, was only a charge upon the profits of the Company for five years, and that the agreement having expired, the Preferred, or vendor, shareholders were only entitled to rank *pari passu* with the other shareholders.

His LORDSHIP thought that Mr. Cozens-Hardy's view of the agreement was the correct one, and gave judgment for the Company accordingly.

## TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

### ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891.

The 1891 edition of our well-known Directory and Handbook is ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division of this Directory will be found extensive and reliable. *Orders should be forwarded at once.*

In the course of a few weeks "The Electrician" Company will publish "THE ELECTRICIAN" PRIMERS in two volumes, price per volume 2s. paper covers, 2s. 6d. cloth.

TENDERS WANTED.—The Aberdeen Town Council are prepared to receive tenders from any company or person willing to undertake the electric lighting of the area covered by the Aberdeen Electric Lighting Order, 1890. The Town Clerk will receive tenders until Friday, May 15th.

EDISON AND SWAN UNITED ELECTRIC LIGHT COMPANY.—This Company announce that they will be glad to receive from their customers lamp ends containing platinum. Notwithstanding the fact that the platinum is mostly covered with glass and often has brass caps attached by solder and plaster to it as well, the Company can estimate with great accuracy the weight of platinum contained in any consignment of ends, and will allow the full weight at the rate of 50s. per ounce, with the reservation that this price is

Digitized by Google

subject to market fluctuations. Bags to hold small quantities of ends will be supplied free. Packages containing lamp ends should be addressed to the Works, Ponder's End, Middlesex.

The Maquay Electric Light Company.—This Company, with works at Limehouse, are opening new show rooms at 9, Frith-street, Soho, where they have on view a large number of "Maquay" primary batteries, used in demonstrating the utility of the Maquay system of electric lighting. It is claimed for this system that it is artistic, convenient, and inexpensive. At a recent visit we were shown a number of very cheap portable lamps suitable for warehouses, stables, offices, &c., where danger from the use of naked lights is great. As these lamps are placed on the market at a guinea each, there should be a wide field for them. There is also an electric mining lamp at the price of 18s. 6d., and included in the particulars issued is an account of some experiments and tests made with the "Maquay" lamp at a large colliery at Rotherham, in May last, by Mr. C. E. Rhodes.

The Forthcoming Electro-Technical Exhibition at Frankfort.—We have received the first number of the official journal of the forthcoming Exhibition, which it is intended to publish weekly, and which will contain particulars of the various exhibits, &c., at the Exhibition. The first number appeared on April 15th, and the series is expected to contain 30 numbers in all. Further particulars can be obtained upon application to Messrs. Haasenstein and Vogler, Frankfort-on-Main. The cost of the 30 issues will be £1. 10s., post free.

The Central Station Companion.—This handy "Companion" for the central station, which was described in our issue of August 15th last, and which, as our readers will remember, is a compact form of testing apparatus designed by Messrs. Dowsing and Day, was shown at Sir William Thomson's reception at the Royal Institution on the 10th inst., and also at the Institution of Civil Engineers last week, and considerable interest was manifested in its practical utility and the many uses to which it can be put. An arrangement has been recently added for use as a potentiometer. The "Companion" is being made by Messrs. Poole and White, of Bread-street, Cheapside, E.C., and will soon be ready for delivery.

National Telephone Company (Limited).—This Company have just issued a circular giving particulars of reductions recently made in the charge for private wires within the Metropolitan area. For a three years' contract a reduction of 25 per cent. off the old one-year tariff is made; for a five years' contract, 10 per cent. off the new three years' tariff, and for a seven years' contract a reduction of 15 per cent. off the new three years' tariff is made. The circular also gives a full list of the call-rooms of the Metropolitan Exchange system, and contains a notification that non-subscribers can use the telephone on payment of 3d. per message of three minutes' duration, with the exception of a few outlying districts (which are charged at the rate of 6d. per three minutes' conversation).

Messrs. W. H. Willcox and Co.—We have received a copy of reduced price list and particulars of Bourdon's patent pressure vacuum compound water and blast gauges, with porcelain and painted dials, issued by this Company. It is claimed for these dials that, being made of the best porcelain, and of pure white, the figures show out in great prominence, and that no discoloration of the dials takes place. Heat does not affect the figures of the dial, which are permanent.

Mr. F. M. Rogers.—Mr. Rogers sends us particulars of an adjunct to a lathe, which may be useful for amateurs. A standard is bolted to the bed of the lathe; upon this slides a face-plate, to which the work is secured. This face-plate is moved up and down by a roller, or guide block, mounted upon a pin bolted to the ordinary lathe chuck-plate. With a tool in the ordinary slide-rest the work may be planed or shaped.

Messrs. O. Berend and Co.—This firm request us to announce that they have been compelled to prosecute two clerks who pleaded guilty to stealing correspondence and goods and embezzling moneys; and as Messrs. Berend and Co. have reason to believe that some hundreds of letters, to the writers of which they have no clue, have been destroyed, they trust that this intimation may be taken as an explanation of the seeming neglect to reply to correspondence. They would be glad if writers of unanswered letters would again communicate with them.

**BRUSH ELECTRICAL ENGINEERING COMPANY.**—The Duke of Marlborough has accepted the position of Chairman of the Brush Electrical Engineering Company, in succession to Lord Thurlow, who has resigned his seat at the Board of that Company.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—At a meeting of the Board of this Company held yesterday, it was decided that, after placing £30,000 to the reserve fund and £5,936 to the Debenture redemption fund, the Directors would recommend at the forthcoming meeting a dividend of 9s. per share, free of income tax, making, with the interim dividend paid in November last, a distribution of £5 per cent. for the year 1890, carrying forward £6,070 to 1891.

# PATENT RECORD.

## APPLICATIONS FOR PATENTS.

March 16, 1891.

4,860. H. Howard. London. Improvements in apparatus for heating and welding by the electric arc.

4,869. H. H. Lake. London. Improvements relating to primary and secondary electric batteries, and to the manufacture of plates or electrodes for use therein (L. A. W. Desruelles, France).

4,877. H. H. Lake. London. Improvements relating to plates or electrodes for primary and secondary batteries, and to the production of compounds or agglomerates for the manufacture of such plates or electrodes (E. A. G. Street, and L. A. W. Desruelles, France).

4,881. A. M. Clark. London. Improvements in electric tramways or railways (S. Schuckert and Co., through Wirth and Co., Germany.)

4,882. F. J. Duck. London. Improvements in electric indicators.

March 19, 1891.

4,904. J. H. Turner. London. Improvements in or connected with electric alarum clocks or time-pieces.

4,949. J. Y. Johnson. London. Improvements in galvanic batteries (A. Tardy, France).

March 20, 1891.

4,988. W. Thompson. Thornton Heath. Improvements in type printing instrument for telegraphic purposes.

5,003. J. Y. Johnson. London. Improvements in holders or supports for incandescent electric lamps (T. Mace, Holland).

5,021. H. H. Lake. London. Improvements in electric accumulators (G. Gandidi, Italy).

5,022. J. Moeller. London. An improvement in incandescent illumination, and apparatus for that purpose.

5,043. A. W. Money and H. Nash. London. An improved apparatus for regulating the approach of the carbons in arc lamps.

March 21, 1891.

5,067. H. Lassen. London. A system of economic and private telegraphing.

March 23, 1891.

5,131. H. N. Lawrence. London. Means for applying electricity through jets, streams, or sprays of fluids and vapours for therapeutic and other purposes.

5,135. B. D. Southard. Manchester. Improvements in armatures for dynamos or electric motors.

5,162. B. J. B. Mills. London. Improvements in devices for transmitting power, the same being specially adapted for use with electric motors propelling cars or vehicles.

5,167. F. E. Elmore and A. S. Elmore. London. An improvement in the manufacture of tubes by electrolysis.

March 24, 1891.

5,192. W. S. Scales. London. Improvements in electric clocks.

5,247. M. W. Dewey. London. Improvements in electric heating apparatus.

5,252. E. D. Graff. London. Electric signal apparatus for railway trains.

5,280. W. P. Thompson. Liverpool. Improvements in electric switches (Willing and Violet, Germany).

March 25, 1891.

5,313. H. Aylesbury. Bristol. An improvement for driving electrical machinery.

5,318. F. R. Boardman and J. S. Fairfax. London. Improvements in or relating to arc lamps.

5,329. L. Bristol. London. Improvements in portable electric safety lamps.

5,338. T. P. C. Crampton and A. Essinger. London. Improvements in the form of carbons used in certain electric arc lamps.

5,341. A. Poleschko. London. Improvements in electrical transformers.

5,342. H. L. Callendar. London. Improvements in electrical thermometers or pyrometers.

5,343. J. Brockie. London. Improvements in electric arc lamps.

5,350. R. R. Harper. London. Mounting electrical dynamo machines or motors to enable them to be easily reversed for driving in alternate directions.

March 26, 1891.

5,370. P. H. Williams. Egham. Improvements in and connected with dynamos, or other electric generators, and motors, and accumulators and other appliances.

5,371. P. H. Williams. Egham. Improvements in and connected with telephones and telegraphs, and apparatus and appliances therefor.

5,404. J. Clift. London. Improvements in or relating to fittings for electric and other lamps.

5,406. H. C. Jobson. London. Improvements in attachments for telegraph poles for carrying insulators.

5,412. T. Parker. London. Improvements in means for supplying electricity to electric tramways or railways.

Digitized by Google

5,435. D. LICHTENSTADT and C. LICHTENSTADT. London. Improvements in electric magnetic massage kneaders. [Date applied for under Patents Act, 1883, Sec. 103, December 8, 1890, being date of application in United States.]

March 28, 1891.

5,461. A. DICKENSON. South Staffs. Improvements in masts and trolleys for the overhead system of electric traction.

5,485. E. MASSIN. London. Improvements in the means for telephonic communication.

March 31, 1891.

5,508. T. L. HEMMING. Birmingham. An improved method of electro-plating wire.

5,518. H. AYRTON and W. E. AYRTON. London. Electric and other meters.

5,547. C. KELLNER. London. Improvements in apparatus for electrolytic decomposition.

5,548. J. D. BISHOP. London. Insulated electric conductors.

5,595. M. W. DEWEY. London. Improvements in electric heating apparatus.

April 1, 1891.

5,617. W. MCGEOCH, junr., and A. J. MCGEOCH. Glasgow. Improvements in electrical meters or measuring instruments.

5,637. R. W. BARKER. London. Improvements in electric converters. (M. G. Farmer, United States.)

5,638. W. A. CROWDUS. London. Improvements in electric batteries, [Date applied for under Patents Act, 1883, Sec. 103, 7th October, 1890, being date of application in United States.]

5,641. A. E. ANGOLD. London. The improvement of electric arc lamps.

5,656. A. L. SHEPARD. London. Improvements in and relating to electric lamps or lighting apparatus.

April 2, 1891.

5,679. R. STEENBERG. Newcastle-on-Tyne. Improvements in or connected with telephones.

5,690. H. C. BULL. Liverpool. Improvements in and connected with electric batteries.

5,711. J. R. THAME. London. Improvements in the manufacture of seamless tubes or conduits for electrical and other purpose, and in the apparatus employed therein.

5,712. S. PITT. London. Improvements in insulating electrical conductors. (E. C. Davidson, United States.)

5,713. S. PITT. London. Improvements in insulating electrical conductors. (E. C. Davidson, United States).

5,714. S. PITT. London. Improvements in insulating electrical conductors. (E. C. Davidson, United States.)

5,715. S. PITT. London. Improvements in insulating electrical conductors. (E. C. Davidson, United States.)

April 3, 1891.

5,766. G. J. PHILPOTT and R. HAMMOND. London. Improvements in electrical apparatus for use as an electric current meter, or as an electromotor.

5,780. J. M. MCHAHAN. London. An improved safety device or cut-out for the protection of electric circuits, and of apparatus connected therewith.

5,790. E. BOEHM and E. BAILEY. London. Improvements in incandescent electric lamps.

April 4, 1891.

5,794. A. R. UPWARD and J. H. MACFARREN. London. Improvements in the application of light, heat, and motive power obtained from electrical circuits to the purposes of advertisement.

5,795. P. H. WILLIAMS. Egham. Improvements in and connected with electric lighting, and apparatus and appliances therefor.

5,802. W. MCGEOCH, junr., and A. J. MCGEOCH. Glasgow. Improvements in holders for incandescent electric lamps.

5,824. J. PITKIN. London. Improvements in the manufacture of filaments for electric glow-lamps.

5,834. G. WILKINSON. London. Improvements in electrical measuring instruments.

5,835. A. D. JONES. London. Improvements in or relating to electrical measuring or indicating instruments.

5,849. H. NEHMER. London. A dry battery for medical purposes.

April 6, 1891.

5,869. G. SCARLETT. Liverpool. Improvements in indicators for electric bells, or for the passage of electric currents.

5,903. J. WALTER and VISCOUNT GRIMSTON. London. An electro-pneumatic rock drill.

5,912. W. SANDWELL. London. Improvements in the transmission of electricity to portable cranes and other machinery, telpher lines, and the like.

5,918. H. I. HARRIS and W. H. POWER. London. Improvements in electric batteries.

April 7, 1891.

5,947. H. CHAPMAN. London. Method of and means for renewing or repairing the filaments of incandescent electric lamps.

5,953. W. A. BYRON and S. GEORGE. London. Improvements in and relating to voltaic batteries.

5,963. H. A. C. SAUNDERS and A. C. BROWN, London. An electric "hooter" or loud sound producing apparatus.

5,972. W. SILLERY. Liverpool. Improvements in electric storage batteries.

5,983. E. A. LE SUEUR. London. Improvements in or connected with means or apparatus employed in electrolysis.

5,989. E. W. LANCASTER. Birmingham. An improved means of wiring brackets, pendants, electroliers, and the like for electric lighting.

5,992. F. E. S. D'ODIARDI. London. Improvements in pneumo-dynamometers.

5,993. F. E. S. D'ODIARDI. London. Improvements in the electric cup.

5,994. F. E. S. D'ODIARDI. London. Improvements in electro-inhalers.

5,995. F. E. S. D'ODIARDI. London. Improvements in liquid electrodes.

5,996. F. E. S. D'ODIARDI. London. Improvements in magneto voltaic and static electrodes.

5,997. F. E. S. D'ODIARDI. London. Improvements in electric atomisers

6,003. J. C. REILLY. London. Terminals for cables of electrical conductors.

6,007. E. W. LANCASTER. Birmingham. Improvements in handles or taps for electrical switches.

April 8, 1890.

6,011. A. P. LUNDBERG. London. Improvements in ceiling roses for electric lighting.

6,012. A. P. LUNDBERG. London. Improvements in switches for electric lighting.

6,048. G. NORTH. London. Improvements in electric power apparatus.

6,072. C. E. CARPENTER. London. Improvements in electro-heating apparatus. [Date applied for under Patents Act, 1883, Sec. 103 September 27, 1890, being date of application in United States.]

April 9, 1891.

6,104. I. A. TIMMIS and A. I. SMITH. London. Improvements in dynamos and motors.

6,125. J. K. RITTER. London. Improvements in electrical apparatus for soldering, boiling, and heating.

April 11, 1891.

6,194. J. A. KINGDON. London. Improvements in electromotors for alternating currents.

6,232. E. GWOSDEFF and A. BUNGÉ. London. Improvements in microphones for telephonic circuits and in the induction coils thereof.

6,243. S. M. L. PATZ and R. GREBNER. London. Improvements in galvanic batteries.

6,247. J. Y. JOHNSON. London. Improvements in automatic regulating apparatus employed in connection with galvanic batteries (F. Gendron, France).

# COMPANIES' MEETINGS & REPORTS.

## The Eastern Extension, Australasia, and China Telegraph Company (Limited).

The thirty-fifth ordinary general meeting of this Company was held on Wednesday last, at Winchester House, 50, Old Broad-street, under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting by the Chairman, the minutes of the last ordinary general meeting, and the minutes of the extraordinary general meetings held, and the same were confirmed and signed. The report and accounts were taken as read.

The CHAIRMAN: Gentlemen, before asking you to approve the report I shall, as usual, put some figures before you, so that you may fully understand what has been done during the last six months. The gross receipts for the past half-year amounted to £279,095, against £264,103 for the corresponding period of 1889, showing an increase of £14,992 for the half-year, which is partly due to profit on exchange during the sudden but temporary rise in the value of silver, and partly from increased traffic with Australasia. The working expenses have been £74,090, against £73,498 for the corresponding half-year of 1889, or an increase of £592. The net revenue for the past half-year was £166,807, against £146,144 for the corresponding period of 1889, or an increase of £20,663, which is explained

Digitized by Google

by the additional revenue already referred to, and the disappearance from the accounts for the past half-year of the item of £6,500 charged in former accounts for the interest and sinking fund in connection with the Five per Cent. Manila Debentures which were paid off last year. The net saving on this account, as mentioned at the last meeting, is £5,000 a-year. The usual interim dividends were distributed during the past year, making, with the dividend proposed to be paid to-morrow, a total dividend of 5 per cent. for the year, which, with the proposed bonus of 4s. per share, will make a total distribution for the year 1890 of 7 per cent. After taking from revenue £100,000 on account of the Madras-Penang duplicate cable. and £1,120 for a new land line at Banjoewangie and additions to staff quarters, there remained a balance of £25,007, which has been carried to the general reserve fund, which now stands at £495,239. During the year 1890 this fund has been credited with £65,130, and debited with £280,004, as follows:—Amount of fund at end of 1889, £710,113; interest on investments during year, £18,786; profit on sale of investments, £21,337; balance from revenue, £25,007; total, £775,243; less cost of New Zealand duplicate cable, £188,433; Madras-Penang partial renewal, £83,678; other cable renewals, &c., £7,893—£280,004; leaving the fund as already stated at £495,239. In addition to this, nearly a million sterling has been taken from revenue for cable renewals and duplications since the Company was formed. The past year was the best the Company has ever had, the gross revenue having amounted to £533,951, or £27,458 in excess of the best previous year, viz., 1885, when the tariffs were in force which were subsequently reduced at the Berlin Conference. As stated in the printed report, the recent conversion of the Company's Six per Cent. Debentures into Four per Cent. Debenture Stock was attended with complete success, the whole of the stock having been taken up at par by the shareholders at a time when the bank rate was at 6 per cent., and the City was passing through a financial panic. An official quotation of the stock has been obtained, and it now stands at 5 to 7 premium. With the exception of a few hundred pounds all the Six per Cent. Debentures have now been lodged at the Company's bankers, and paid off. By this operation an annual saving of £6,400 a-year has been effected, making, with the saving of £5,000 already referred to, a permanent saving of £11,400 per annum. A further drawing of 320 of the Five per Cent. Australian Government Subsidy Debentures took place on the 7th instant, which, when paid off on July 1st next, will reduce the amount of the Australian Debenture debt outstanding to £354,500, the total issue having originally been £640,000. You will have observed from the report and Press announcements that the negotiations which have been so long in progress with the Governments of Australasia for a substantial lowering of the tariffs to Australia have at last been brought to a successful termination, and that the reductions will come into force on May 1st proximo. The agreement is made with the colonies of Victoria, New South Wales, South Australia, West Australia, and Tasmania, who guarantee the Company against one-half the risk of any loss resulting from the reductions, the Company accepting the other half; and the arrangement is for a tentative period of one year, to be extended if found to work satisfactorily; consequently, the continuance of the reduced rates depends upon the telegraphing public giving the experiment their hearty support, and thus making it a success. It was hoped that Queensland and New Zealand would have taken part in the arrangement, especially as in the case of the latter colony a substantial reduction of tariff would have followed between New Zealand and Australia; but after considerable negotiation between the various Governments, Queensland and New Zealand declined to take part in the arrangement, and the tariffs to those colonies will therefore remain unchanged. Since the report was issued an agreement has been formally concluded between the Company and the Indo-European department of Her Majesty's Indian Government, the Eastern Telegraph Company, and the Indo-European Telegraph Company, by which the guarantee and risk are shared between the parties according to their respective interests in the Australasian traffic. The maximum liability, if no increase of traffic were to result from the reduction, would be £131,810, of which the contracting colonies' share would be one-half, or £65,905, and the Extension Company's proportion, £42,500, the balance of £23,405 being divided between the Eastern and the Indo-European Companies and the Indo-European department. Should, however, the traffic increase by 25 per cent., the Extension Company's liability would be reduced to £34,000; 50 per cent., £25,000; 75 per cent., £17,000; and 100 per cent., £8,000. Since the close of the year the Telegraph Construction and Maintenance Company have successfully completed their contract with the Company for the duplication of the Madras-Penang cable (1,388 knots in length), and the Eastern Company's new cables between Suez, Aden, and Bombay having also been laid, the service is now in a thoroughly efficient condition to meet all requirements that may arise in connection with the reduced rates to Australia. As already stated, a sum of £100,000 has been taken from last year's revenue towards the cost of the duplicate Madras-Penang cable, and it is also proposed to pay the balance of £150,000 out of revenue as opportunities occur, so as not to increase the capital account. The total length of our system is now 15,700 nautical miles of cable, and owing to the policy so frequently referred to, and approved by the shareholders, of renewing and duplicating our lines out of revenue instead of adding to the capital, these cables now stand in our books at a comparatively low figure (applause). I have probably read you a report which it would be very difficult to beat. I think we must all congratulate ourselves on our affairs being in such a satisfactory condition. I am satisfied myself that the policy which your Directors have pursued in keeping down the capital, and paying as much as possible out of income, has been the real root, foundation, and success of these submarine telegraph companies (applause). We are now making a new departure, namely, the arrangement with the Australian Governments, and if it is successful, no doubt it will be extended elsewhere; but we are more likely to be successful in Australia, because every man there is more or less a merchant, large or small. A great many people desire to become merchants; and my view of this reduction is that a man spending to-day say, £1,000 upon telegrams will continue to spend the same amount with the reduced tariff. The reduction will also bring in a class that could not afford to send telegrams at the previous rates. Therefore, I think we shall not only have the money we have been hitherto receiving, but a number of additional customers coming forward. The vitality in the Colonies is very remarkable indeed. Six years ago at the Berlin Conference we were called upon to make reductions in our tariff, which involved us in an estimated loss of about £60,000, and the Australian proportion of this loss was recouped in less than three years. I hope the details I have given you will have convinced you that the present reduction is not going to put us in a disagreeable position. I think that we have shown that we have the courage to cope with great occasions of this kind, and, if successful, I think it will be a new era in submarine telegraphy. As you all know, submarine telegraphy is regulating the commerce of the world, and as the world grows and the colonies increase, so will the old country become more prosperous. Now, gentlemen, a great many people will be claiming the merit of having made this bold venture. I see in print sometimes the statements of people which make me smile. At the same time, every man has his own views on the subject; but I want you to know exactly what are the facts, because you are all, more or less, as members of this Company, entitled to the credit of what I may call this very remarkable departure. Well, then, the guarantee was first suggested to the Queensland Government in 1885, to the New Zealand Government in 1886, to the Jubilee Conference in 1887, and subsequently submitted to several conferences in Australia and elsewhere. I can only tell you that we have been working at this for six years, and you will appreciate our difficulties when I say that we have had to deal with Continental Governments, such as Germany and Russia, as well as all the different colonies of Australia, who are very jealous of one another. They are now, as you are aware, talking of federation, and probably this is the first step towards the accomplishment of that end, but it will take a long time, as we know, to bring federation about, but when it is accomplished I believe it will prove an immense benefit to the colonies themselves. You will see that we are taking a large risk in this reduction. Nobody knows the working of the system better than we do, and we think we are quite warranted in taking this step. I believe that the loss will be very small the first year, and probably the second year it will disappear altogether; but we have set the example, and after all, in securing the guarantee of those colonies we are practically securing upon the whole of our capital something like 2 per cent., which ought to materially improve the value of our stock, and give the investing public confidence in it. Some people say that you cannot have universal telegraphy, and that the working people do not benefit by it. I take a very different view. I think that the working people do benefit by every forward movement of this kind. You cannot have cheap telegraphy in a country without giving the working classes a share of its benefits. Some people say that we are taxing the products of the country. We are certainly taxing commerce to a certain extent, but when that commerce recoups itself many times over in the course of a year from such enterprise the working classes derive the benefit in increased wages. I must here express my regret that Queensland and New Zealand have not agreed to take part in the experiment. If they had done so, I think it would have been almost a complete federation, but from the beginning of this Company Queensland, more especially, has always stood aloof from us. She had a sore 20 years ago that has never been entirely healed, but as Queensland and New Zealand will practically participate to some extent in the benefits which we are conferring on the other colonies, I believe that by-and-by, when they see the advantages accruing to the other colonies, they will consider it a wise thing to join in the general guarantee. In concluding my remarks in regard to these protracted negotiations, I should like to bear testimony to the assistance and encouragement I have all along received from the Agents-General who so ably and intelligently represent their respective colonies in this country, and who are necessarily in a position to appreciate the advantages that must accrue to the colonies from cheaper telegraphic communication with the mother country and the rest of the world. Our relations with our friends the Great Northern Telegraph Company continue to be most satisfactory, and we are working together in a way to ensure success. I hope the next time that I shall have the pleasure of addressing you to be able to make a communication which will show that your interests are well guarded, and that we have completed with the Great Northern Company further negotiations for the purpose of making our Company more sound and prosperous. With these remarks I beg to move the following resolution:—

*"That the report and accounts of the Directors now submitted be received and adopted, and that a dividend for the quarter ended December 31st last be now declared of 2s. 6d. per share, together with a bonus of 4s. a share—both free of income tax—making, with previous distributions, 7 per cent. for the year 1890."*

The MARQUIS of TWEEDDALE seconded the motion, which was carried unanimously without discussion.

The CHAIRMAN: The next resolution is:—

*"That the Right Hon. Viscount Monck, who now retires by rotation, be and he is hereby re-elected a Director of this Company."*

Sir JAMES ANDERSON seconded the motion, which was carried unanimously.

The CHAIRMAN: The next resolution is:—

*"That George Garden Nicol, Esq., who now retires by rotation, be and he is hereby re-elected a Director of this Company."*

The resolution, having been seconded, was carried *nem. con.*

Mr. HAUKINS: Are both gentlemen here?

The CHAIRMAN: I shall be very plain with you. Lord Monck has

Digitized by Google

been associated with this Company from its inception. At the present moment he is suffering from illness. You have got a very efficient Board. I think that the report I have made to you to-day shows that. Every point affecting your interests is carefully considered. If I felt that the absence of any of the Directors weakened even for a time the deliberations of the Board, I should be the very first to call the attention of that member to the fact. But seeing that Lord Monck has been so long a member, and that he is in bad health, having specially requested to be allowed to be absent for a time, I think it would be ungracious and unkind on the part of his old colleagues if they had not granted that, and I am sure that the general body of the shareholders will share this opinion with me. But thinking that the question might be asked, I hold in my hand Lord Monck's resignation, which I can put into effect the moment that the interests of the Company require it. I may mention to you that these remarks not in the slightest degree apply to Mr. Nicol. I do not believe Mr. Nicol has ever missed a Board meeting. Some of his colleagues probably think that it would be better if he missed a few occasionally. I daresay you recognise Mr. Nicol as being always present. I am very pleased, indeed, Mr. Haukins, to find you looking so sharply after the Company's affairs.

Mr. HAUKINS thought it was a very wise policy to reduce the tariffs as proposed.

Mr. LEWIS proposed the re-election of the retiring auditors, Mr. Henry Dever, and Messrs. Welton, Jones and Co.

Mr. WELLS seconded the resolution, which was agreed to *nem. con.*

Mr. LEWIS congratulated the Chairman on the recent honour conferred upon him in Paris. It was an honour conferred not only upon him, but upon everybody connected with the Company (applause).

The CHAIRMAN: Gentlemen, I thank you most cordially on behalf of my colleagues and myself. The honour you refer to is a very great one, but it is one that applies to you all. You have been all, more or less, working with me, and have been backing me up in the great works we have successfully carried out for bringing the distant places of the earth nearer to each other. I accept the honour in that light, and also in the broad view that this is a great international system from which every one benefits alike. It is one of those enterprises that benefits humanity at large. It is a very high position to be at the head of such an institution, and when nations like France recognise our work in the way she has done in my person, I think we may all be satisfied that we are of importance to the world at large.

The proceedings then terminated.

## South of England Telephone Company.

A meeting of the preference shareholders of this Company, convened by Mr. Thomas Welton, the liquidator was held on Monday, at Winchester House, Old Broad-street, with reference to the proposal that the preference shareholders should have transferred to them 4½ per cent. debenture stock of the National Telephone Company (which, as reported in *The Electrician*, recently acquired the undertaking of the South of England Company), in satisfaction of their claims to be repaid £3. 10s. per share upon the preference shares of the South of England Company.

The CHAIRMAN stated that the meeting had been called in a great measure for the purpose of enabling the preferred shareholders to attend and ask any questions which they might think fit regarding the debenture stock which they now had the option of receiving in exchange for their preference shares. He might, perhaps, save them some little trouble by stating at the outset that of the whole amount of £70,000 of stock which was to be issued to him, he had received intimation from preference shareholders desirous of receiving the stock to the extent of very nearly two-thirds of the whole amount. With regard to the balance of £23,000 odd, unless any further assents came in, he considered it very probable that he could dispose of it at round about par. He had brought with him a copy of the prospectus of the National Company on the issue of £350,000 of this stock which was made by them a short time ago, and it was open to the inspection of any preference shareholder who desired to see it. This £350,000 would be increased by the £70,000 which was to be handed over to him, and the amount of the stock might be increased until it reached a sum not exceeding half the share capital of the National Company. The £350,000 required a net amount for interest of £15,750, and the present £70,000 would, of course, require an increased amount for interest; but there would still remain an extremely large margin, because the net revenue for the year ended April 30, 1890, was £185,000. Perhaps the important point for the consideration of the preference shareholders generally was that the most astute and the cleverest people who were interested in the shares had agreed to accept the debenture stock now offered to them instead of cash. It was obvious that by getting the debenture stock in the manner now proposed, holders would be saved any trouble in regard to stamps, as the stock would be transferred to them clear. His object originally in making this proposal was to prevent the necessity from being cast upon him of realising the whole £70,000 in the market at a blow—a proceeding which might have depreciated its value. The debenture stock now offered was not included at present under the quotation granted by the Stock Exchange for the £350,000, but it would be brought under that quotation at as early a date as possible. There would be no difficulty in obtaining an extension of the quotation.

In reply to questions, Mr. WELTON added that the quoted debenture stock was, he understood, sold at a premium. He had heard that its price had been something like 103, but he did not know the present quotation. He believed that only two of the shareholders out of the entire number had intimated their preference to have cash, but the amounts they held were only £350 and £140, and these holders had no special wisdom to bring to bear which should guide the holders as a body. What he would do now was to intimate what had taken place at that meeting to those who had not yet responded to the offer which had been made to them to take debenture stock for the preference shares. He would give these holders a few days more to make up their minds, and if they did not within a few days determine to take up the stock he would sell the amount and offer the holders of the shares their cash. If, however, he obtained a premium on the debenture stock thus sold, the preference shareholders would not get the benefit of the premium, simply receiving the amount in cash, and on the other hand, if he had to realise the stock at a discount the holders of the shares would have to put up with that discount.

The proceedings then terminated.

## Reuter's Telegram Company (Limited).

The following is the Report of the Directors to be presented at the twenty-seventh ordinary general meeting of the shareholders, to be held at the Company's offices, No. 24, Old Jewry, London, E.C., at noon, on Wednesday, the 29th day of April, 1891:—

The Directors beg to report that the net profits for the year ending December 31st last, after payment of Directors' remuneration, current expenses, and deducting rebate on unexpired subscriptions, amount to £4,594. 7s., including £113. 4s. 6d. brought forward from the last account.

An interim dividend of 4s. per share was paid in October last, and the Directors now recommend a further dividend of 4s. per share, making a total distribution for the year of 5 per cent. free of income-tax. This will absorb £3,691. 2s. 6d., and leave a balance of £903. 4s. 6d. to be carried forward. The dividend warrants will be payable on May 2nd next.

The High Court has sanctioned the alteration of the Memorandum of Association, enabling the Company to undertake Advertisement business,

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.
The best for overhead Telephone and Telegraph Lines,
AND ALL ELECTRICAL PURPOSES.
Hard Drawn High Conductivity Copper Wire.
ROLLED AND DRAWN PHOSPHOR BRONZE.

and otherwise to enlarge the scope of its operations. Active measures are being taken to give effect to this extension of the Company's powers.

In conformity with the Articles of Association, Baron de Reuter retires from the direction, but offers himself for re-election. Mr. George de Reuter and Mr. Frederick J. Griffiths have been appointed Directors. Messrs. Welton, Jones and Co. offer themselves for re-election as Auditors.

## Metropolitan Electric Supply Company (Limited).

The following is the report of the Directors of this Company for the period commencing October 1, 1889, and ending December 31, 1890, to be presented to the shareholders at the fourth ordinary general meeting to be held at Winchester House on Wednesday, the 29th inst., at 11:30 a.m. :

The form in which this statement is presented is that prescribed by the Board of Trade under the provisions of the Electric Lighting Acts of 1882 and 1888.

It should be remembered that the period under review commences one month after the date when Parliamentary powers were granted, and comprises the time during which the greater portion of the Company's works of construction were being carried out. The growth of business may best be realised by comparing the gross revenue for the last three months of 1889, which was £2,866. 15s. 7d., with the corresponding period in 1890, when it amounted to £10,726. 19s. 0d. The number of lamp connections which, at the close of 1889, were 14,000, amounted at the close of 1890 to 48,000. This number has been since increased to 58,000, and the demand for the light in the Company's districts is steadily on the increase.

Having regard to the fact that the period under review has been mainly one of construction, it is a matter for congratulation that the Company's income, which was to a great extent the result of the last three months' working, has resulted in a profit, which, though a small one, gives the strongest grounds for confidence in the immediate future.

The earnings of the first three months of the present year are so encouraging that the Directors have decided to make an interim distribution of 2s. per share, which will be paid on May 1st next.

The Company's stations at Whitehall, Sardinia-street, Rathbone-place, and Manchester-square, are now completed, and their working has so far given great satisfaction to the Board. It is confidently anticipated that the new station for the Paddington district, the machinery for which is in a forward state, will be at work in time for next winter's lighting. These stations, with the mains and other necessary plant, will about absorb the Company's present issue of capital, but, as the demand for electric lighting increases, the Directors will be prepared to recommend steps being taken to meet it.

In accordance with the Articles of Association the following Directors, viz., Alderman Sir Robert N. Fowler, Bart., M.P., J. E. H. Gordon, Esq., and J. C. Parkinson, Esq., retire from the Board. Sir Robert Fowler and Mr. Parkinson, being eligible offer themselves for re-election. The Directors regret that Mr. Gordon, owing to his increasing business as a consulting engineer, has considered it advisable not to seek re election ; he will, however, continue to act as one of the Company's consulting engineers. The Auditors, Messrs. Deloitte, Dever, Griffiths, and Co., retire, and offer themselves for re-election.

## NEW COMPANIES REGISTERED.

**BRILL BRICK AND TILE COMPANY (LIMITED).**—The objects of this Company, which has been registered with a capital of £10,000 in £5 shares, with registered office at Brill, Bucks, include, in addition to those indicated by its title, the production and use of electricity, magnetism, or other power.

**CARBON ELECTRIC (LIMITED).**—Registered with a capital of £20,000 in £5 shares. Object: To carry on the business of manufacturers of carbon rods and plates for electrical purposes, in accordance with an agreement made March 7th between Henry J. Chappell of the one part and G. B. Cook of the other part.

**COLLIER AUDIBLE TELEPHONE SYNDICATE (LIMITED).**—Registered with a capital of £9,000 in £100 shares. Object: To acquire and develop the inventions of Arthur T. Collier in respect of improved telephonic receivers and transmitters. Arthur T. Collier is appointed Managing Director.

**INTERNATIONAL ELECTRIC SYNDICATE (LIMITED).**—Registered with a capital of £12,000 in £10 shares. Objects: To acquire and hold the rights granted by letters patent to J. F. Weyde, F. Clas, and J. Elsner, for improvements in the construction of electric accumulators ; to buy other patents, and to sell, deal in, work and develop the said patents and others that may be acquired. The first signatories (with one share each) are W. D. Edwards, G. L. Russell, A. Foglar, R. W. Davey, H. V. Tyrrel, T. H. Deakin, and J. A. Elsner. Registered office: 5, Guardian-buildings, Manchester.

**JOHNSON, MATTHEY AND CO. (LIMITED).**—Registered with a capital of £900,000 in £15 shares. Object: To acquire, as a going concern, the business of Johnson, Matthey and Co., and to carry on generally the businesses of assayers, refiners, and metallurgical chemists, and dealers in gold, platinum, silver, and in metals and chemicals of all descriptions.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—The receipts of this Company for the past week amounted to £5,750.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The traffic receipts of this Company for the week ended April 19th amounted to £816.

**EASTERN TELEGRAPH COMPANY.**—This Company announce that, in view of the reduction of the telegraph rates to Australia to come into operation on May 1st next, and to meet all requirements that may arise in connection with the anticipated increase of traffic, two new cables of great carrying capacity have been laid between Suez and Aden, and Aden and Bombay, thus affording increased speed and security in the transmission of traffic over its lines. The Company also announce the payment by warrants, on May 1st next, of interest for the half-year ending April 30th on their Four per Cent. Mortgage Debenture stock. The transfer books will be closed from April 28th to May 1st both days inclusive.

**ELECTRIC TANNING (GROTH v. THE BRITISH TANNING COMPANY).**—This action was in the list for hearing on Tuesday, before Mr. Justice Charles ; but no one appearing on behalf of the plaintiff, Mr. Bray, who represented the Company, asked that the action might be dismissed with costs, which his Lordship directed should be done.

**LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).**—At a Meeting of the Board of this Company on Thursday last, it was decided that, after placing £6,000 to the reserve fund, the Directors will recommend at the forthcoming meeting a dividend of five shillings per share, free of income tax, making with the interim dividend paid in November, a distribution of £4½ per cent. per annum for the year 1890.

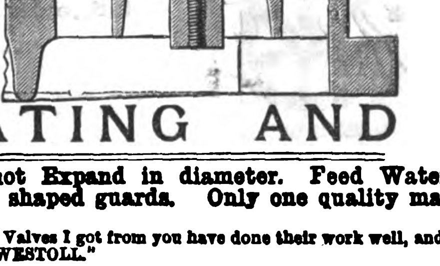
**WEST COAST OF AMERICA TELEGRAPH COMPANY (LIMITED).**—The offices of this Company have been removed from Winchester House to 120, Cannon-street, London, E.C.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended April 17, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,640.

**WEST INDIA AND PANAMA TELEGRAPH COMPANY.**—At a meeting of the Directors of this Company held on Wednesday it was decided to recommend that, subject to final audit, the following dividends be declared, viz., 6s. per share for the six months to December 31st last on the First Preference shares ; 34s. 6d. per share on the Second Preference shares (*i.e.*, 28s. 6d. balance of arrears and 6s. dividend for the six months to December 31st) ; and 9d. per share on the ordinary shares, and carrying forward £668. The receipts of this Company for the half-month ended April 15th show an increase of £21 as compared with the corresponding period.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

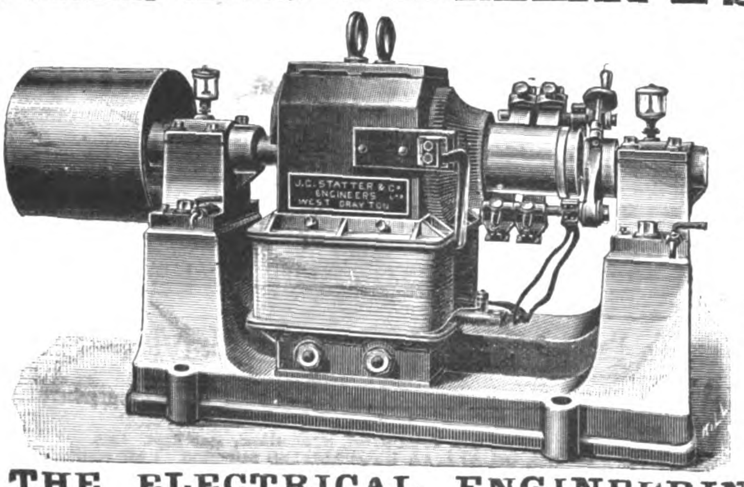
IMPROVEMENTS IN DYNAMOS



STATTER-BRUNTON
DYNAMO.

The latest design in the market, made with all the advantages of the latest scientific knowledge and the highest mechanical skill.

The woodcut represents our B TYPE DYNAMO. A most efficient machine, working noiselessly, and without sparking or overheating; is highly finished and well proportioned. The output is so rated in our Catalogue that the machines may be worked very much in excess of their stated full output for short periods.

STOCK SIZES UP TO 77 KILOWATTS.
MACHINES BUILT TO 500 KILOWATTS.

THE (STATTER'S) ELECTRICAL ENGINEERING CORPORATION, LIMITED, (UNITED.)
68, Victoria Street, London, S.W. WORKS:—ALLIANCE ENGINEERING WORKS, WEST DRAYTON, NEAR LONDON.

# THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 676.—Vol. XXVI. FRIDAY, MAY 1, 1891. Price Fourpence.

## NOTES.

A few interesting facts may be gathered from time to time from the accounts and reports presented, and the statements made at the annual general meetings of electric lighting companies, even if those statistics be withheld which Mr. Crompton invites and which he alone supplies. It was stated some years that on an average each lamp connected to the mains would be used for about two hours a day and this figure was considered ridiculously low. The experience of the Metropolitan Company has shown that each 8 c.p. lamp earns a revenue of about 12s. per annum. This, at 32 watts, is equivalent to 625 hours, or very nearly 1¾ hours per day. This Company, we may add, does business with fairly large customers, since each one has an average of 125 lamps connected.

The establishment of an electric lighting plant at the massive building which contains the offices of the Metropolitan Police is an indication that where light is wanted on a tolerably large scale, it is undoubtedly cheaper to put down the generating plant than to make use of the energy provided by the supply companies. It is true that New Scotland Yard is situated a little too far East to allow of connection with the mains of the Westminster Company, and is out of reach also of the Whitehall station, and therefore would have to depend upon the current from Deptford, but the advantages of the separate plant, which has been erected by Messrs. Drake and Gorham, are very marked. Immunity from breakdown may thus be provided for by spare plant, and the insulation of the circuits is in the hands of the engineer and not at the mercy of the supply company or its customers.

It is difficult to define the exact point at which a private plant can successfully compete with a supply company. There are numerous private houses where the gas engines continue to run, charging the batteries in the morning, although the supply mains pass within a few yards. These little stations have no difficulty in generating a unit for 4d., and it is the trouble, and in some cases the noise, rather than the actual expense, which has induced so many clubs and theatres to take their supply from central stations rather than from their own machinery. The lighting of the Imperial Institute would have been a welcome addition to the load factor of the Kensington and Knightsbridge Company, but it has been decided to provide a separate plant for this huge building also. These large installations are rather apt to make sudden demands upon the central stations unless the switching arrangements are carefully carried out, and much as some of the West End companies long for a few theatres and clubs, the supply of such establishments calls for special attention and alertness on the part of the station attendants.

The value of the point gained by the Kensington and Knightsbridge Electric Lighting Company, in bringing a motion to restrain the Lane Fox Company from issuing threats to their customers and others, does not appear to be of any great or permanent importance. Not long ago a cry was raised, with some justice, that a long forgotten patent was being suddenly sprung upon the users of electric light; and it was urged that, be the patent valid or void, and Mr. Lane Fox an inventor or a thrower out of half-considered guesses, he ought to give fair warning to those from whom he expects to receive royalties. No amount of warning would undo the annoyance caused by the exhumation of the old patent, since batteries have been bought and sold for these ten years past by engineers and private customers in complete ignorance of the existence of any such patent as No. 3988**, of 1878.

A warning was, however, issued, after a considerable delay, not only to supply companies, but to their customers, and the text of it will be found in our Legal Intelligence. It was called a "threat," this being no doubt a legal expression, though it is as difficult to distinguish between a threat and warning in this instance as when the Quaker said, "Have a care, friend, lest thou run thy face against my fist." As is shown by Mr. Lane Fox's letter in another column, the Company "with due diligence" commenced an action; but, as we stated in *The Electrician* of November 14th, p. 27, it was necessary that he himself should be the sole plaintiff. He is entitled, and indeed is in duty bound, to issue proper notices, be they entitled warnings or threats.

At the same time it is, of course, very annoying for supply companies to find that the confidence of their customers is being shaken by these missives, and from their own point of view the Kensington and Knightsbridge Company have scored a point in obtaining an order for an injunction to restrain the continuance of such threats on the part of the Lane-Fox Company.

We publish this week a very able analysis by Lord Rayleigh on the sensitiveness of the Bridge Method when used with periodic currents. Simple as it is to measure resistance with

Digitized by Google

the Wheatstone's Bridge, the theory which indicates the best conditions of tests is very involved, and the complexity becomes very much more pronounced when alternating currents are employed; as not only have the resistances of the six arms to be considered, but the inductance of each one of these arms must be taken into account. Anyone unaccustomed to live in a world of symbols would carefully avoid such an investigation, but Lord RAYLEIGH, no doubt, found it easy enough. Many of the results obtained are simple extensions of those known to hold when steady currents are used, and on this account the meaning of some of the conditions can be easily realised. Thus, SCHWENDLER's rule, that the galvanometer used should have a resistance equal to the parallel resistance of the bridge between the terminals with which it is connected, is true for alternate currents provided we substitute the word impedance wherever the word resistance occurs; and a similar rule of Mr. HEAVISIDE's, with reference to the battery circuit, can likewise be extended. A remarkable characteristic of inductance is that it may be either positive or negative, and may, without sensible alteration of any of the resistances in circuit, be reduced to zero, or any more convenient value, by the addition of suitable condensers or induction coils, or by alterations in the speed of alternation. While, however, it would thus appear that the experimenter has great power of modifying and adjusting his apparatus to favourable conditions, his control is in reality greatly restricted by the magnitude of the capacities and inductances required.

**Cable Extensions.**—A second cable is to be laid between Corsica and the mainland.

**Trunk Wire Extensions in Switzerland.**—It is proposed to connect Lugano, Locarno and Bellinzona by telephone.

**Personal.**—The Secretary of State has appointed Mr. A. A. Campbell Swinton permanent consulting electrical engineer to the Metropolitan Police.

**Berlin.**—The Directors of the Berliner Elektricitatswerke have applied for permission to make considerable extensions in their electric light cable system in Berlin.

**Royal Society.**—Amongst the Papers down for reading yesterday before the Royal Society was one on "The Passive State of Iron and Steel, Part III.," by Mr. T. Andrews, F.R.S.

**Obituary.**—The death is announced of M. Zédé, who died at Marseilles on Sunday night, at the age of 66. M. Zédé was one of the designers of the electric submarine torpedo boat "Gymnote."

**Cement for Leather Belts.**—The following recipe for leather belt cement is due to *La Papeterie*:—Bisulphide of carbon 100 parts, indiarubber 10 parts, essence of turpentine 10 parts, shellac 10 parts.

**Vienna.**—The International Electricity Company now supplies the equivalent of 30,000 eight c.p. lamps from its central station, and it is probable that this will be enlarged so as to supply 40,000 lamps next year.

**Institution of Electrical Engineers.**—A general meeting of the students was held on Friday, April 24th, when a Paper was read on "Alternate Current Motors," by Mr. G. U. Yule. The next meeting will be held on Friday, May 8th.

**Medical Electricity.**—The Grafton College for training nurses and others in medical electricity and massage has recently been started at 35, Fitzroy-square, W., by Mr. H. Newman Lawrence, M.I.E.E., and Dr. Arthur Harries.

**Electro-Harmonic Society.**—The annual meeting of this Society will be held on Tuesday, May 12th, at 4:30, at 28, Victoria-street, London, S.W. Members of the Committee are requested to meet at four o'clock for the election of members and for other business.

**Amsterdam.**—The concession for the electric lighting of Amsterdam has been granted to a local Company called "Electra," and the establishment of a central station and a system of mains for the supply of current equivalent to 40,000 8 c.p. lamps alight simultaneously has been undertaken by the Helios Company of Cologne. The plant will comprise one 160 kilowatt and three 320 kilowatt Zypernowski alternators. The station will be situated about 2¼ miles from the centre of the town.

**Southampton.**—The central station of the Southampton Electric Light Company came into operation on Saturday evening last. The Company have guaranteed to supply the first 50 customers with light gratis for three months. The Harbour Board has decided to light the new pier and the town quay by electricity, and to employ two electric cranes. The contractors to the Southampton Company were Crompton and Co., and the dynamos, accumulators, and mains are all of that firm's manufacture.

**An Acid-resisting Varnish.**—The following patented recipe for an acid-resisting varnish is due to Messrs. Helbig, Bertling, and Reinecke, of Baltimore:—Pour 20lbs. of molten lead into a cast-iron vessel containing about 1 gallon of linseed oil and stir well. After the mixture has cooled, some 17lbs. of lead will be found at the bottom of the vessel. The lead is again melted and the operation repeated. When this has been done about five times the oil attains the consistency of ordinary varnish, and is ready for use.

**Aluminium.**—The works at Hemelingen, near Bremen, which were employed in the manufacture of aluminium and magnesium, have, says *Industries*, now ceased to manufacture the first-named metal. They were using a modified Graetzel-Castner process, but the cost of working was too high, and they could not compete with the large plant at Neuhausen-on-the-Rhine, which works the electrolytic process and utilises the Schaffhausen water-fall. This company has reduced its prices to about a third of what they were a year ago.

**Central Institution.**—A course of lectures, commencing on Monday, May 11th, will be given at this Institution by Prof. Ayrton. These lectures will include "The Elementary Portions of the Theory and Practice of the Electric Distribution of Light and Power with Alternating Currents," "Self and Mutual Induction," "Phase Difference between Currents and Pressures," "Transformers" (Construction, Use and Mode of Testing), "Safety Devices," "High Pressure Mains," "Telegraphy and Telephony." The lectures will be at 3 p.m. on Mondays and Wednesdays.

**Old Students' Association.**—On Friday, the 24th ult., the last of the series of smoking concerts given by the Old Students' Association was held at Masons' Hall Tavern. A most excellent programme was provided, very high-class music being given both vocally, and by such players as Mr. Gatehouse on the violin, while at the same time a most excellent humorous selection was given by Messrs. Keeler and Melrose. A vote of thanks was passed to the Musical Committee at the close of the evening for their successful efforts in getting up such an excellent series of Concerts.

**Interruptions and Repairs of Telegraph Lines**:—

| Line. | Date of Interruption. | Date of Repair. |
|---|---|---|
| Mollendo-Arica-Iquique Cable | March 5 | — |
| Pernambuco-Ceara Cable | ,, 14 | — |
| Santa-Elena-Payta Cable | ,, 31 | April 3 |
| ,, ,, | April 8 | ,, 8 |
| ,, ,, | ,, 9 | ,, 13 |
| Marseilles-Barcelona Cable | ,, 4 | ,, 14 |
| Chorrillos-Mollendo Cable | ,, 6 | ,, 7 |
| Moulmein-Bangkok line | ,, 18 | ,, 22 |
| Saïgon-Bangkok line | ,, 21 | ,, 25 |

**Governmental Regulation of Industrial Enterprises.**—The settlement of the Boy Messengers' case, says *Industries*, is so far satisfactory; but the extent to which the Post Office and other creations of Parliament are interfering to strangle private enterprise is becoming serious enough to justify a drastic re-

Digitized by Google

examination of the whole system. . . . . . It is absurd to regard the Post Office and the Board of Trade as fetiches which must not be touched. . . . . . As regards the Board of Trade, it exists almost wholly for the purpose of preventing other people from conducting their business, or at least for placing as many obstacles in the way of their doing so as possible.

**Rectifying Alternating Current.**—Mr. T. D. Bottome, of Hoosich, New York, has devised an "asymmetrical resistance," which allows a current to pass in one direction but not in the other. It consists of an electrode of aluminium and one of platinum or carbon immersed in a liquid. Owing to the peculiar nature of electrolytic action on aluminium, a non-conducting basic oxide is said to form when the current passes in one direction, and this is decomposed into a soluble sulphate on reversal. All this may be true, but to rectify alternating currents for exciting magnets, &c., by this means, as Mr. Bottome suggests, does not sound hopeful.

**Steep Gradient Electric Traction.**—At Seattle, Wash., a novel method of running electric cars up steep inclines is about to be put into operation. The electric railway there runs up a steep incline about 800ft. long, and it has been found that the motors on the cars are inadequate to surmount it. To overcome the difficulty a small conduit, about 2ft. square, has been constructed, and in this runs a counter-balance car. When an ordinary car is attached to the rope the counter-balance car runs down the hill, but when the passenger car reaches the top of the hill and runs down on the other side, it pulls up the counter-balance, which is now ready to bring up another car.

**Telephone Trunk Wire Extensions.**—The National Telephone Company have arranged to run a direct trunk wire from Glasgow to Dumfries, and thence to Carlisle. The line will be specially constructed to give efficient long-distance speaking, and will be the first telephone line to cross the border. Glasgow and the West of Scotland will then be put in direct communication with the iron districts of Cumberland and Westmoreland, which are already connected with Carlisle, and this will form an important link in the proposed chain of communication between the principal towns and cities of Scotland and England.

**Ether as a Source of Motion.**—Mr. Tolver Preston writes to point out that at the end of the first paragraph of his article in our last issue the passage should read: "Coal must be regarded as a *mere machine* for deriving motion from the ether," and adds—"The old idea of a sort of *quasi* metaphysical 'force' between attracting bodies (assumed to be propagated to a distance without time), which 'force' would be, of course, quite beyond our control, or incapable of modification in any way, has practically received its *quietus* by the late ether (electric) discoveries. When, instead of this supposed mysterious and unalterable 'force,' we have palpable waves and distance action produced by ether disturbance, may we not hope to direct and control it to our advantage?"

**Cologne.**—The municipal central station is rapidly approaching completion, and on April 26th current was sent through the mains for the first time for the purpose of running some alternate-current motors in connection with a lecture of Herr Hegener, Manager of the Municipal Gas and Electric Works. The current was not, however, obtained from the station itself, but from a 10-pole alternator in the show rooms of the Helios Company. The central station alternators are by Ganz and Co., the engines by Sulzer, and the boilers by Steinmüller. The smaller alternators will have an output of 110 H.P., and the larger ones will be of 500 H.P. The foundations are complete, the engines ready, and the dynamos have just arrived. So far over 6,000 (8 c.p.) lights have been applied for.

**Glasgow.**—The Special Sub-Committee of the Town Council on Electric Lighting, after considering the whole subject, have resolved to recommend that the Corporation should undertake the laying down of the necessary works and plant for generating and supplying electricity for private and public lighting within the compulsory area scheduled in the Glasgow Electric Lighting Provisional Order. In the event of the recommendation being approved of by the Town Council, the Electric Lighting Sub-Committee will forthwith invite tenders for the work. It is expected that in the course of the next few days the Electric Lighting Committee will issue the reports they have received from Mr. R. E. Crompton, Prof. Jamieson, and Sir William Thomson.

**Electric Lighting Orders.**—In reply to Mr. S. Balfour, Sir M. Hicks-Beach stated in the House of Commons on Thursday last week that the Board of Trade had no power to revoke a Provisional Order unless the undertakers failed to comply with the requirements of the Order within the prescribed time. In the only case in which the Board of Trade proposed to grant a third Order in a district this Session they had reason to believe that one of the existing companies would not be in a position to comply with the requirements of their Order within the time prescribed thereby. If this should be so, the Board of Trade would, when the proper time arrived, consider any application for the revocation of the Order that might be made to them by the County Council or the Local Authorities.

**Electrolysis Applied to Qualitative Analysis**—At a recent meeting of the Liverpool Section of the Society of Chemical Industry a Paper was read by Dr. Charles A. Kohn, on the "Application of Electrolysis to Qualitative Analysis." Dr. Kohn described a series of experiments he had made on the detection of small quantities of the mineral poisons, antimony, lead, mercury, and copper, taking advantage of the quantitative electrolytic methods of analysis, an account of which he had given to the Society on a previous occasion. The methods were very delicate, clean, and decisive, and likely to be of value in cases of medical and of medico-legal inquiry. Very small quantities of silver and of gold could also be detected electrolytically with ease, and the methods had the further advantage of being made approximately quantitative when desirable.

**Frankfort Exhibition.**—A correspondent writes us to the effect that things are in a rather backward state at Frankfort. A week or ten days ago all that there was to be seen in the Machinery Hall were an Esslingen engine, and a 600 H.P. Suizer engine coupled to a large 40-pole alternator, forming part of the joint exhibit of Ganz and Co., of Budapest, and the Helios Company, of Cologne. The exhibitors are in a bad humour, owing to the Executive Committee having demanded the payment of insurance premiums at the rate of 1·5 per cent., which is generally considered excessive, being ten times that in force for private property.—Plant illustrating Haselwander's rotary current system will be exhibited at the Frankfort Exhibition by Messrs. Lahmeyer and Co.—A Committee has been appointed to make preparations for a three days' Congress of Civic Functionaries to be invited from the chief towns of Germany, Austria-Hungary, Switzerland, Belgium, Holland, Italy, and Scandinavia. The object of the Congress is to consider the application of electric light and power to municipal purposes.

**Telegraphic Extension in Upper Burmah.**—Military necessities gave rise during the year 1890 to telegraphic extensions in Upper Burmah amounting in all to some 375 miles of line. From the point of view of mileage these extensions are of minor importance, but the nature and state of the country through which the lines had to be carried rendered the task one of exceeding difficulty. The longest line constructed was that running from Pauk to Haka, a distance of 195 miles, and the following brief account may give an idea of the difficulties encountered:—One portion of the route was such a sea of mud that four days were consumed in advancing six miles. The lime in the clay attacked the men's feet, and completely disabled many of them. Fever seized the party, and when a station called Achelban was reached everyone was ill, and only 10 men could stand upright. On the 26th November, when the wire had been carried to Gangaw, only 26 debilitated men remained together out of more than 100 who started. By the time the line was finished two officers had died, and seven had been invalided, and out of the hundred odd employés 12 had died and 60 had been invalided.

**Science at South Kensington.**—A memorial is about to be presented to the Marquis of Salisbury expressing a strong opinion that the development and efficiency of the Science Museum and of the Science School and laboratories of the Department of Science and Art at South Kensington will be seriously jeopardised by erecting an Art Gallery upon that

Digitized by Google

portion of the land which was recently purchased by Parliament. The memorialists state that this site is none too large, seeing the progress that is being made in the matter of scientific and technical instruction, to provide for the future requirements of the collections and schools controlled by the Department of Science and Art; and they, therefore, earnestly entreat that another site should be found for the proposed Gallery of British Art. Amongst the signatures already appended to the memorial are those of Sir William Thomson, Lord Rayleigh, Sir Douglas Galton, Mr. W. H. M. Christie (Astronomer Royal), Dr. Hugo Müller, Dr. E. Frankland, Prof. Raphael Meldola, Mr. Shelford Bidwell, Dr. J. H. Gladstone, Prof. W. E. Ayrton, Prof. John Perry, Prof. W. Grylls Adams, Prof. William Crookes, Sir Henry Roscoe, Sir G. G. Stokes, Sir Frederick Bramwell, and Prof. G. Carey Foster.

**Accumulator Cars at Philadelphia.**—According to the *Electrical Engineer* of New York the withdrawal of the accumulator cars which have been running on the Lehigh Avenue Railroad, Philadelphia, from May 1, 1890, to January 16, 1891, was due to the unfavourable character of the line. Only four cars were in regular work, the traffic was subject to great fluctuations, and the track (3·15 miles long) had scarcely a level spot on it, 5 per cent. gradients and sharp curves being frequent. The total weight of the cars when fully loaded was between 9 and 10 tons. Two 116 cell batteries were employed per car, and the mean horse-power required per ton was ultimately reduced to 1·15. Worm and worm wheel gears were employed, the ratio of worm to wheel being 1 to 8. Tests of the gear at speeds equivalent to between 5 and 10 miles an hour of the car showed that the mean efficiency was 82 per cent., with a mean of 12 mechanical horse-power on the axle. The maximum efficiency was 85 per cent. at 550 revolutions of the armatures (equal to about 5½ miles an hour of the car). During the 8½ months that the cars were in operation they carried 336,454 passengers.

**The Paris Electric Lighting Companies.**—The net profits of the Compagnie Parisienne du Gaz amounted last year to close on 1¼ million sterling. Its subscribed capital is 11¼ millions, and it has been 35 years in existence. At the last meeting of shareholders it was announced that the million of additional capital authorised in 1887 had been exhausted, and power was asked to raise another million sterling. These facts, says the *Bulletin International de l'Electricité*, should not surely be lost on those engaged in electrical enterprises. The lighting industry, whether gas or electric, demands incessant additions to capital. A system, as soon as it has passed the period of first establishment, develops so rapidly and so extensively that it is useless to expect the annual profits to cover the additional expenditure entailed. If an old, solidly established company is obliged to borrow, the young electric companies will not be able to avoid doing likewise. It being thus necessary to unceasingly augment the capital of electrical companies on the one hand, while on the other it has to be redeemed within a comparatively brief period (in Paris at the most eighteen years), the conclusion one must come to is that in Paris either the area of operations must be strictly limited, or the concessions must be prolonged.

**Electric Light Cables.**—Under this title the India Rubber, Gutta Percha, and Telegraph Works Company, of Silvertown, have recently brought out a very readable pamphlet, advocating, it is needless to say, the employment of rubber cables on the frequently reiterated ground that other kinds of insulated conductors will be found "more expensive in the long-run." Useful hints are given with regard to the erection of overhead wires, the laying of underground mains, and the testing of electric-light mains. The Board of Trade regulations in connection with overhead conductors are embodied in the pamphlet and somewhat criticised. It is pointed out that a minimum size of conductors should be specified, and that although care is taken to ensure that an insulator of the proper thickness shall be employed, no test of its resistance is specified. The danger of shocks from electrostatic charges when the bearer wires are insulated as laid down by the rules is pointed out, and it is suggested that if the rule is adhered to it would be a good thing to break the bearer wires up into sections and attach them separately, as by this means the discharge received would be limited to the charge on a single section. Attention is also drawn to the excessive wind-pressure allowance of 50lb. per square foot.

**The Comparative Cost of Arc and Sunbeam Lamps.**—At a meeting of the South Wales Institute of Engineers, Mr. Polyblank gave, says *Engineering*, some interesting particulars of his experience with arc and sunbeam lamps at Swansea Docks. He finds that a 2,000 c.p. 10-ampere arc with two 11 mm. carbons 12in. long, burns 12 hours. The cost of such a lamp, working from sunset to sunrise throughout the year, or about 4,374 hours, was as follows:—

| | £ | s. | d. |
|---|---|---|---|
| Carbons per annum, at £5. 5s. 1,000 | 5 | 14 | 7 |
| Coal—8 tons per lamp, at 14s. | 5 | 12 | 0 |
| Labour—cleaning lamps, changing carbons and globes, one man to every 20 lamps = 3d. per lamp per day | 4 | 12 | 0 |
| Making a total of | 15 | 18 | 7 |

per lamp per annum, or £3. 12s. 10d. per 1,000 hours.

The average length of life of a 500 c.p. sunbeam lamp, Mr. Polyblank's experience shows to be about 1,500 hours, though some break after only 400 hours' work. The cost of working was as follows:—

| | £ | s. | d. |
|---|---|---|---|
| Renewal of lamps, three per annum at 22s. each | 3 | 6 | 0 |
| Coal—12 tons per annum at 14s. | 8 | 8 | 0 |
| Labour—in changing lamps three per annum, say | 0 | 5 | 0 |
| Making a total cost of | 11 | 19 | 0 |

per lamp per year, or £2. 14s. 8d. per 1,000 hours.

The lamps when first put up took 10 amperes at 100 volts, but after the lapse of from 800 to 1,000 hours, the current is reduced to 8·5 amperes. The globes blacken somewhat, but not so seriously as might be imagined.

**The Electrolytic Preparation of Chlorate of Potassium.**—For the past ten months the manufacture of chlorate of potassium by the Gall-Montlaur electrolytic process has been successfully carried out at Vallorbes. The daily output now amounts to one ton of refined chlorate. According to *La Lumière Electrique*, M. Lunge states that one H.P. day = one kilogramme of potassic chlorate, hence a daily production of one ton requires 1,000 H.P. The process is based on the transformation of a 25 per cent. solution of chloride of potassium (KCl) at a temperature of from 45°C. to 55°C., into chlorate ($KClO_3$) by the action of the chlorine and potassium liberated by electrolysis. The chlorate is precipitated, collected, washed, dried, and purified. One of the preliminary difficulties was the selection of suitable connections for the electrodes, since the slightest trace of certain metallic oxides in the solution arrests the process. The vats are 270 in number (half being in use at one time), rectangular in shape, and arranged so as to permit of the rapid handling of a volume of liquid amounting to 11,000 gallons per diem. A porous diaphragm separates the kathodes from the anodes, the former being of iron and the latter of platinum (four mils thick). The solution is kept at the proper temperature by the current itself. Power is obtained from the falls of the Orbe, which can supply 2,500 H.P. At present there are installed at the generating station 10 150-H.P. Riether turbines, and 10 105-kilowatt Thury dynamos. The generating plant is at the foot of a mountain, the works themselves being 330ft., and the reservoir 230ft. above the station. This arrangement has the two-fold advantage of obtaining a great head of water and of removing the machinery out of reach of the fumes given off in the process. The hydrogen liberated at the kathode amounts to 3,530 cubic feet per ton of chlorate turned out, and as this large volume of gas escapes into the air, carrying with it a certain amount of chloride of potassium, the vicinity of the works is coated with a thick, white saline deposit of a highly erosive character. With ample water-power available, the electrolytic process can undersell the chemical process, although at present only 400 tons per annum is being being produced by it as against 8,000 tons by the older method. Some 5,000 tons of this total is produced by the works of the Chemical Union. The electrolytic process is cleaner, simpler, quicker, leaves no residue, and needs no coal for mere heating purposes.

## ELECTROMAGNETIC THEORY.—IX.

BY OLIVER HEAVISIDE.

(Continued from page 722.)

§ 53. In order to clearly understand the sense in which motion of a charge through a medium, or motion of the medium itself, or of both together with respect to fixed space, is to be understood, and of the part played therein by the motional electric and magnetic forces, it will be desirable to give a few illustrative examples of such a nature that their meaning can be readily followed from a description, without the mathematical representation of the results. It does not, indeed, often happen that this can be done with profit and without much circumlocution. In the present case, however, it is rather easier to see the meaning of the solutions from a description, than from the formulæ.

In the first place, let us start with a single charge $\rho$ at rest at any point A in an infinite isotropic non-conducting dielectric —ether, for example—which is also at rest. Under these circumstances the stationary condition is one of isotropic radial displacement from the charge at A according to the inverse-square law, and there is nothing to disturb this distribution.

Now, if the whole medium and the charge itself are supposed to have a common motion (referred to an assumed fixed space, in the background, as it were), no change whatever will take place in the distribution of displacement referred to the moving charge. That this should be so in a rational system we may conclude from the relativity of motion (the absolute motion of the universe being quite unknown, if not inconceivable) combined with our initial assumption that the electric flux (and the magnetic flux not here present) represent states of the medium, which may be carried with it just as states of matter are carried with matter in its motion. But as the charge, and with it the displacement, move through space as a rigid body without rotation, the changing displacement at any point constitutes an electric current, and therefore would necessitate the existence of magnetic force, if we treated the first law of circuitation in its primitive form, referred to a stationary medium. Here, however, the motional magnetic force, which is (§§ 44, 49) the vector-product of the displacement and the velocity of the medium, comes into play, and it is so constructed as to precisely annul all magnetic force under the circumstances, and leave the displacement (referred to the moving medium) unaffected; or, in another form, it changes the law of circuitation (curl $\mathbf{H} = \mathbf{J}$) referred to fixed space, so as to refer it in the same form to the moving medium.

The result is $\mathbf{H} = 0$, and $\mathbf{D}$ moves with the medium.

Similar remarks apply to other stationary states. They are unaffected by a common motion of the whole medium and the sources (or quasi-sources), and this result is mathematically obtained by the motional electric and magnetic forces.

§ 54. But the case is entirely altered if the charge and the medium have a relative translational motion.

Start again with charge and medium at rest, and the displacement stationary and isotropically radial. Next, introduce the fact (the truth of which will be fully seen later) that the medium transmits all disturbances of the fluxes through itself at the speed $(\mu c)^{-\frac{1}{2}}$, which call $v$; and let us suddenly set the charge moving in any direction rectilinearly through the medium at this same speed, $v$. The question is, what will happen?

A part of the result can be foreseen without mathematical investigation; the remainder is an example of the theory of the simplest spherical wave given by me in "Electromagnetic Waves." Let A (in Fig. 1) be the initial position of the charge when it first begins to move, and let AC be the direction of its subsequent motion. Describe a sphere of radius $AB = vt$; then, at the time $t$ the charge has reached B. Now, from the mere fact that the speed of propagation is $v$, it follows that the displacement outside the sphere is undisturbed. It is clear that there cannot be any change to the right of B, because the charge has only just reached that place, and disturbances only travel at the same speed as it is moving itself. Similar considerations applied to the expanding sphere through this charge at every moment of its passage from A to B will show that no disturbance can have got outside the sphere. The radial lines, therefore, represent the actual displacement, as well as the original displacement, though of course, in the latter case, they extended to the point A.

We have now to complete the description of the solution. There is no displacement whatever inside the sphere BEDF. The displacement emanating from the charge at B, therefore, joins on to the external displacement over the spherical surface. We can say beforehand that it should do so in the simplest conceivable manner, by the shortest paths. On leaving the pole B it spreads uniformly in all directions on the surface of the sphere, and each portion goes the shortest way to the opposite pole D. But it leaks out externally on the way, in such a manner that the leakages are equal from equal areas. The displacement thus follows the lines of longitude.

This completes the case so far as the displacement is concerned. But the spherical surface constitutes an electromagnetic sheet, and corresponding to the displacement there is a distribution of coincident induction. This induction is perpendicular to the tangential displacement, and therefore follows the lines of latitude. Its direction is up through the paper above A (at E for example), and down through the paper below A (at F for example). The tangential displace-

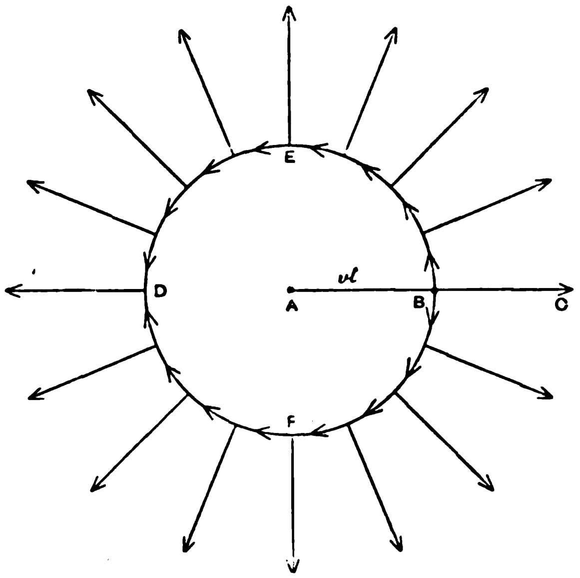

Fig. 1.

ment and induction surface-densities (or fluxes per unit area of the sheet), say, $D_0$ and $B_0$, are connected by the equation

$$B_0 = \mu v D_0,$$

or,
$$D_0 = cvB_0.$$

Or, if $E_0$ and $H_0$ be the equivalent forces got by dividing by $c$ and by $\mu$ respectively, then, since $\mu c v^2 = 1$,

$$H_0 = cvE_0,$$
$$E_0 = \mu v H_0.$$

Or, expressing the mutual directions as well,

$$\mathbf{H}_0 = \mathrm{V}\mathbf{v}\mathbf{D}_0,$$
$$\mathbf{E}_0 = \mathrm{V}\mathbf{B}_0\mathbf{v};$$

where $\mathbf{v}$ is the vector velocity of the electromagnetic sheet at the place considered. These last are, in fact, as we shall see later, the general equations of a wave-front or of a free wave, which though it may attenuate as it travels, does not suffer distortion by mixing up with other disturbances.

Now, as time goes on, the charge at B moves off to the right, the electromagnetic sheet simultaneously expanding. The external displacement, therefore, becomes infinitesimal; likewise that on on the D side of the sphere. Practically, therefore, we are finally left with a plane electromagnetic sheet moving perpendicularly to itself at speed $v$, at one point of which

is the moving charge, from which the displacement diverges uniformly in the sheet, following, therefore, the law of the inverse first power (instead of the original inverse square), accompanied by a distribution of induction in circles round the axis of motion, varying in density with the distance according to the same law, and connected with the displacement by the above equations. In the diagram, AB has to be very great, and the plane sheet is the portion of the spherical sheet round B, which is then of insensible curvature.

§ 55. Having thus turned the radial isotropic displacement of the stationary charge into a travelling plane distribution, let us suddenly reduce the charge to rest. We know that after some time has elapsed, the former isotropic distribution will be reassumed; and now the question is, how will this take place?

Let B in Fig. 2 be the position of the charge at the moment of stoppage and after. Describe a sphere of radius $vt$, with B for centre; then the point C is where the charge would have got at time $t$ after the stoppage had it not been stopped, and the plane DCE would have been the position of the plane electromagnetic sheet. Now, the actual state of things is described by saying that:—

(1). The plane sheet DCE moves on quite unaltered, except at its core C, where the charge has been taken out.

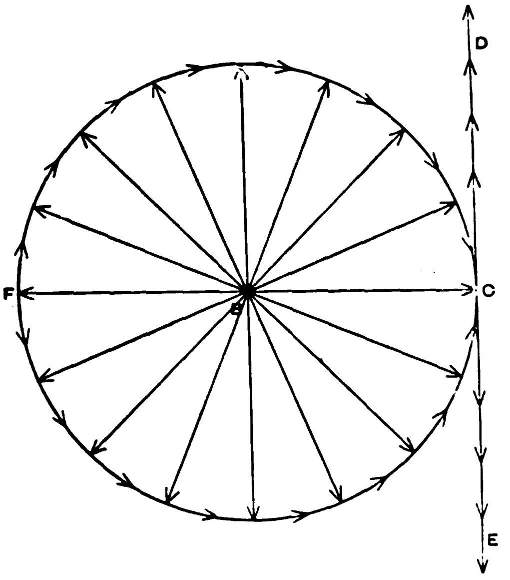

Fig. 2.

(2). The stationary radial displacement of the charge in its new position at B is fully established within the sphere, without any induction.

(3). The internal displacement joins itself on to the external in the plane sheet, over the spherical surface, by leaking into it and then following the shortest route to the pole C. That is, the tangential displacement follows the lines of longitude.

(4). The induction in the spherical sheet is oppositely directed to before, still, however, following the lines of latitude, and being connected with the tangential displacement by the former relations.

In time, therefore, the plane sheet and the spherical sheet go out to infinity, and there is left behind simply the radial displacement of the stationary charge.

§ 56. Now, return to the case of § 54, and referring to Fig. 1, suppose it to be the charge that is kept at rest, whilst the medium is made to move bodily past it from right to left at speed $v$, so that the relative motion is the same as before. We must now suppose B to be at rest, the charge being there originally, and remaining there, whilst it is A that is travelling from right to left, and the spherical surface has a motion compounded of expansion from the centre A and translation with it. Attending to this, the former description applies exactly.

The external displacement is continuously altering, and there is electric current to correspond, but there is no magnetic force (except in the spherical sheet), and this is, as before said, accounted for by the motional magnetic force.

The final result is now a stationary plane electromagnetic sheet, as, in fact, described before in § 45, where we considered the displacement and induction in the sheet to be kept up steadily by electric and magnetic forces impressed by the motion.

Now stop the motion of the medium, without altering the position of the charge, and Fig. 2 will show the growth of the radial stationary displacement, as in § 55, as it is in fact the same case precisely after the first moment.

We can in a similar manner treat the cases of motion and stoppage of both charge and medium, provided the relative speed be always the speed $v$, however different from this may be the actual speeds.

§ 57. From the two solutions of §§ 54, 55 (either of which may be derived from the other) we may deduce a number of other interesting cases.

Thus, let initially a pair of equal opposite charges $+\rho$ and $-\rho$ be moving towards one another, each at speed $v$ through the medium (which for simplicity we may consider stationary) each with its accompanying plane electromagnetic sheet.

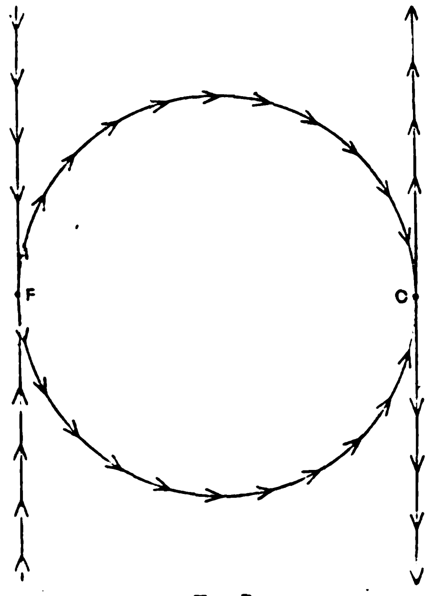

Fig. 3.

When the charges meet the two sheets coincide, the two displacements cancel, leaving none, and the two inductions add, doubling the induction. We have thus, momentarily, a mere sheet of induction.

Now, if we can carry the charges through one another, without change in their motion, the two sheets will immediately reappear and separate. That is, the plane waves will pass through one another, as well as the charges.

But if the charges cancel one another continuously after their first union, a fresh case arises. It is, given a certain plane sheet of induction initially, what becomes of it, on the understanding that there is to be no electrification?

The answer is, that the induction sheet immediately splits into two plane electromagnetic sheets, joined by a spherical sheet, as in Fig. 3. For it is the same as the problem of stoppage in § 55 with another equal charge of opposite kind moving the other way and stopped simultaneously, so that there is no electrification ever after. Touching the sphere at the point F in Fig. 2 is to be placed the additional plane wave, and the internal displacement is to be abolished. That is to say, in Fig. 3 the displacement converges uniformly to F in the plane sheet there, then flows without leakage to the opposite pole C along the lines of longitude, and there diverges uniformly in the other plane sheet. Each displacement sheet has its corresponding coincident induction, according to the former formulæ.

Digitized by Google

They all move out to infinity, leaving nothing behind, as there is no source left.

§ 58. Similarly, let there be a pair of coincident or infinitely close opposite charges, with no displacement, and let them be suddenly jerked apart, each moving at the speed of propagation of disturbances. The result is simply a single spherical wave, without plane appendages, and without leakage of the displacement. The charges are at opposite poles, at the ends of the axis of motion, and the displacement just flows over the surface from one to the other symmetrically. There is the usual induction $B_0 = \mu v D_0$ to match.

Fig. 3 also shows this case, if we leave out the plane sheets and suppose the positive charge to be at F and the negative at C.

After a sufficient time, we have practically two widely separated plane electromagnetic sheets, although they are really portions of a large spherical sheet.

Now, imagine the motion of the two charges to be reversed; if we simultaneously reverse the induction in the spherical sheet, without altering the displacement, it will still be an electromagnetic sheet, but will contract instead of expanding. It will go on contracting to nothing when the charges meet. If they are then stopped nothing more happens. But if the charges can separate again, the result is an expanding spherical electromagnetic sheet as before.

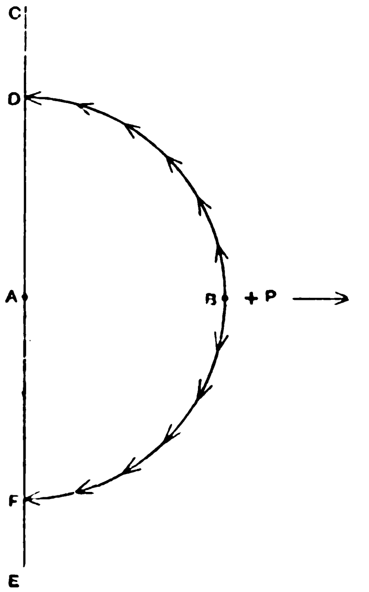

Fig. 4.

§ 59. If, in the case of colliding plane sheets with charges, § 57, they be of the same name, then, on meeting, it is the induction that vanishes, whilst the displacement is doubled. That is, we have momentarily a plane sheet of displacement.

If the charges be kept together thereafter, this plane sheet splits into two plane electromagnetic sheets joined by a spherical sheet. At the centre of the last is the (doubled) charge $2\rho$, which sends its displacement isotropically to the surface of the sphere, where it is picked up and turned round towards one pole or the other. The equator of the sphere is the line of division of the oppositely flowing displacements. The displacement gets greater and greater as the poles are neared, the total amount reaching each pole being $\rho$ (half the central charge), which then diverges in the plane sheet touching the pole.

The final result, when the waves have gone out to infinity, is, of course, merely the stationary field of the charge $2\rho$.

§ 60. If a charge be initially in contact with a perfectly conducting plane, and be then suddenly jerked away from it at the speed $v$, the result is merely a hemispherical electromagnetic shell. The negative charge, corresponding to the moving point-charge, expands in a circular ring upon the conducting plane, this ring being the equator of the (complete) sphere.

This case, in fact, merely amounts to taking one half of the solution in § 58, and then terminating the displacement normally upon a conductor.

In Fig. 4, A is the original position of $\rho$ on the conducting plane CAE, and when the charge has reached B the displacement terminates upon the plane in the circle DF.

Instead of a plane conducting boundary, we may similarly have conical boundaries, internal and external (or one conical boundary alone), with portions of perfect spherical waves running along them at the speed $v$.

If the two conical boundaries have nearly the same angle, and this angle be small, we have a sort of concentric cable (inner and outer conductor with dielectric between), of continuously increasing thickness. The case of uniform thickness is included as an extreme case; the (portion of the) spherical wave then becomes a plane wave.

§ 61. The nature of a spherical electromagnetic sheet expanding or contracting at speed $v$, when it is charged in an arbitrary manner, may also be readily seen by the foregoing. So far, when there has been electrification on the sheet, it has been a solitary point-charge or else a pair, at opposite poles. Now, the general case of an arbitrary distribution of electrification can be followed up from the case of a pair of charges *not* at opposite ends of a diameter, and each of these may be taken by itself by means of an opposite charge at the centre or externally, so that integration does the rest of the work. When there is a pair of equal charges of opposite sign we do not need any external or internal complementary electrification, but we may make use of them argumentatively; or we may let one charge leak outward, the other inward, and have the external and internal electrification in reality. The leakage should be of the isotropic character always. But the internal electrification need not be at the central point. It may be uniformly distributed upon a concentric sphere. This, again, may be stationary, or it may itself be in motion, expanding or contracting at the speed $v$. The external electrification, too, may be on a concentric spherical surface, which may be in similar motion. The sheets, too, may be of finite depth, and arbitrarily electrified, so that we have any volume-distribution of electrification moving in space in radial lines to or from a centre, accompanied by electromagnetic disturbances arranged in spherical sheets.

There is thus a great variety of ways of making up problems of this character, the nature of whose solutions can be readily pictured mentally.

Two charges, $q_1$ and $q_2$, for example, on a spherical sheet. One way is to put $-q_1$ and $-q_2$ at the centre, and superpose the two solutions. Or the charges $-(q_1$ and $q_2)$ may be put externally, with isotropic leakage. Or part may be inside, and part outside. Or we may have no complementary electrification at all, but lead the displacement away into plane waves touching the sphere.

Only when the total charge on the spherical sheet is zero can we dispense with these external aids (which to use depending upon the conditions of the problem); then the displacement has sources and sinks on the sheet which balance one another. The corresponding induction is always perpendicular to the resultant tangential displacement, and is given by the above formula, or $\mathbf{B}_0 = \mu V \mathbf{v} \mathbf{D}_0$, where $\mathbf{D}_0$ is the tangential displacement in the sheet (volume density × depth).

One case we may notice. If the density of electrification be uniform over the surface, there is no induction at all. That is, it is not an electromagnetic sheet, but only a sheet of electrification, without tangential displacement, and therefore without induction.

So, with a condenser consisting of a pair of concentric shells uniformly electrified, either or both may expand or contract without magnetic force. This is, however, not peculiar to the case of motion at speed $v$. Any speed will do. But in general, if the speed be not exactly $v$, there results diffused disturbances. The electromagnetic waves are no longer of the same pure type.

## THE MAGNETIC CIRCUIT OF TRANSFORMERS: CLOSED VERSUS OPEN.

BY S. EVERSHED.

(*Concluded from page 757.*)

§ **78.** So much for the theory of idle current supply by condensers. It is too soon to expect any practical results of importance, but there is no reason to expect any insurmountable difficulties in making large condensers capable of withstanding 2,000 volts or more. Meanwhile it may be useful to give a rough calculation of the probable dimensions of a condenser to supply one ampere at 2,000 volts with a frequency of 100 ∿. According to our formula,

$$K = \frac{C}{2\pi E F} = \frac{1}{2\pi \times 2{,}000 \times 100} = \cdot 8 \text{ microfarad.}$$

This must be converted into electrostatic units before we can determine the size, number, and thickness of the dialectric films. One microfarad is equal to $1 \times 10^{-15}$ C.G.S. (magnetic) units, and to convert this into static units it must be multiplied into $v^2$, or $(3 \times 10^{10})^2$, so that

$$\begin{aligned} \cdot 8 \text{ microfarad} &= \cdot 8 \times 10^{-15} \times 9 \times 10^{20} \\ &= \cdot 8 \times 9 \times 10^{5} \\ &= 7{\cdot}2 \times 10^{5} \text{ electrostatic units.} \end{aligned}$$

§ **79.** If each film has an area of 1,000 square cms. (roughly one square foot), and a thickness of ·05cms., and if we further assume the dielectric constant to be about twice that of air, the capacity per film will be

$$\frac{2 \times 1{,}000}{4\pi \times \cdot 05} = 3{,}200 = \cdot 032 \times 10^{5}.$$

and $\frac{7{\cdot}2}{\cdot 032} = 225$ nearly enough, so that it would require 225 films of dielectric to supply one ampere. If the conducting plates are half the thickness of the films the total thickness of the condenser will be nearly 17cms. Such a condenser would go into a box 14in. by 14in. by 8in., but this is the size wanted to supply one 10 H.P. open transformer—No. 2 as a Hedgehog required about ·9 ampere—and a fair output for a central station would mean from 50 to 100 such condensers, but even then the space occupied by them is not a very serious matter. Of course, a dielectric may be discovered, a very thin film of which would suffice to withstand 2,000 volts; but it is reasonable to suppose that in the fierce race for the best covering for high-tension mains all the really serviceable materials have already been unearthed. It is curious that one of the best materials from a mechanical point of view, turns out to be about the worst electrically; in seeking for a strong dielectric one naturally expects to find glass a thoroughly satisfactory material. It is usually supposed to be capable of standing enormous electrical stresses, though so far as the writer is aware no determinations of the potential differences required to pierce glass of given thickness and composition have ever been published, and he can therefore only quote from results noticed by himself while using a large induction coil. The coil terminals being connected to glass Leyden jars, it was noticed that when the latter were giving sparks some three or four inches in length they would usually burst after a short time, although a jar here and there would successfully stand the enormous force. The glass of these jars was about ·5cm. thick, and taking a four-inch spark to represent 100,000 volts, we may conclude that 200,000 volts per cm. is certainly very close to and probably beyond the breaking stress for the glass of which these particular jars were composed. Taking this figure as a guide, a glass film ·015cm. thick would be at its breaking point with 3,000 volts, or say 2,000 effective volts from an alternate current circuit. Allowing a factor of safety of 4, the films would require to be about ·06cm. thick. The dielectric "constant" for glass is one of those puzzling quantities which are only called constant because it would be so extremely convenient if they were so. The specific inductive capacity for glass is given by Fleming Jenkin (Electricity and Magnetism) as 1·9, while Dr. Hopkinson found values ranging from 6·7 to 9·9. The true constant might be expected to be equal to the square of the refractive index for infinitely long light waves, and the index for the glass used in Hopkinson's determinations is given as ranging from 1·5 to 1·6 (Fleming's "Alternate Current Transformer," Vol. I, p. 345). These figures indicate the value 2·5 as the electric constant required by Maxwellian theory. It seems probable that the large discrepancy between this value and those observed by Dr. Hopkinson is due to something akin to electrolytic conduction, in which case we should expect glass to ultimately break down from decomposition even supposing it able to stand without cracking, the rise of temperature due to the local conduction currents in it. Evidently glass has too complex a composition for use in alternate current condensers.

§ **80.** Since writing the above Mr. Swinburne has described the progress made by Mr. Bourne and himself in the search for dielectrics, in a short Paper read at the Physical Society. The best results have been obtained from paper saturated with some hydrocarbon oil, and probably condensers made on some such lines will ultimately come into general use. One small difficulty not apparently noticed by Mr. Swinburne in the course of his experiments is that most hydrocarbon oils contain traces of the acids used in refining, and this naturally tends to diminish their specific resistance. Solid hydrocarbons on the other hand, while excellent in their insulating quality are liable to crack, and any discontinuity in the dielectric film is fatal. We may take it for granted then, that condensers are quite feasible. Their cost is another matter altogether and one which time alone can settle.

§ **81.** We are now in a position to give some sort of answer to the question we set out to discuss, namely, which are the more economical, closed or open transformers? Perhaps the best way of putting the conclusions arrived at before the reader will be simply to consider the annual cost of the power wasted in the cores of the typical transformers which have served as examples in these Papers. Take the case of a supply company running a 600 kilowatt station. According to the figures adduced by Mr. Crompton, in his celebrated Paper on Central Station Lighting (*Journal* Soc. Tel. Eng., Vol. XVII., p. 361), the total cost of the plant, inclusive of mains and transformers, would be about £60,000. Suppose for the sake of argument we assume Mr. Crompton's coefficient to be nearly two, and put the capital outlay at £100,000 for the 600 kilowatt plant. The maximum transformer capacity must be about 1,000 h.p., and we may conveniently divide this into 100 transformers of 10 h.p. each. If the Ravenshaw transformer is used with its original winding, the core waste will amount to 9·6 B.T. units per diem, or 3,500 units per annum per transformer. It is impossible at present to obtain reliable information as to the actual running expenses of alternate current plants but it has been stated at about fourpence per unit delivered to the consumer; but in reckoning the cost of waste power it is clear that we must only take the coal and oil consumption into account, the only appreciable saving to be effected by a diminution in waste power being in cost of materials. Wages and fixed charges remain as before. Probably one penny per unit is a reasonable sum to allow in the case of waste power. At this rate 3,500 units will cost about £15; that is to say, the Company will virtually spend £1,500 per annum in heating the cores of its transformers. This, let it be remembered, is a fixed charge depending solely on the design and average size of the transformers, and not at all on their useful output. They may run at full load continuously from one year's end to another, and the engineers of the company may point with pride to the 95 per cent. efficiency of their converters, but the waste goes on just the same and the company which succeeded in cutting down the whole of the core waste would add nearly 1½ per cent. to its dividend.

§ **82.** Replace the transformers by the No. 2 closed modification, wasting 3·94 units per diem or just under £6 per annum; the waste in 100 such transformers will be £600 per annum, as against £1,500 for the original transformers, a clear gain of £900 per annum. But there is the additional capital outlay in copper. The saving in running expenses is effected by putting something like 180lbs. more copper in the coils adding

Digitized by Google

perhaps £25 to the price of each converter, so that for an additional outlay of £2,500 a saving of £900 per annum is effected. Evidently a good investment. Will it pay to convert No. 2 into a Hedgehog like Fig. 15? So far as the transformers themselves are concerned it certainly will. No. 2 as an open transformer with small Hedgehog ends (Fig. 15), wastes 1·94 units per diem in its core, to which the constant $C^2R$ waste for exciting current must be added, bringing the whole constant waste up to 2·14 units costing £320 per annum for 100 such transformers. This is an additional saving of £280, compared with the same transformers with closed magnetic circuits. Of course one cannot be sure of this saving unless the idle current is supplied by condensers, so that the light load may be taken by a portion of the station plant fairly well loaded. It should be noticed that transformer No. 2 would certainly cost less to build with an open than with a closed magnetic circuit, so that although £280 seems hardly worth saving by itself, the saving in capital outlay is an additional advantage. What that saving would be it is impossible to say, as manufacturers of electrical plant do not publish their prime costs and list prices are generally meaningless. The whole point really turns on this: To effect any appreciable saving by means of open transformers condensers must be used. Inclusive of condensers can they be supplied at the same cost as transformers with closed cores? If that question is decided in favour of open magnetic circuits there would still be the extra complication and liability to breakdowns introduced with condensers to be taken into account. A single disaster with the condensers would probably more than wipe out the whole annual saving in the transformers.

§ **83.** Since an open transformer is economical by reason of the small amount of iron in its core, why not take the next step and use no iron at all? The dimensions of a coreless transformer are

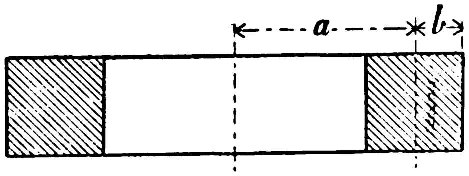

Fig. 25. Section through circular coil forming primary and secondary windings of 10 h.p. coreless transformer. 1/10 full size.

easily calculated if we assume some convenient shape for the coils. Suppose we design a coreless transformer which shall require the same weight of copper as No. 2 (either open or closed) and work with the same resistance drop, namely 2·8 per cent.; the problem then reduces itself to finding the size of a bobbin on which to rewind the coils used in No. 2, and as we want to keep down the exciting current to its smallest possible value, we must evidently wind the wire so that the product of induction due to unit current into the number of turns on the coil (in short L) is a maximum. A solution of this problem has been given by Gauss but it will be better to work it out here independently.

The self induction in a coil whose average diameter is large compared with the cross sectional area of the winding is approximately:—

$$L = 4\,\pi\,N^2\,a\left(\log_e \frac{8\,a}{R} - 2\right), \quad . \quad . \quad . \quad (1)$$

where N is the number of turns of the coil, $a$ is the average radius and R the average distance of the wires from each other (geometrical mean distance). We may take the cross section of the bobbin as being square, as shown in Fig. 25. The area of section is $4\,b^2$, one-half of which may be taken to represent insulation, the remainder being available for copper. In calculating for minimum exciting current we have only to deal with the primary coil, the copper of which will have a cross section equal to $b^2$. Its volume is known, for as we have 240lbs. of copper on No. 2 we may assume that we shall use 120lbs. on the primary, or the volume will be

$$V = 6055 \text{ cc.}$$

The primary and secondary being supposed to be well mixed will each cover the whole cross section, so that the geometrical mean distance of the primary winding from itself will be

$$R = \cdot447 \times 2\,b = \cdot894\,b.$$

§ **84.** From these equations we are able to eliminate N and $a$ from (1) for

$$a = \frac{V}{2\,\pi\,b^2}$$

and

$$N^2 = \frac{r\,b^4}{\rho\,V}$$

where $\rho$ is the specific resistance of copper, and $r$ is the resistance of the primary, which must be 7·6 ohms. to make the full load-drop equal 2·8 per cent. as before. Substituting the values of $N^2$ and $a$ so determined, we get

$$L = \frac{2\,r\,b^2}{\rho}\left(\log. \frac{4\,V}{\cdot894\,\pi\,b^3} - 2\right), \quad . \quad . \quad . \quad (2)$$

so that

$$\frac{d\,L}{d\,b} = \frac{2\,r}{\rho}\left\{2\,b\,(\log. 4\,V - \log. \cdot894\,\pi - 3\log. b - 2) - 3\,b\right\}.$$

The right-hand side vanishes if $b = 0$, which is an impossible but obvious solution, and the maximum we are seeking occurs when $\frac{d\,L}{d\,b}$ is made to vanish by writing

$$\log. 4\,V - \log. \cdot894\,\pi - 3\log. b - 2 - \frac{3}{2} = 0 \quad . \quad . \quad (3)$$

solving (3) for $b$ we find $b =$ 6·38 cms.

and, therefore, $a = 23·7$ „
R = 5·7 „
N = 1100 turns.

With these values we can determine the induction threading the coil due to one ampere, for

$$L = B_{10} N,$$

where $B_{10}$ is the induction for 10 amperes (*c.g.s.* unit), and putting real values into (1) we find

Induction per ampere = 49,500 thoms *

If the coil is run at 2,000 volts, at a frequency of 70 ∿, the exciting current will be given by the equation

$$B' = 49{,}500\ C' = \frac{2{,}000 \times 10^8}{4{\cdot}4 \times 1{,}100 \times 70},$$

from which C′ = 12 amperes,

or

$$C = \frac{12}{\sqrt{2}} = 8{\cdot}5 \text{ amperes.}$$

§ **85.** Of course, no one would dream of working with an exciting current more than twice as great as the full load current which for 10 h.p. is 3·75 amperes. To obtain a reasonable exciting current we may either use more copper or raise the frequency, and we will adopt the latter expedient, for there being no core there is no reason for running at a low frequency, at least so far as the transformer is concerned. Neither is there any reason to reduce the exciting current below that required for No. 2 as a Hedgehog, namely, ·9 ampere. The exciting current being inversely proportional to the frequency, we must raise the latter to:—

$$F = 70\ \frac{8{\cdot}5}{\cdot9} = 660 \ \text{∿ per second.}$$

this is far higher than anything yet adopted in practice, and at such a frequency eddy currents in every part of the system from alternator to transformers would be a serious item. But the whole of the exciting current is idle in a coreless transformer, and if it is supplied by a condenser we may arrange the frequency so that the condenser used for No. 2 would serve for the coreless transformer, for the idle current output of a condenser is directly proportional to the frequency. To find the appropriate frequency to fit the condenser required by No. 2 we have first the following data:—

Condenser supplies ·9 ampere at 70 ∿

It therefore supplies $\frac{\cdot9}{70}$ „ at 1 ∿

* One *thom* = one "magnetic line of force." B throughout this investigation stands for *total* induction.

Digitized by Google

Or current supplied by condenser at frequency F is:—

$$C = \frac{\cdot 9}{70} F \quad . \quad . \quad . \quad . \quad . \quad . \quad (1).$$

Also, as we have seen the frequency needed to make the exciting current equal to ·9 ampere was 660∿, so for a current C it must be

$$F = 660 \frac{\cdot 9}{C} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2).$$

Eliminating C we have

$$F^2 = \sqrt{660 \times 70}$$

and $F = 215$ ∿ per second,

and therefore $C = 2{\cdot}76$ amperes.

§ **86.** The frequency just found is by no means excessive although somewhat higher than is now generally considered advisable. The efficiency of the coreless transformer is very high in spite of the large exciting current. At full load it is as follows:—

| | | |
|---|---|---|
| Output | 7,500 | watts. |
| $C^2R$ for exciting current | 58 | ,, |
| $C^2R$ for load | 212 | ,, |
| | 7,770 | |

$$\text{Efficiency} = \frac{750}{777} = 96{\cdot}5 \text{ per cent.}$$

and on the time load assumed throughout these articles its efficiency works out thus—

| | | |
|---|---|---|
| Output | 24,000 | watt hours |
| 24 hours' $C^2R$ for exciting | 1,390 | ,, ,, |
| 6 hours' $C^2R$ for load | 360 | ,, ,, |
| | 25,750 | |

$$\text{All day efficiency} = \frac{240}{258} = 93 \text{ per cent.}$$

§ **87.** Coreless transformers have many advantages. They are necessarily less wasteful than any other form of converter, they are far simpler to build, the trouble of insulating the coils from the core vanishes with the core, and the power wasted is so small that the transformer would keep perfectly cool. The 10 H.P coreless transformer just described would occupy a space of about 2 feet diameter and 6 inches deep, and it is difficult to imagine a safer arrangement than such a bobbin placed in an earthenware pan filled with oil and closed by an oil-tight lid. There are some disadvantages, perhaps serious ones; the high frequency leads to difficulties in designing alternators, and all eddy current effects would be nine times as great at three times the frequency and this may easily become a serious matter. Some trouble also would probably arise from the induction due to the load currents in the primary and secondary coils unless the windings were thoroughly mixed. The engineers of a company which had an eye to good dividends in spite of competition might be expected to overcome all these obstacles, though it is in the last degree unlikely that any directors will sanction an increase in capital outlay for the sake of a moderate saving in working expenses, until they have to supply energy at fourpence a unit or lose their trade. When that millennium arrives, and it most certainly will, the directors will worry the engineers. In the meantime it is clear that the condenser is the key of the whole question. If condensers are practicable, open cores for transformers will supersede closed magnetic circuits, and both may have to give place to the coreless transformer.

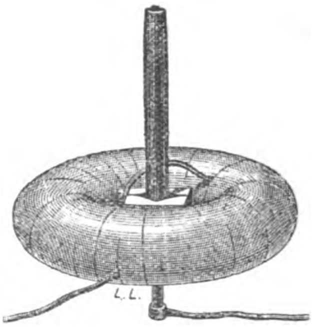
**A Submarine Cable Museum.**—According to the *Oesterreichisch-Ungarische Post*, Herr Schachner, superintendent of the Zara telegraph section, possesses an interesting collection of submarine cable samples which he has been twenty years collecting. It consists chiefly of lengths obtained when new cables were laid or old cables were repaired. The collection comprises specimens of gutta-percha, Hooper, and india-rubber cables. Examples of standard joints and cable apparatus, not to mention shells and marine animals, are also to be found in this museum. In every case where the defects of a cable were due to the injury done by the sea bottom, samples of the same are exhibited side by side with the cable injured.

## EXPERIMENTS WITH THE ELECTRIC ARC.

In *La Lumière Electrique* of April 25th, M. E. Raverot, referring to the experiments of Mr. Stanley, jun. (*The Electrician*, March 27th), in connection with a rotating arc, and to the application of that phenomenon made by Mr. J. D. F. Andrews (*The Electrician*, April 3rd), describes some attempts of his own to construct a continuous current electric candle on the same principle.

M. Raverot devoted his attention solely to the construction of continuous current candle to work under normal conditions of current and voltage. The diameter of the central carbon varied from 3 to 8 millimetres, and the maximum distance between the inner and outer carbons was 2mm. The directing solenoid was of the shape shown in the accompanying Figure. It consisted of a coil of 2·5mm. copper wire. It was used sometimes alone, and sometimes with a short iron tubular core When sufficient care was taken to obtain accurate centrality, no difficulty was experienced in securing satisfactory rotation of the arc. With regard to a suitable material for insulating the two carbons it was, however, quite otherwise. With air as the insulator it was practically not possible to easily obtain accurate centrality with the dimensions employed. This point is, however, an important one, because even without a solenoid and using a solid insulator, the arc always takes the curved shape and does not spread in a sheet between the carbons.

As a solid insulator it was natural to try first of all the well-known mixture of plaster and baryta which constituted the columbium of the Jablochkoff candle. This mixture, however, proved to be too fusible in the case of the



Continuous Current Candle with Rotating Arc.

continuous-current candle with the rotating arc. Perhaps it was not sufficiently baked, but it seems more probable that its inefficiency was due to the conditions of cooling, which are quite different to those which usually obtain. The following result affords an additional reason for so thinking:—On becoming acquainted with the dimensions given by Captain Gregory Ignatiev, for his annular candle in *La Lumière Electrique*, Vol. XXIV., p. 365, an attempt was made to reproduce it. The result was that the central carbon became incandescent from one end to the other. It seemed, therefore, that the arrangement of C. Binks described in *La Lumière Electrique*, Vol. XI., p. 203, was the one to follow. In this the central carbon is positive, and the two carbons are separated by refractory insulating substance. Ignatiev reversed this arrangement, and even proposed to use air only as the insulating medium.

M. Raverot is of opinion that the desired substance will be found to be one of the refractory oxides of the earthy metals, such as aluminium, magnesium, chromium, or zirconium, but as the use of these involves some manufacturing difficulties he experimented with porcelain, and he points out that upon the volatility of the refractory substance chosen depend the diameters and sizes of the carbons and the importance of the directing solenoid. Fine plaster, moulded and well baked, gave a practical result, and continuous-current candles, taking 12 amperes and 55 volts, were constructed for a private installation.

The excellent working of most modern arc lamps diminishes the interest of the continuous-current candle, but M. Raverot, nevertheless, thinks that a good solution of the problem would still meet with favour.

## FARADAY'S INSULATED ROOM.

The following communication has been sent us by Mr. F. C. Webb, together with a copy of his Paper from the *Philosophical Magazine* :—

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Sir William Thomson, in his interesting lecture on Electric and Magnetic Screening, alludes to Faraday's celebrated experiments with an insulated room.

I also performed an experiment with an insulated room, which I think deserves notice on such a subject.

Faraday electrified the *outside* of the room, and found no effect on electrometers, &c., *inside*.

I electrified the *in*side of the room, and found no effect on electrometers *out*side. Now, this would not in itself appear, at first sight, very important. But I performed my experiments in 1869, at Keyham Dockyard, to prove the truth of important theories I had published in 1860.

Up to that date all text-books alluded to the "earth as the great reservoir of electricity," and when any electricity disappeared it was always conveniently consigned to "the earth." I fought against the earth and the text-books for many a year, but not even my experiment of 1869 has kept the poor old earth from being maligned as a receiver of stolen goods.

Now, I appeal to you, Sir, when a plain, practical man takes advantage of Her Majesty's Dockyard, &c., in the pursuit of pure scientific truth, should not the results find a place in the books and papers connected with the subject?

I enclose you a copy of my article "On an Electrical Experiment with an Insulated Room," excerpt from the *Phil. Mag.* of September, 1872.—Yours, &c.

F. C. WEBB.

The following extract from the Paper describes the very interesting experiment :—

"The room was about 8ft. by 9ft. and about 8ft. high. The floor was of wood, and the sides of wooden framework covered with calico and with pieces of tinfoil pasted about it to make it a good conductor. It had a door and two windows of wire gauze. A small table was placed in it, and a frictional electrical machine was placed on this. The room was suspended by four double parts of half-inch round gutta percha band to a wooden frame, the floor being about 4ft. from the ground. The gutta percha was covered with paraffin; and the whole room was tested for insulation with five hundred Daniell's elements with a delicate astatic Thomson's reflecting-galvanometer, and gave no perceptible loss. A Peltier electrometer was placed on the ground outside; and a wire from the brass knob of this was connected to the gauze of the window. The table was connected with the tinfoil that was pasted about the surfaces of the room, so that when the rubber or prime conductor was connected to the table it was in connection with the sides of the room. Thus arranged, the machine acted to all appearance exactly the same as in an insulated room. When the rubber was connected to the table, on turning the glass disc the prime conductor was charged so as to give off sparks the same as when the room was uninsulated; and the conductor was completely discharged when touched to the insulated room. Not the slightest effect was produced on the electrometer, even when sparks were flashing from the prime conductor to the wire gauze of the windows to which the wire from the electrometer was attached. Connecting the room to the earth made no difference. A sphere about a foot in diameter was then charged when the room was insulated, and then handed out by an insulating handle, when the electrometer immediately diverged to about 50 degrees, showing that the outer surface of the room had become negative. On taking the sphere back into the room, the electrometer fell to zero."

It is evident that equal and opposite quantities of electrification were produced, and there was no reason why the electrometer outside should give any indication. The experiment of passing a charged ball out of the room is a very pretty proof of the immediate result of disturbing the balance of opposite electrifications. It appears probable that the machine would not have worked indefinitely, and that the results were due to the capacity of the room. For if the room be reduced to a minimum, or abolished, it is well known that a mere machine well insulated will not work. Our correspondent is not quite accurate in saying that he electrified the inside of the room. Faraday's "ice-pail" experiment is so well known to every student that we need not describe it here. Suffice it to say that any attempt to give a charge to the interior of a conductor can only result in electrification of its exterior.

## MEETINGS OF SCIENTIFIC SOCIETIES, &c.

**FRIDAY, May 1st.** (To-night).

ROYAL INSTITUTION.

*5 p.m.* Annual Meeting.

*9 p.m.* Evening Discourse. "Hawks and Hawking." By J. E. HARTING, F.L.S.

INSTITUTION OF MECHANICAL ENGINEERS.

*7.30 p.m.* Ordinary General Meeting.

**SATURDAY, May 2nd.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture. "The Dynamo." By Prof. SILVANUS P. THOMPSON, D.Sc.

**MONDAY, May 4th.**

ROYAL INSTITUTION.

*5 p.m.* General Monthly Meeting.

SOCIETY OF ENGINEERS.

*7.30 p.m.* Ordinary Meeting. Paper to be read: "Modern Coal Gas Manufacture." By C. C. CARPENTER.

**TUESDAY, May 5th.**

INSTITUTION OF CIVIL ENGINEERS.

*8 p.m.* Ordinary Meeting. Paper to be read with a view to discussion: "On Railway-Train Lighting." By WILLIAM LANGDON. At this meeting the monthly ballot for members will be taken, and after the adjournment at 9 p.m., the President and Council will hold a reception in the library.

**WEDNESDAY, May 6th.**

ROYAL SOCIETY.

*9 p.m.* Annual Conversazione.

SOCIETY OF ARTS.

*8 p.m.* Ordinary Meeting. Paper to be read: "The Sources and Applications of Borax," by E. L. FLEMING.

**THURSDAY, May 7th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture. "Recent Spectroscopic Investigations," by Prof. DEWAR, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS.

*8 p.m.* Ordinary General Meeting. Papers to be read: (1) "On some Effects of Alternating Current Flow in Conductors having Capacity and Self-induction," by Dr. J. A. FLEMING. (2) "Some points connected with Mains for Electric Lighting," by W. H. PREECE, F.R.S.

CHEMICAL SOCIETY.

*8 p.m.* Ballot for Election of Fellows, and Papers to be read.

**FRIDAY, May 8th.**

INSTITUTION OF CIVIL ENGINEERS.

*7.30 p.m.* Students' Meeting. Paper to be read: "Malta Dockyard Caisson." By J. WALTER BROWN, Stud. Inst. C.E.

ROYAL INSTITUTION.

*9 p.m.* Evening Discourse. "Liquids and Gases." By Prof. W. RAMSAY, F.R.S.

**SATURDAY, May 9th.**

ROYAL INSTITUTION.

*3 p.m.* Afternoon Lecture: "The Artificial Production of Cold." By H. GRAHAM-HARRIS, M. Inst. C.E.

*** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.

**Magnetic Screening.**—In a recent number of *Nature*, J. J. Borgman, of St. Petersburg, describes a neat lecture experiment in connection with magnetic screening. A Lecher's tube is put, by means of two cork rings, into another large (4 cm. diam.) glass tube, with a crane on one end. Holding the tube in one hand, and approaching it to a wire in which electrical waves are produced, a continuous illumination is to be seen in the Lecher's tube. This remains even if the large tube is filled with water. But if the tube is filled with dilute sulphuric acid the light disappears. When the crane is opened, and the acid flows out, the light is seen again, but only in that part of Lecher's tube which is not surrounded with the acid. The light in the Lecher's tube penetrates but very little below the level of the acid in the surrounding tube,

# The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
*Telephone No.* 2714. *Telegrams:* "ELECTRICIAN NEWSPAPER, LONDON."

*All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher, "*THE ELECTRICIAN,*" Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "*THE ELECTRICIAN*" Printing and Publishing Company, Limited, and be crossed "Coutts and Co." All other letters to be addressed to the Editor.*

*All letters intended for insertion in "*THE ELECTRICIAN,*" or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

*New Volumes of "*THE ELECTRICIAN*" commence in May and November.*

## SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

| | 3 months s. d. | 6 months. s. d. | 12 months. s. d. |
|---|---|---|---|
| For the United Kingdom | 5 0 | 10 0 | 19 6 |
| For Foreign Parts and Colonies:— Within Postal Union | 6 6 | 12 6 | 24 0 |
| For Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar | 7 6 | 14 6 | 28 0 |

## TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.*
**It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

*Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.*

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

## TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

## THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

*Early in each year is issued "*THE ELECTRICIAN*" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. The DIRECTORY was established in 1883, and the 1891 Edition, published on the 23rd February, 1891, consists of 900 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

*The issue for 1891 is ready, and should be ordered at once. Price 5s., post free 5s. 9d. Abroad postage extra. Full particulars on application.*

## ELECTRICAL BOOKS AND PUBLICATIONS

*All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "*THE ELECTRICIAN*" Printing and Publishing Company, who are proprietors of the well-known "*ELECTRICIAN*" Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

## ELECTRIC SHOCKS.

When Major CARDEW confessed that the Paper which he presented to and partly read before the Institution of Electrical Engineers last week was somewhat dry, none of his audience were disposed to disagree with him, but as the author of the next Paper did not care about beginning to read it at ten minutes to nine, he proceeded to open the discussion, and rather skilfully withdrew the attention of the meeting from the actual topic—"A Few Calculations on Electrical Shocks from Contact with High-Pressure Conductors"—and discussed shocks in general and in particular. The short but lively discussion contrasted not only with the heavy mathematics which it followed, but the levity with which the subject was treated jarred strangely with the sad results to which allusion was naturally made. It is possible, however, to be witty about dismal matters and to laugh about pain, without joking at the sufferings of others or treating the subject in a callous style. This being so, the discussion was all too brief, and was worthy of being adjourned, if only it could have been carried on without becoming a mere recital of disasters. The dangers of engineering operations are pretty well understood, and the degree of danger which attaches to various hazardous occupations is well known. Architects are sometimes surprised to learn from insurance offices that their profession

Digitized by Google

is fraught with divers perils, since they may be called upon in the execution of their duties to climb ladders and may often stand in jeopardy of falling bricks. On the other hand, it was the magnitude of the works at the Forth Bridge, and not any special hazard in the operations, which gave a certain prominence to the hospital which was provided there. Taking the number of men into account, it was found that there was no extraordinary danger in their work, and the provision which was made merely sufficed for those casualties which are inseparable from any constructive undertaking of the same kind. Within the past ten years there have been fatal accidents at the well-known electrical works at Lambeth, but it is extremely satisfactory to learn that while many hundreds of high pressure dynamos have been turned out, not a single death has been caused by electricity, since those which have unfortunately occurred have been due to the accidents which must from time to time take place in any engineering establishment. It must be remembered that it is only during the testing of dynamos that any risk can arise, and the testing is part of the duties of the skilled staff, who, of course, know exactly where the danger lies. As far, then, as manufacture is concerned, it is proved by the experience of this firm who practically first introduced high-pressure dynamos into this country—and their experience is confirmed by that of many other manufacturers—that the precautions which are practically dictated by comfort suffice in the most complete manner for the protection of life.

The overhead wires which recently spread over the West End in all directions from the Grosvenor Gallery seemed, not only to the public, but to many engineers, to be as dangerous as they were ugly; but they will soon be a matter of past history, and the accidents attributable to them are singularly few. With the double system of distributing mains which the London Electric Supply Corporation are laying, there will be no occasion to make joints on live conductors, and the "ring mains" employed by the Metropolitan Company also avoids any difficulties of this kind. The narration by Mr. ADDENBROOKE of his perilous exploit in jointing a new branch to an overhead wire charged with 2,400 volts, perched in mid-air on a rubber-covered bracket as he worked, held his audience in suspense, and as an anti-climax Major CARDEW observed that, according to the calculations contained in his Paper, and set forth geometrically upon the black-board, a careless workman who both gave and received a shock by touching a stick of solder held by Mr. ADDENBROOKE altered the phase angle of the voltage and reduced the pressure by perhaps one-third.

We are not much nearer the solution of the question as to the magnitude of the shock which will prove fatal, and it is becoming very apparent that no more accurate answer is to be expected than could be given to an inquiry as to the exact height from which a man must fall to ensure killing him. A distinct advance is made in recognising that the effects of the shock do not depend merely on the pressure. It is obvious that the mere voltage of the spark which may be taken with no discomfort whatever from a frictional or influence machine is very considerable, but the current is infinitesimal; and even from such a source as an ordinary induction coil the quantity of electricity is extremely small. The varying resistance due to the condition of the skin in different individuals, and the variation at different times with the same person, is well known. The degree of discomfort and of pain experienced by different patients, though not as yet to be expressed in the C.G.S. system, has been sufficiently determined to enable some estimate to be made of the most extreme limit of safety. Numerous experiments have been carried out with ordinary continuous current machines, with alternating currents, and with batteries. The currents have been measured with more or less accuracy in milliamperes, and a rough notion has been arrived at of the point where discomfort begins and of the point where the pain is insupportable. Experiments have also been made with the discharge of Leyden jars and induction coils, but these do not throw much light on the subject. The element of time has been disregarded in most of these observations, and this is probably an important factor in determining the effects of a strong current through the body. The millicoulombs are probably as much more worthy of consideration than the milliamperes, as the milliamperes are of more consequence than the volts. The capacity of the human body is altogether too small to produce any appreciable condenser current into and out from it, and actual conduction need only be considered.

We cannot here enter into the physiological details of the matter, as there is at present very little more to go upon than the barest hypotheses. The information given by experts is of a very negative character. They say that the body does not act like an ordinary conductor, that the current does not act as a powerful or tetanic stimulus to the nerves, they tell us that we must not mention electrolysis of the tissues, but they always have plenty of generalities to bring forward. If there be any electrolytic action its effects would be sensible only at the parts in contact with the conductor. But the tissues have been examined for accumulations of gas, which might be evolved in the capillary vessels, but none has been found. The physiological question of electrotonus is complicated enough for small laboratory currents, but, for all practical purposes, the effect of a strong current, whether momentary or prolonged and acting on either nerve or muscle, may be described in plain English as a shock. When physiologists have something definite to tell us, they may be able to give a more scientific word, but the word "shock" used in this sense is comparable to a mechanical or an emotional shock, since the magnitude at which either of these shocks becomes fatal is as ill defined as that of an electric shock.

## REVIEWS.

**Coal and What We Get from It.** RAPHAEL MELDOLA, F.R.S. Romance of Science Series, S.P.C.K., London, 1891.

This little book contains little that directly concerns the electrical engineer, but much that may fill him with envy; for he uses coal for the purpose of obtaining energy. He succeeds in getting about one-fifteenth of it in a useful form, and has nothing more than ashes and clinkers as a waste product. The gas engineer, on the other hand, could, in some cases, give away his gas and yet make a profit out of the gas-liquor, the coke, and the tar. Smelly oils, gaudy dyes, essences, spirits, photographic developers, and a host of other things are produced by the modern chemist from coal tar. This book gives a very clear idea of the general nature of these compounds, the history of their discovery, and briefly describes some of the processes of manufacture. From a rough computation of the index it appears that some 300 different substances are discussed by the author.

**Screws and Screw-making.** (Britannia Company, Colchester, 1891.)

Many treatises are ill-disguised advertisements, but this book, which, to be commended for its honesty, is an excellent work on screw-making, containing numerous tables and formulæ, a reprint of the British Association reports, illustrated with the Britannia Company's tools, and winding up with a full catalogue of their goods. The tables are very complete, 17 pages are devoted to a table of change-wheels for cutting screws of various pitches in both inches and millimetres. It is the most complete book that we have seen on the subject.

## NEW METROPOLITAN POLICE BUILDINGS.

The whole of the new Metropolitan Police Offices at New Scotland Yard have been fitted with the electric light by Messrs. Drake and Gorham as contractors, with Mr. A. A. Campbell Swinton as consulting engineer. There are about 1,100 lamps at present fixed, and the total number will eventually be about 1,250. Every effort has been made to render this installation as complete and perfect as possible, and it is believed that every possible contingency which could produce a failure of the light has been provided against. The engine house has been excavated in the yard between the main building and Whitehall, and the whole of the generating plant has been placed well away from the offices.

The steam plant consists of three "Lancashire" boilers by Davey, Paxman and Co., each 22ft. 6in. × 6ft. diameter, each containing two flues 2ft. 3in. diameter with three circulating tubes and Paxman's patent strengthening and expansion joint. The heating surface of each boiler is 480 sq. ft., and the three boilers are capable of evaporating from 6,000 to 8,000lb. of water per hour.

The chimney shaft is 12 sq. ft. in sectional area, and is carried up to a height of 80ft., the lower 40ft. being lined with fire-brick. The steam is conveyed to the engine-room by a duplicate system of steam-pipes divided by nine valves which enable any length to be cut out of circuit as required, and provides for the continuation of the working in the event of a failure of the steam pipe at any point. The feed-water heater is of a special type, consisting of a tank into which the feed water is admitted by a ball valve, the water being blown into a spray by the exhaust steam from the engines which enters immediately under the ball valve.

A bye-pass is provided to carry the exhaust direct to the chimney, and thereby the amount of steam entering the heater can be varied, and the temperature of the water can be regulated from cold to boiling as required.

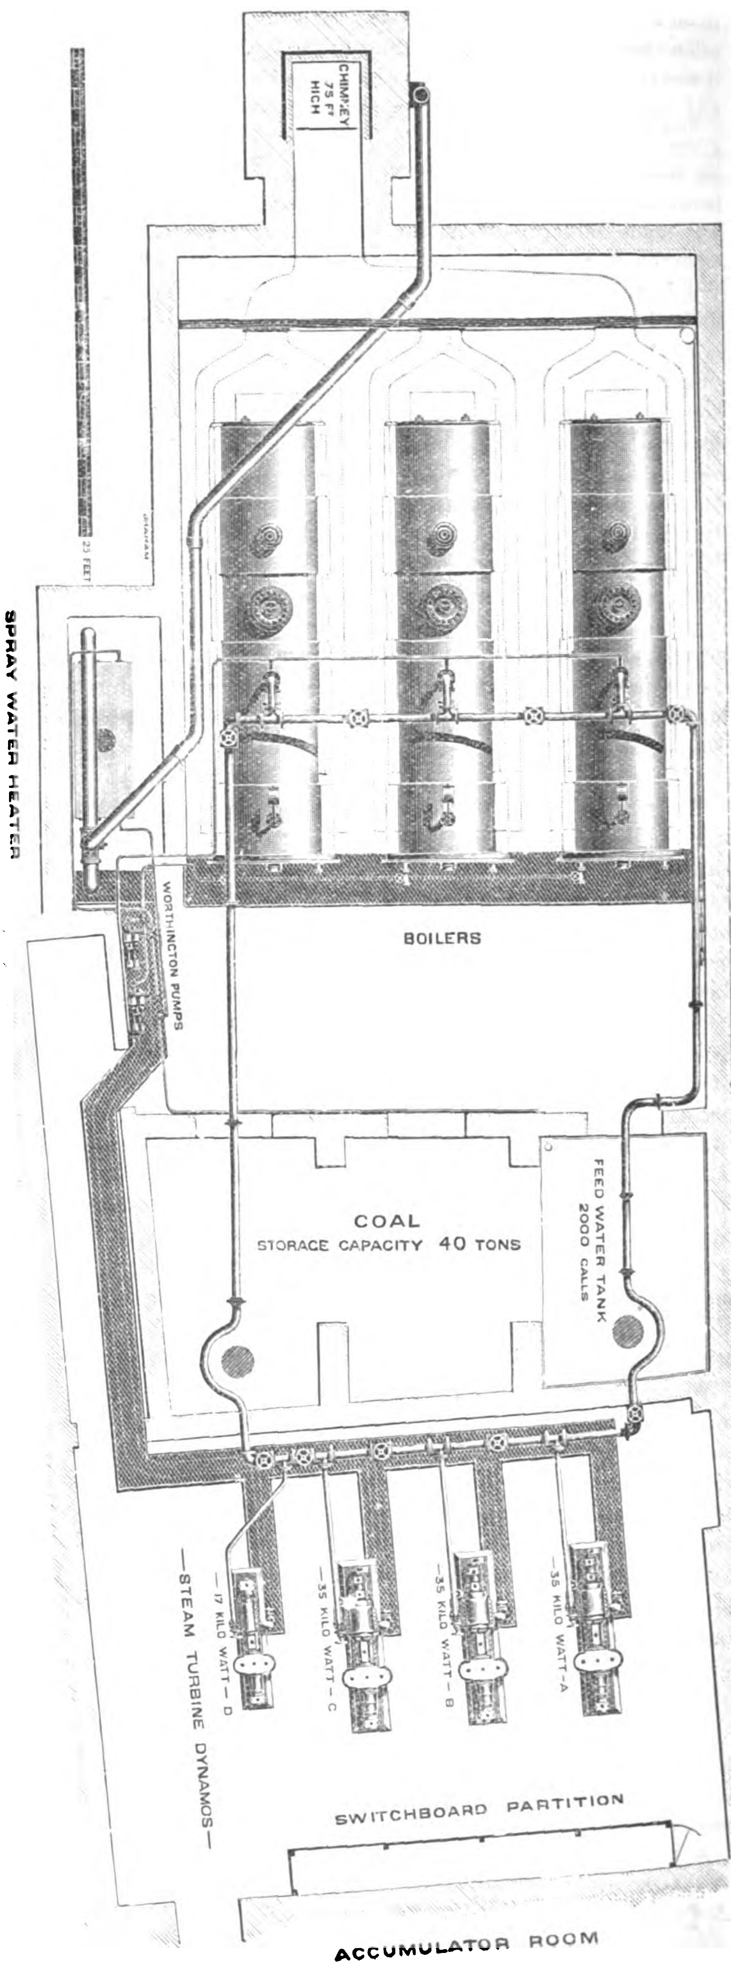
Two "Worthington" steam pumps are so arranged as to draw water from the feed-water heater, or direct from the mainfeed-water tanks, which contain 2,000 gallons of water, and are so connected that either pump can feed any one of the boilers at will.

The current is obtained from four of the new "Parsons" steam turbines and shunt-wound dynamos, three of these being capable of giving an output of 35 units each, and a smaller generator giving an output of 120 amperes × 130 volts for the charging of accumulators. These machines differ chiefly from the older forms of "Parsons" generators, in that they run at a lower speed; and the turbines are on the radial flow principle, instead of parallel, as previously. They are also fitted with a new form of variable expansion electrical governor, which secures additional economy at light loads, and is designed to maintain a constant E.M.F. under all conditions.

The accumulators consist of 106 cells, capable of discharging at a rate of 120 amperes for nine hours for the supply of 200 lamps of 16 c.p. each. The main distributing switchboard is placed 2ft. 6in. from the wall, and doors provide access to the back of the partition, so that all the connections at the back and front can easily be inspected at any time.

The lamp circuits from the main building are brought to a special distributing board fitted with cross connections, and Drake and Gorham's patent ring contact switches, the design permitting both positive and negative connections to be shifted from any one of the sources of generating power to another instantaneously. The ordinary lighting for the building is supplied direct from the steam turbine dynamos, which supply a perfectly steady light, the extremely sensitive automatic governor keeping the E.M.F. constant within a very small percentage.

The battery is charged from the smaller generator during the day, and except in cases of emergency, is used only for



the night service after 10 p.m., and for any few lamps required in dark places during the daytime.

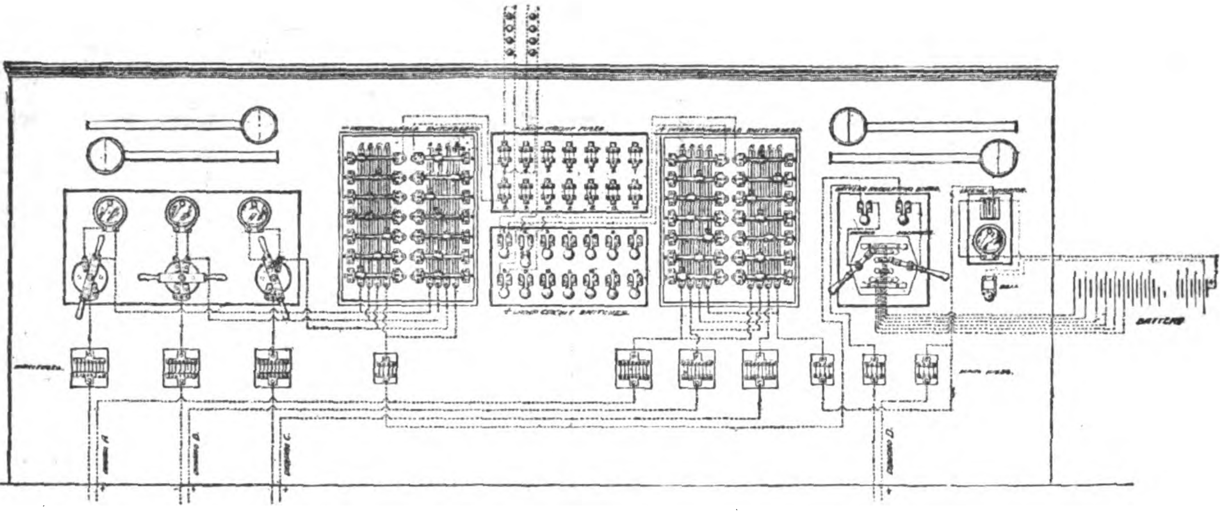
The voltmeters are of the "Cardew" pattern, made with specially large dials, so that the voltage may be seen at a glance from any point in the engine-room.

The wiring of the main building has been carried out so as to obtain the greatest security and immunity from failure of the light, a number of small mains being run from the distributing board in preference to large conductors.

Every alternate lamp throughout the building is supplied from a different circuit, so that in the event of a breakdown only half the lights would be extinguished. Throughout the passages the casing is let in flush with the face of the plaster, conductors braided with white cotton, are carried to each lamp on the face of the concrete ceilings, and supported with eyelets bushed with ebonite. This arrangement enables the position of the light to be shifted at any time without difficulty, and provides one solution of the extremely difficult problem of running the branch wires in modern fireproof buildings in which no lath and plaster is used.

In order to ensure economy, a separate switch has been provided for every individual lamp throughout the rooms and offices.

The generating plant also provides electrical power to the printing office, where the Police reports and notices are now all printed by a machine worked by an electric motor.



Main Distributing Switchboard for putting any Circuit in connection with any Dynamo. Fitted throughout with Drake and Gorham's Patent Ring Contact Switches.

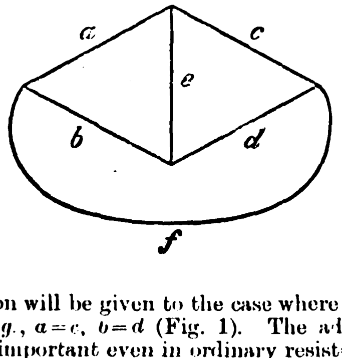
so as to render the conductors accessible without being an eyesore. The branch conductors are carried to small distributing fuse boxes, with glass fronts, placed over the doors in the different offices, from which point special vulcanised twin

New Scotland Yard is, it is believed, the first Government office lighted entirely and exclusively with the electric light. The whole installation is now practically complete, and the new illuminant is giving general satisfaction to the occupants.

## ON THE SENSITIVENESS OF THE BRIDGE METHOD IN ITS APPLICATION TO PERIODIC ELECTRIC CURRENTS.*

BY LORD RAYLEIGH.

The most favourable conditions in the ordinary measurement of resistance have been investigated by Schwendler† and by O. Heaviside.‡ It is here proposed to treat the problem more generally, so as to cover the application to conductors endowed with self-induction, or combined with condensers. The receiving instrument may be supposed to be a telephone, which takes the place of the galvanometer employed in ordinary testing. In the conjugate "battery" branch a periodic electromotive force of given frequency is the origin of the currents.



Special attention will be given to the case where the branches are equal in pairs, *e.g.*, $a=c$, $b=d$ (Fig. 1). The advantages of this arrangement are important even in ordinary resistance testing, and in the generalised application are still more to be insisted upon. By mere interchange of $a$ and $c$ and combination of results, the equality of $b$ and $d$ can be verified independently of the exactitude of the ratio $a : c$.

If any element in the combination, for example $a$, be a mere resistance, the difference of potentials at its terminals (V) is connected with the current, $x$, by the relation

$$V = ax.$$

We have, however, to suppose that $a$ is not merely a resistance or even combination of such. It may include an electro-magnet,* and it may be interrupted by a condenser. So long as the current is strictly harmonic, proportional to $e^{ipt}$, the most general possible relation between V and $x$ is expressed by

$$V = (a_1 + ia_2)\,x,$$

where $a_1$ and $ia_2$ are the real and imaginary parts of a complex coefficient $a$, and are functions of the frequency $p/2\pi$. In the particular case of a simple conductor, endowed with inductance L, $a_1$ represents the resistance, and $a_2$ is equal to $p$ L. In general, $a_1$ is positive; but $a_2$ may be either positive, as in the above example, or negative. The latter case arises when a resistance, R, is interrupted by a condenser of capacity C. Here $a_1 = R$, $a_2 = -1/pC$. If there be also inductance L,

$$a_1 = R, \qquad a_2 = pL - 1/pC.$$

Since the parts of $a^2$ may be either positive or negative, there is nothing to hinder its evanescence by compensation. In the above combination of an electromagnet and condenser compensation occurs, when $p^2LC=1$, that is, when the natural period with terminals connected coincides with the forced period. The combination is then equivalent to a simple resistance†; but a variation of frequency will give rise to a positive or negative $a_2$.

The case of two electro-magnets in parallel is treated in my Paper on "Forced Harmonic Oscillations‡; and other combinations have

Digitized by Google

been discussed by Mr. Heaviside and myself. But the above examples will suffice to illustrate the principle that the relation of V to $x$ is one of proportionality, and may be expressed by the single complex symbol $a$. We fall back at any time upon the case of mere resistance by supposing $a$ to be real. In like manner $b$, $c$, $d$, $e$, and $f$ are symbols expressing the electrical properties of the remaining branches.

In all electrical problems the generalised quantities $a$, $b$, &c., combine just as they do when they represent simple resistances. Thus, if $a$, $a'$ be two complex quantities representing two conductors in series, the corresponding quantity for the combination is $a+a'$. Again, if $a$, $a'$ represent two conductors in parallel, the reciprocal of the resultant is given by addition of the reciprocals of $a$, $a'$. For, if the currents be $x$ and $x'$, corresponding to a difference of potentials V at the common terminals,

$$V = a\,x = a'\,x',$$

so that

$$x + x' = V\,(1/a + 1/a').$$

If $\psi_1$, $\psi_2$, $\Psi_1$, $\Psi_2$ represent respectively the currents and electromotive forces in the battery and telephone branches of the bridge, it follows that $\psi_1$, $\psi_2$ are linear functions of $\Psi_1$ and $\Psi_2$, and, conversely, $\Psi_1$, $\Psi_2$ may be regarded as linear functions of $\psi_1$ and $\psi_2$. We may therefore set

$$\left.\begin{aligned}\Psi_1 &= A\,\psi_1 + B\,\psi_2\\ \Psi_2 &= B\,\psi_1 + C\,\psi_2\end{aligned}\right\} \quad \ldots\ldots \quad (1),$$

the coefficient of $\psi_2$ in the first equation being identical with that of $\psi_1$ in the second by the reciprocal property. The three constants A, B, C are in general complex quantities, functions of $p$.

If $\Psi_2 = 0$,

$$B\,\psi_1 + C\,\psi_2 = 0,$$

and

$$\psi_2 = \frac{B}{B^2 - A\,C}\,\Psi_1 \quad \ldots\ldots \quad (2).$$

In like manner, if we had supposed $\Psi_1 = 0$, we should have found

$$\psi_1 = \frac{B}{B^2 - A\,C}\,\Psi_2 \quad \ldots\ldots \quad (2);$$

showing that the ratio of the current in one branch to an electromotive force operative in the other is independent of the way in which the parts are assigned to the two branches.

We have now to determine the constants A, B, C in terms of the electrical properties of the system. If $\psi_2$ be maintained zero by a suitable force $\Psi_2$, the relation between $\psi_1$ and $\Psi_1$ is $\Psi_1 = A\psi_1$. In our application, A therefore denotes the (generalised) resistance to an electromotive force in the battery branch, *when the telephone branch is open*. This resistance is made up of $f$, the resistance in the battery branch, and of that of the conductors $a+c$, $b+d$ combined in parallel. Thus,

$$A = f + \frac{(a+c)\,(b+d)}{a+b+c+d} \quad \ldots\ldots \quad (4).$$

In like manner,

$$C = e + \frac{(a+b)\,(c+d)}{a+b+c+d} \quad \ldots\ldots \quad (4').$$

To determine B, let us consider the force $\Psi_2$ which must act in $e$ in order that the current through it ($\psi_2$) may be zero, in spite of the operation of $\Psi_1$. We have $\Psi_2 = B\,\psi_1$. The total current $\psi_1$ flows partly along the branch $a+c$, and partly along $b+d$. The current through $a+c$ is

$$\frac{\dfrac{1}{a+c}}{\dfrac{1}{a+c}+\dfrac{1}{b+d}}\,\psi_1 = \frac{(b+d)\,\psi_1}{a+b+c+d} \quad \ldots \quad (5).$$

and that through $b+d$ is

$$\frac{(a+c)\,\psi_1}{a+b+c+d} \quad \ldots\ldots \quad (6).$$

The difference of potentials at the terminals of $e$, supposed to be interrupted, is thus

$$\frac{c\,(b+d)\,\psi_1 - d\,(a+c)\,\psi_1}{a+b+c+d};$$

or

$$B = \frac{bc - ad}{a+b+c+d} \quad \ldots\ldots \quad (7).$$

By (4), (4′), (7) the relationship of $\Psi_1$, $\Psi_2$ to $\psi_1$, $\psi_2$ is completely determined.

The problem of the bridge requires the determination of the current $\psi_2$, as proportional to $\Psi_1$, when $\Psi_2 = 0$, that is, when no electromotive force acts in the bridge itself, and the solution is given at once by simple introduction into (2) of the values A, C, B from (4), (4′), (7).

If there be an approximate balance, the expression simplifies. For $bc - ad$ is then small, and $B^2$ may be neglected relatively to AC in the denominator of (2). Thus, as a sufficient approximation in this case, we have

$$\psi_2 : \Psi_1 = \frac{\dfrac{ad - cb}{a+b+c+d}}{\left\{e + \dfrac{(a+b)\,(c+d)}{a+b+c+d}\right\}\left\{f + \dfrac{(a+c)\,(b+d)}{a+b+c+d}\right\}} \quad . \quad (8)$$

in agreement with the equation used by Mr. Heaviside for simple resistances.

The form of (8) enables us at once to compare the effects of increments of resistance and inductance in disturbing a balance. For let $a\,d = b\,c$, and then change $d$ to $d + d'$ where $d'_1 + i\,d'_2$. The value of $\psi_2/\Psi_1$ is proportional to $d'$, and the amplitude of the vibratory current in the bridge is proportional to Mod $d'$, that is to $\sqrt{(d'^2_1 + d'^2_2)}$. Thus $d'_1$, $d'_2$ are equally efficacious when numerically equal.

The next application that we shall make of (8) is to the generalised form of Schwendler's problem. When all else is given, how should the telephone, or other receiving instrument, be wound in order to get the greatest effect?

If by separation of real and imaginary parts we set

$$e = e_1 + i\,e_2 \qquad \frac{(a+b)\,(c+d)}{a+b+c+d} = r_1 + i\,r_2 \quad \ldots \quad (9)$$

the factor in the denominator of (6) with which we are concerned becomes

$$e_1 + r_1 + i\,(e_2 + r_2)\,;$$

and the square of the modulus is given by

$$\text{Mod}^2 = (e_1 + r_1)^2 + (e_2 + r_2)^2 \quad \ldots \quad (10).$$

In this equation $e_1$, $r_1$ are essentially positive, while $e_2$, $r_2$ may be either positive or negative. If $e_1$ and $e_2$ are both at disposal, the minimum of (10), corresponding to the maximum current, is found by making

$$e_1 = 0, \qquad e_2 = -r_2 \quad \ldots \quad (11).$$

But this is not the practical question. As in the case of simple resistances, what we have to aim at is not to render the current in the bridge a maximum, but rather the *effect* of the current. Whether the receiving instrument be a galvanometer or a telephone, we cannot in practice reduce its resistance to zero without at the same time nullifying the effect desired. We must rather regard the space available for the windings as given, and merely inquire how it may best be utilised. Now the effect required to be exalted is, *cæteris paribus*, proportional to the number of windings ($m$); and, if the space occupied by insulation be proportional to that occupied by copper, the resistance varies as $m^2$. So also does the inductance; and accordingly, if the instrument be connected to the bridge by leads sensibly devoid of resistance and inductance,

$$e_1 + i\,e_2 = m^2\,(\epsilon_1 + i\,\epsilon_2) \quad \ldots\ldots \quad (12),$$

where $\epsilon_1$, $\epsilon_2$ are independent of $m$. The quantity whose modulus is to be made a minimum by variation of $m$ is thus

$$\frac{e_1 + i\,e_2 + r_1 + i\,r_2}{m} = \frac{r_1 + m^2\epsilon_1 + i\,(r_2 + m^2\,\epsilon_2)}{m}\,;$$

and we have

$$\text{Mod}^2 = \frac{(r_1 + m^2\epsilon_1)^2 + (r_2 + m^2\epsilon_2)^2}{m^2}$$

$$= (r_1^2 + r_2^2)\,m^{-2} + 2\,(r_1\epsilon_1 + r_2\epsilon_2) + (\epsilon_1^2 + \epsilon_2^2))m^2.$$

This is a minimum by variation of $m$ when

$$m^4 = \frac{r_1^2 + r_2^2}{\epsilon_1^2 + \epsilon_2^2},$$

or

$$\text{Mod}\,(r_1 + ir_2) = \text{Mod}\,(e_1 + ie_2) \quad \ldots\ldots \quad (13).$$

We may express this result by saying that to get the best effect the instrument must be so wound that its *impedance* is equal to that of the compound conductor $r_1 + ir_2$. If for any reason the inductances can be omitted from consideration, then the resistance of the instrument is to be made equal to $r_1$, in accordance with Schwendler's rule.

The case of the "battery" branch may often be treated in like manner. As Mr. Heaviside has shown, if a number of cells are available for ordinary resistance testing, they should be combined so that their resistance is equal to that ($s_1$) of the corresponding combination of wires in parallel. Periodic currents may be conceived to arise from the rotation of a coil in a magnetic yield of given strength. If the space occupied by the windings of the coil be supposed to be given, their number $m$ will be determined by the condition of equal impedances. Thus, if

$$\frac{(a+c)\,(b+d)}{a+b+c+d} = s_1 + is_2 \quad \ldots \quad (14),$$

$$\text{Mod}\,(f_1 + if_2) = \text{Mod}\,(s_1 + is_2) \quad \ldots \quad (15).$$

in analogy with (13).

Digitized by Google

The above is the solution of the problem, if the coils of the sending and receiving instruments represent the whole of their respective branches, and are limited to occupy given spaces. The inductances and resistances cannot then be varied independently. But there would often be no difficulty in escaping from this limitation. The inclusion of additional resistance, external to the instrument, can only do harm; but the case is otherwise with inductance, positive or negative. If the inductance of the instrument added to $r_2$, or to $s_2$, be positive, the total inductance may be reduced to zero by the insertion of a suitable condenser, and this without material increase of resistance. If the inductance be already negative, the remedy is not so easily carried out; but, theoretically, it is possible to add the necessary inductance without sensible increase of resistance. The greater the frequency of vibration, the more feasible does this course become. We may, therefore, without much violence, suppose that the inductances of two branches can be reduced to zero without additional resistance. Thus,

$$e_2+r_2=0, \qquad f_2+s_2=0 \quad . \quad . \quad . \quad . \quad (16);$$

and the condition of maximum efficiency of the transmitting and receiving coils is then given by Schwendler's rule,

$$e_1=r_1, \qquad f_1=s_1 \quad . \quad . \quad . \quad . \quad . \quad (17).$$

These suppositions form a reasonable basis for further investigation; but conclusions founded upon them will be subject to re-examination, especially in extreme cases.

We may now introduce a simplification by supposing the branches of the bridge are equal in pairs

$$a=c, \qquad b=d$$

and find the best arrangement of resistances, &c., so as to make a maximum the value of $\psi_2/\Psi_1$, or the ratio of the current produced in the telephone branch to the electromotive force acting in the battery branch.

In the first place, suppose there is no inductance in any arm of the bridge, so that simple resistances alone are dealt with. By substitution in the above equations and applying (13) and (15) we can obtain

$$\psi_2/\Psi_1=\frac{d_1-b_1}{8b_1(a_1+b_1)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (18).$$

Here $a_1$ is still at disposal, and we see that according to (18) it ought to be diminished without limit. This conclusion does not harmonise with one obtained by Mr. Heaviside.* It must be observed, however, that $a_1=0$ is unpractical, involving, as it does, $s_1=0$, $f_1=0$. Even according to (18) there is little to be gained by diminishing $a_1$ below, say, $\frac{1}{2}b_1$. In this case

$$a_1=\tfrac{1}{2}b_1, \qquad e_1=r_1=\tfrac{3}{4}b_1, \qquad f_1=s_1=\tfrac{3}{8}b_1 \quad . \quad . \quad (19).$$

Such an arrangement as (19) may be recommended for practical use.

When $b_1$ is large, there may be advantage in taking $a_1$ relatively smaller than in the above example. In such cases we approach the limiting condition of things, and have approximately

$$e_1=r_1=\tfrac{1}{2}b_1, \qquad f_1=s_1=2a_1 \quad . \quad . \quad . \quad . \quad . \quad (20)$$

$$\psi_2/\Psi_1=\frac{d_1-b_1}{8b_1^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (21)$$

And the smallness of $f_1$ in comparison with $b$, may sometimes be a convenience.

The next remark that has to be made is that, even when the conductors, $b$ and $d$, to be compared are endowed with sensible inductances (positive or negative), the problem may still, theoretically, be brought under the above head. Suppose, for example, that $b$, $d$ represent nearly equal electro-magnets. Their inductances may be compensated by the introduction (in series) of suitable equal condensers into these branches, so that $b$ and $d$ are reduced to $b_1$ and $d_1$. If then we assume $a$ to be a simple resistance ($a_2=0$), the solution is as before. Two objections may here be raised. First, on the theoretical side it has not been proved to be advantageous to assume $a_2=0$; and, secondly, the introduction of extraneous condensers †, even with interchange, into the branches to be accurately compared may be a complication unfavourable to success.

We will now suppose that

$$e=e_1+ie_2=r_1-ir_2, \qquad f=f_1+if_2=s_1-is_2 \quad . \quad . \quad . \quad (22).$$

It can then be shown that

$$\psi_2/\Psi_1=\frac{d-b}{16}\,\frac{s_1+is_2}{br_1s_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23);$$

and the question before us is how to make the modulus of the second fraction on the right a maximum by variation of $a$.*

Consideration of this expression shows that the sensitiveness may theoretically become infinite by suitable choice of $a_2$, the inductance component of $a$. The investigation is not particularly satisfactory as it leads to conditions of test which it is impossible to realise. It is, however, useful in showing in what direction we must tend in the search for sensitiveness. In practice $a_1$ cannot be reduced indefinitely, and we may inquire the best value of $a_2$ for a given value of $a_1$.

The required relation is denoted by the equation

$$a_1^2+a_2^2=\frac{a_1(b_1^2+b_2^2)}{b_1}$$

under which circumstances it is found that

$$\text{Mod.}\,\psi_2/\Psi_1=\frac{\text{Mod.}\,(d-b)}{16b_1\sqrt{a_1b_1}}$$

independent of $b_2$.

The consideration of a few numerical cases shows that when $a_2=o$ there is little to be gained by further reduction of $a_1$; but when $a_2$ is suitably chosen, the gain may be worth having. The use of $a_2$ may be advantageous, even when the subject of measurement is a mere resistance. The sign of $a_2$ is immaterial.

So far as the general theory is concerned, it is a matter of indifference whether the indicating instrument be in the branch $e$, or in $f$. The latter corresponds to the connections in De Sauty's method of testing condensers by means of the galvanometer. In practice, more space would probably be available for the coils of a transmitting instrument than of the receiving instrument, at least, if the latter be a telephone; and this would tell in favour of choosing that branch for the transmitter which should have the larger time constant (L/R).

To get an idea of the relative capacities, resistances, and inductances involved, we must assume a particular pitch. A frequency suitable for telephonic experiments is 1,000 per second, for which $p=2{,}000\,\pi$. Thus, if the value of $a_2$ for a condenser of capacity C, and for an inductance L, and that of $a_1$ for a resistance R, are all numerically equal,

$$\text{R}=2{,}000\,\pi\,\text{L}=\frac{1}{2{,}000\,\pi\,\text{C}}.$$

If R be 1 ohm, equal to $10^9$ C.G.S., the corresponding capacity is $1{\cdot}6\times10^{-13}$ C.G.S., equal to 160 microfarads, and the corresponding inductance is $1{\cdot}6\times10^5$ C.G.S., equal to ·00016 henry. Again, if C be one microfarad, equal to $10^{-15}$ C.G.S., R is 160 ohms, and L is ·025 henry.

In the preceding calculations $e$ and $f$ are supposed to be adjusted to the values most favourable to the effect in the receiving instrument. A question, which arises quite as often in practice, is how to make the best of given instruments. The full answer is necessarily somewhat complicated; for there could be no objection to the insertion of a condenser, for example, if the sensitiveness could be improved thereby. Suppose, however, the transmitting and receiving branches to be fully given, so that $e$ and $f$ are known complex quantities, the only question to be considered is as to the most suitable value of $a$, assumed to be equal to $c$.

For this purpose it will be found necessary to make the modulus of

$$(a+b+2e)\left(\frac{1}{a}+\frac{1}{b}+\frac{2}{f}\right) \quad . \quad . \quad . \quad . \quad . \quad (24)$$

a maximum by varying $a_1$ and $a_2$.

The required condition is expressed by the equation

$$a^2=\frac{b+2e}{2/f+1/b} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25).$$

In taking the square root, the ambiguity must be so determined as to make $a_1$ the real part of $a$, positive equation (25), coincide with that obtained by Mr. Heaviside for the case where all the quantities are real.

## NOTES ON THE DESIGN OF MULTIPOLAR DYNAMOS.†

BY W. B. ESSON.

DISCUSSION.—(AUTHORISED ABSTRACT.)

Prof. S. P. THOMPSON said he regretted that Mr. Esson had used the word "volume" for something which was not of the nature of *volume*, and he thought that the meaning assigned to it was not the *ampere-turns* on the armature, but twice that number. The formulæ for the theoretical load limit given seemed incorrect owing to neglect of leakage. Speaking of the comparison of the two and four-pole machines shown in Figs. 3 and 4 (reproduced on next page), he said a better comparison would have been obtained by

* *Loc. cit.*, p. 120, "In conclusion, if, to measure a certain resistance, the best resistances for the galvanometer, battery, and the three sides, $a$, $b$, $c$, were required, then we should have to make $a=b=c=d=e=f$."

† The use of condensers or electro-magnets in the branches $e$ and $f$ stands, of course, upon a different footing.

* These conditions require no attention in galvanometric testing with steady currents, being satisfied by $p=0$, independently of the nature of the instrument.

† Paper read before the Institution of Electrical Engineers, April 9, 1891.

considering Fig. 4 to be a two-pole machine with a double magnetic circuit, both the top poles being N (say) and the two bottom ones S. The surface of the two armatures would still be the same, and so far as he could see, their limiting outputs would remain unaltered. It was thus not a question of the number of poles, but of the number of magnetic circuits. Again, on slip 3 relations between the "volume of current" and the diameters of ring and drum armatures were given, but no mention as to whether these were intended to apply to machines with single or double magnetic circuits was made. In his (Prof. Thompson's) opinion it would have been better to

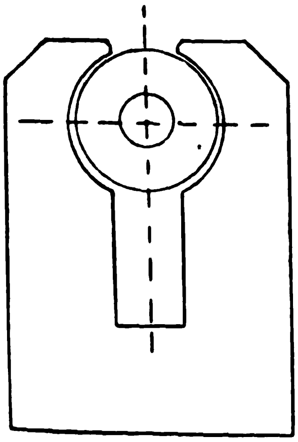

Fig. 3.

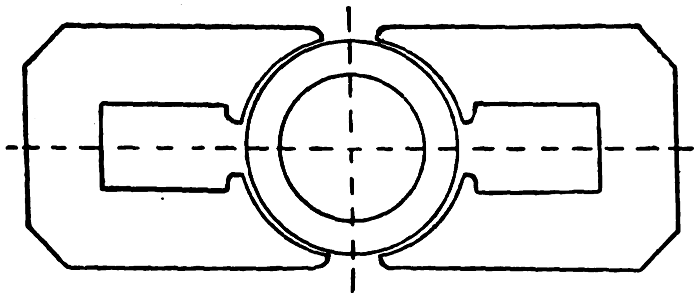

Fig. 4.

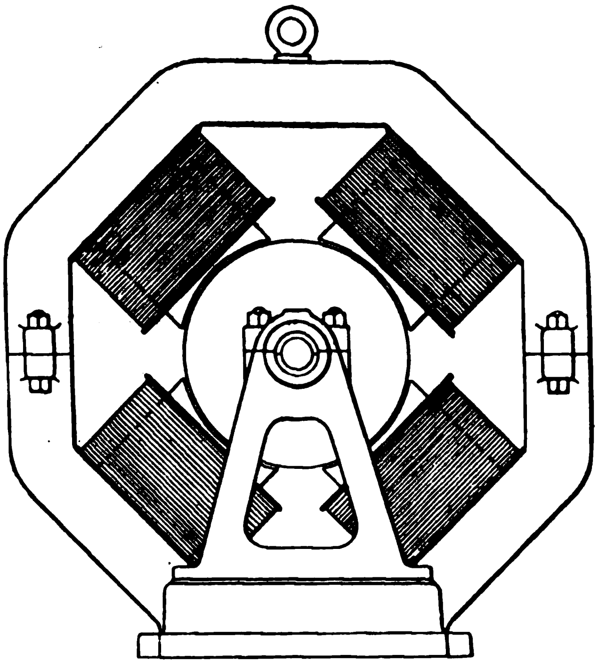

Fig. 6.

distinguish between the two types, for he believed the proportions should be different, and that an armature working in a double circuit field could safely carry a greater current than when in the field of a single magnet. Referring to "cross-induction," he remarked that some years ago he suggested that pole-pieces should be laminated, or have air-spaces parallel to the lines of force, in order to counteract the weakening of the field near the trailing horns. As regards the proportions of iron and copper in the magnets of direct and alternate current multipolar dynamos, he thought a more modern type of alternator should have been chosen, for the amount of copper was prodigious. In c nclusion, he thanked the author for the many good things contained in the Paper, and said the data there given would be very useful in designing machines.

Mr. KAPP, speaking of the laminated pole-pieces mentioned by Dr. Thompson, said Mr. Joel adopted a similar plan in 1885, with the idea of getting more corners on his magnet, and consequently obtaining a greater magnetic pull. He himself had also designed multipolar machines with a deep slot in the middle of each pole-piece, and found that the armature reactions were halved thereby. Referring to magnetic circuits of four-pole machines he did not agree with Mr. Esson that a field of the Elphinstone-Vincent type (Fig. 4) was more efficient than the symmetrical Gramme field shown in Fig. 6 (reproduced below), and thought that the author's conclusions might be due to wrought iron being wholly used in the one, and mostly cast iron in the other. Taking the same material he (Mr. Kapp) found that of the three kinds of four-pole magnets shown in Figs. A, 4, and 6, the first or "Ironclad" form (Fig. A) was the heaviest and required most wire whilst the last (Fig. 6) was lightest and required the least wire. In comparing bi-polar machines with multipolar ones, he pointed out that it was necessary to make the armatures of the latter machines larger in order to obtain sufficient space between adjacent pole-pieces. This, together with the fact that only shallow armature cores are needed, makes the ventilation of multipolar machines very much better than bi-polar ones. This point, he thought, had been overlooked by the author: although Mr. Esson's formulæ for the "volume of current," carried by armatures, agreed fairly well for well-designed machines, it must not, he said, be used indiscrimi-

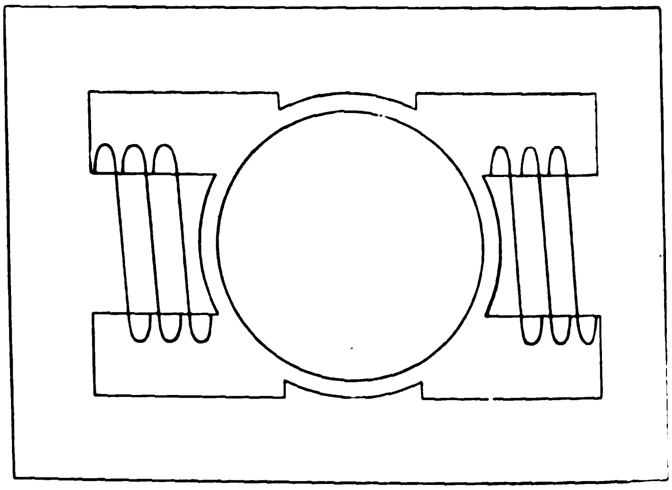

Fig. A.—"Ironclad" Four-Pole Field Magnet.

nately, and if a larger armature be made with a view to increasing the "volume" of current, the field-magnets must also be increased.

Mr. F. V. ANDERSEN remarked that Mr. Esson's formulæ for the load which could be safely carried by armatures without sparking did not include the number of commutator segments. He thought that increasing the number of such segments tended to diminish sparking, and inquired whether sparking could not be prevented by this means.

The further discussion of the Paper was adjourned to the 16th inst.

### Thursday, April 16th.

Mr. F. V. ANDERSEN supplemented his former remarks by saying that in considering the question of sparklessness in dynamos account should be taken of the lead of the brushes, for very large currents could be collected without much sparking if the lead was not limited to a small angle Mr. Esson's formula for the limiting currents was doubtless true if the brushes be at the polar tips; this, however, meant a considerable lead, and a change of, say, 10 per cent. in the load would necessitate the readjustment of the brushes. Now, for central station work, it was desirable that machines should have a very small lead, and this could be obtained by having long powerful fields. Referring to the cost of multipolar machines, he said that their chief characteristics were short fields and shallow armature cores. There was, however, no difficulty in making two-pole machines with short fields provided large lead was permissible or the maximum load decreased as the limbs were shortened. He, therefore, considered that there was no gain in splitting up the constructive material to form multipolar fields.

Mr. HOUSMAN greatly appreciated Mr. Esson's term "volume of current," but thought the fact that it meant twice the ampere turns should have been made more clear. The whole of the author's argument in favour of multipolar machines, he said, depended on the length of the air space necessary to prevent sparking being generally greater than that required for the copper. As regards the relations of "volume of current" and output to the diameter of armature, he thought that for equal rise of temperature the "volume" $v$ was proportional to diameter to the power three-halves, $d^{\frac{3}{2}}$, hence the output for the same circumferential velocity would vary as $d^{\frac{5}{2}}$. Under the same conditions of circumferential speed and induction, the loss by hysteresis varies as $d^2$, and consequently the rise of temperature due to this loss was the same for all sizes of armature. Foucault current losses, however, varied as $d^3$, and in general these were much greater than those due to hysteresis. In practice he had observed that the maximum safe output for a given armature was reached when the sum of the hysteresis and Foucault current losses was about equal to the losses in the conductors. The rapidity with which heating due to Foucault currents increased with the diameter, prevented the output varying in so great a

Digitized by Google

ratio as $d^3$, and as a rule it increased in a ratio somewhere between $d^2$ and $d^3$. Referring to the limiting non-sparking load, he said that Mr. Swinburne's hypothesis (on which the author bases his arguments), which says that the self-induction of an armature coil is small, and therefore only a weak field is required to effect sparkless reversal, was not justified. The coefficient of self-induction of an armature section, as measured by a ballistic galvanometer placed in circuit with a coil wound close to a disconnected section, he found to be very considerable; and, by passing various currents through the latter, the zero variation of the coefficient with armature current had been ascertained. From the coefficients so determined he had calculated the strengths of field necessary to effect reversals, and by measuring the field round the armature had determined the non-sparking lead for various currents. These calculated values agreed fairly closely with those found by actual trial; and in the case of a small air-space dynamo, a field of 3,000 C.G.S. units was necessary to produce sparkless commutation, the maximum field being 7,000. To further investigate how far Mr. Swinburne's hypothesis was correct, he had run a dynamo at half load with different brushes, the first set covering one commutator segment, and the next bearing only half a segment. In the latter case the lead required was much greater than in the former. If the hypothesis was correct, a very small change of lead should double the field; but in practice the additional lead was considerable. The difficulty of variable lead could, as was well known, be got over by using "commutating magnets" or "reversing pole pieces." Those shown in Mr. Swinburne's Paper on "Armature Reactions" were quite inadequate as regards size, for in practice they had to be much more substantial. As a rule, the number of series turns on these "commutating magnets" was about ·75 times the effective armature turns for single-magnet machines, and for double magnet machines 1·25 times the effective turns. On the question of efficiency, he said that multipolar machines could not compete with two-pole ones, for the weight of iron was not diminished in so great a ratio as the increase in number of poles, and hence both the hysteresis and Foucault current losses for a given output were greater in multipolar maches. Neither would the magnets be so light as stated in the Paper, and the economy obtained by having all the winding on one magnetic circuit was all in favour of the two-pole type. A difficulty, however, was met with in large two-pole machines, owing to the energy stored up in a single section of a large machine when a strong current is passing being very great, and this caused considerable trouble, but he thought it might be overcome by subdividing the winding.

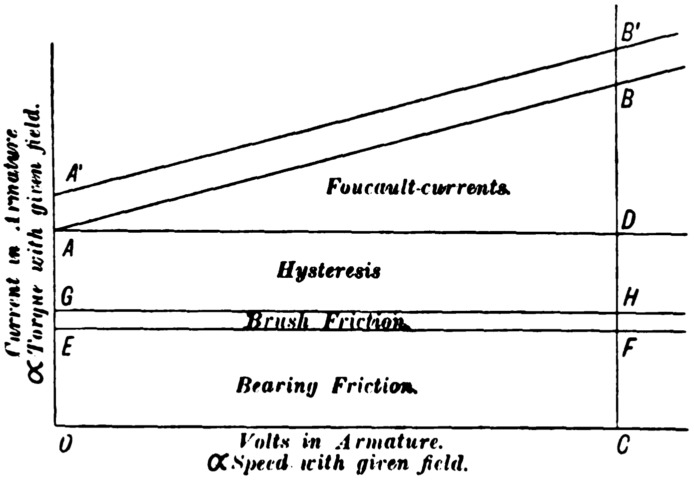

Fig. B.

Mr. SWINBURNE said, Mr. Esson should be congratulated on bringing forward a subject that had never before been systematically discussed. In England, engineers had settled down into making a regular type of two-pole single magnet drum machines; and on the Continent, even small machines were made with a large number of field magnets without any obvious reason. On the subject of prevention of sparking, he said Mr. Esson had hinted that because his (Mr. Swinburne's) formulæ were calculated, they might be inaccurate, and had, therefore, given empirical formulæ for maximum output without sparking, taken from the practice of various makers. These he said, were often misleading, because, perhaps, none of the machines taken were near their sparking point. His own formulæ were founded on experiment and observation, as well as calculation. As far as efficiency was concerned a small number of poles was advisable, but the limiting output for a two-pole drum was about 100 kilowatts, whereas a four-pole drum would give several hundred kilowatts without sparking. Mr. Esson had, he thought, not dwelt sufficiently on two of the chief advantages of having more than two poles. A four-pole drum armature had very simple end-connections, could be perfectly ventilated, and was easily accessible for repair and inspection. The proper ventilation of large machines he considered to be of the first importance. The coupling up of multipolar armatures was, he said, to be condemned most strongly. Considering a large machine with its armature so coupled and supposing the bearings to wear a little, he pointed out that a very small eccentricity would decrease the lower air-gap and increase the upper gap by one per cent.; this means that in an armature having a loss of two per cent., the bottom half would do double work, thus involving great waste of power and heating. This objection, he believed, had not been urged before, but it was very serious in large machines. The armature conductors should therefore be in series or connected partly in series and partly in parallel as suggested by Fritsche.

Mr. HOUSMAN explained his method of analysing Foucault current and hysteresis losses in dynamo armatures by running them as separately-excited motors without load, and observing the volts and amperes required at different speeds. The results when plotted give an inclined straight line A B (Fig. B), from the position of which the Foucault losses may be determined. Friction and hysteresis are not separated in the initial diagram, but the former may be determined by other experiments. The results obtained with various exciting currents show that a certain excitation gives a minimum total loss.

Mr. A. T. SNELL thought the term "volume of current" would be very useful as a name for a quantity often used by designers. His own experience as regards "volume" and diameter agreed with the formulæ given by the author, and the ratio of the constants ·048 and ·072 in formulæ (5) and (6), for the output of cylinder and drum armatures were in the same ratio as the coefficients ·01 and ·015, given by himself about two years ago. He did not agree with the Esson that the output of an armature was independent of the number of poles, for he found that the output could be considerably increased by using four poles instead of two. This he illustrated by the following table, which expresses results obtained from two machines in which the air-gaps, speed, and heating were about the same:—

| Machine. | Diameter of armature. | "Volume of current." | Volts. | Amperes. | Watts. |
|---|---|---|---|---|---|
| Two-pole ... | 60 cms. | 26,600 | 700 | 70 | 50,000 |
| Four-pole ... | 60 „ | 14,700 | 250 | 300 | 75,000 |

The advantages of four-pole machines generally he considered due to the air-gaps, magnets, and cross-magnetising forces being small, whilst the peripheral velocity for a given speed of the shaft could be large. This last was of great importance in direct driven machines. Their disadvantage was that they usually had a large magnetic density in the iron and air-space, but the latter could be obviated by spreading out the polar extremities.

Mr. MILLER remarked that in the case of dynamos for the transmission of power, the design was influenced by the voltage of the machine, for there was a limit to the difference of potential that could safely and conveniently be used between commutator sections of ordinary construction. For example, a machine to give 2,000 amperes and 50 volts could best be made multipolar; but not so one for 2,000 volts and 50 amperes. In the latter case it would not be advisable to concentrate the volts in a fourth or sixth of the circumference. On the question of the utility or otherwise of cross connections in multipolar machines between sections which theoretically should be at the same potential, he said, that in practice the evil consequences of various inequalities were minimised thereby. In his opinion, based on experience, the extra expense of cross connections was well worth incurring, for they produced a distinct diminution in sparking. He also said that Mr. Esson had not even mentioned unipolar machines, presumably because he considered they were worthless. This, he thought, was a mistake. One of the chief faults usually attributed to them, viz., that there was a great fall of volts between no load and full load, did not exist if they were properly designed.

Mr. CROMPTON said the information contained in the Paper would be very useful to engineers. Some speakers had implied that there was no gain in making multipolar machines. This he thought was not correct, for his firm had constructed large four-pole machines quite as efficient as the two-pole type, with an economy of 40 per cent. in material. He then directed attention to the small losses in the armatures of two-pole machines as shown on a diagram illustrating his Paper, read recently before the Institution of Civil Engineers, and he doubted whether the losses in multipolar machines could be got equally small if the armature circuits were connected in parallel instead of in series. Fritsche's windings, as had been pointed out by Mr. Swinburne, could be employed satisfactorily in multipolar armatures. In his opinion no machine lends itself so well to the production of high voltages as the multipolar type.

The discussion was adjourned to the 23rd inst.

THURSDAY, APRIL 23RD.

Mr. MORDEY read a communication from Mr. W. B. Sayers.

Mr. ESSON, he pointed out, had made no mention of slotted armatures in his Paper, although many of the results contained in it could, by suitable modification, be applied to them. A mistake made by nearly all designers in considering this kind of machine was to assume that they required much less magnetising power than ordinary smooth core machines. It was clear, however, that the ratios of the magnetising forces of the back and cross turns respectively on the armature to those on the magnet must have limiting values irrespective of the air-space, which values could not be exceeded without giving rise to great distortion of field and serious sparking. Short air-space machines had the disadvantage of a large induction in the armature at light loads, and the drop of volts with increase of current was serious. To make slotted armature machines satisfactory they should have the same air-space as those with smooth cores, that space being reckoned from the top of the iron projections. A slotted armature had, therefore, to be slightly larger than a smooth-cored one for a given output. The *sine quâ non* of a good slotted armature machine was that the sum of the areas of the teeth under a pole piece was not less than the section of the core. The coils of these machines being nearly surrounded by iron had a greater self-induction, and, therefore, more lead was usually required to prevent sparking. The advantages of such armatures were that they combined positive driving and large clearance with considerable immunity from injury when removed for inspection or repair. To apply Mr. Esson's formulæ for the "volume of current" to slotted armatures

Digitized by Google

the air-space should be reckoned from the tops of the projections. Obviously, the radial depth of the core must be measured from the bottom of the slots. Speaking of Prof. Thompson's remarks on the comparison of Fig 4, considered as a two and a four-pole machine, he said that if correctly reported, he (Prof. Thompson) had apparently overlooked the fact, that for a two-pole machine the radial depth of the armature core would require to be doubled, and if used as shown, the E.M.F. as a two-pole machine would not be much increased, but the external current would be halved.

Mr. ESSON, in his reply to Prof. Thompson's objections to the expression "volume ofurrent," said it was to avoid the confusion which had arisen from using "ampere turns" that he used the word "volume." The ampere turns on any armature were $\frac{w\,C}{p}$, where $w$ was the number of wires counted all round the outside, C the total current, and $p$ the number of poles; and the fraction of this which produced the cross field was $\frac{\phi\, p}{360}$. This gives $\frac{w\,C}{p}\,\frac{\phi}{360}$ as the cross-magnetising ampere turns, and for simplicity he wrote it $\frac{v\,\phi}{360}$, where $v$ represented $\frac{w\,C}{p}$. Respecting the comparisons of a double magnet two-pole machine with a four-pole one, he said that the best comparison all depended on the size of the machine. Even if it were so large that it was desirable to make it of the four-pole type, there was still the alternative that it might be made two-pole, if the double horseshoe were practically split where the like poles abutted together. It would, he said, be a mistake to compare a small two-pole machine with a four-pole one, since a single magnet where it could be used was better; and it was only when the air-gap necessary to prevent sparking was greater than that needed for the copper that a multipolar machine was to be preferred. Speaking of the ratio of copper to iron in the machines shown in Figs. 1 and 2, he pointed out that this ratio might be anything, depending on the efficiency of the machines. Mr. Kapp had contended that the four-pole Gramme field was lighter than the double horseshoe shown in Fig. 4, when the same materials were used; this he thought was a mistake, for owing to the greater length of yoke in the former, the weights were as 4 to 3. With reference to the relation between the temperature and peripheral velocity of armatures, he had no very precise data, but from some preliminary experiments he believed that connection was approximately represented by $C^0 = \frac{W\;330}{\cdot 0005\;V\,S}$ where $C^0$ was the rise in degrees centigrade, W the watts expended, V the velocity in feet per minute, and S the surface in square centimetres. He agreed with Mr. Andersen that increasing the number of sections diminished sparking, but he had wished to emphasise the fact that if the load exceeded a given value no non-sparking position could be found for the brushes: this was true whatever the number of sections. He had then pointed out that in no actual machine did the load exceed half the limiting value. As regards Mr. Swinburne's remarks, he said he had no desire to hint that because the formulæ were calculated they were wrong. On the contrary, the calculations were most valuable, but the equations could only indicate relations and not absolute values, and one had to go to practice to obtain data. He entirely agreed with Mr. Crompton about the economy of material effected by making multipolar machines, for his own experience showed the saving to approach very closely the 40 per cent. mentioned by Mr. Crompton.

## PRESENTATION TO SIR WILLIAM THOMSON.

On "graduation day" at Glasgow University last week, the following address was presented to Sir William Thomson by the students of the University:—

To Sir William Thomson, Knight, LL.D., D.C.L., M.D., President Royal Society, Past President Royal Society of Edinburgh, Past President British Association, Past President Institute of Electrical Engineers, Grand Officer of the Legion of Honour, France; Knight of the *Ordre Pour le Merite* of Germany, Commander of the Order of Leopold of Belgium, Foreign Associate of the French Academy.

From the Students of Glasgow University.

DEAR SIR: In name and in behalf of the students of Glasgow University we beg to tender you our most sincere and cordial congratulations on the occasion of your election to the most honourable position which the sphere of British science affords—the presidency of the Royal Society—now for the first time held by a Scotch Professor. We recognise with feelings of pleasure and pride your unexcelled qualifications to fill this distinguished office, and to uphold its noblest traditions. We are satisfied that of all the brilliant names upon the presidential roll from the foundation of the society none will be held in brighter or more enduring remembrance than your own.

We would avail ourselves of this opportunity to give expression to our warm esteem and unaffected admiration for you in your more immediate relation to us. During your long tenure of the Chair of Natural Philosophy in the University you have won the affection of your students by your uniform courtesy and kindness, as you have gained their respect by your rare gifts as a scientist and a scholar. Your fame has attracted students from all parts of the world to your class-room and laboratory. You have in no small degree assisted the prosperous development of our ancient university, and added lustre to its name.

We would also recall your services to the cause of university reform, your work upon the University Commissions of recent years; and we would gratefully remember your exertions to bring about the present disposition of the surplus funds of the Exhibition of 1851, in the benefits of which our own university will share.

In regard to the wider aspects of your scientific work, we could not presume to refer in detail to the world-famous inventions, discoveries, and speculations which have placed you in the foremost position among living men of science. These achievements, splendid in themselves, and of inestimable practical importance, have met with well-merited recognition from our Queen and Government, as not only of national but of universal interest and value.

We would, in conclusion, express the heartfelt hope that you may long enjoy health and vigour to continue your labours for the advancement of science and the good of humanity.

University of Glasgow, April 24, 1891.

Sir William Thomson, who was received with cheers, in acknowledging the address, said,—Gentlemen of the Students' Representative Council and students whom you represent, I thank you all most warmly, most cordially, for your great kindness in presenting me with this address. It is, indeed, as you have said, an honour to have been elected to the presidency of the Royal Society. It is an honour which I feel deeply, an honour which entails very serious responsibilities and duties. The pleasure of receiving it is enhanced in no small degree, I can assure you, by what you have done for me this day. The sense of the weight of duty entailed by such a position is greatly lightened, indeed, by the feeling that you sympathise with me in it, by feeling that you have looked upon this position in which I have been placed as being interesting to yourselves. And I must lastly say this—if you will allow me to thank you as one of yourselves for it—that while you have shown sympathy with me I wish to express my sympathy with you. I have been a student of the University of Glasgow for 55 years to-day, and I hope to continue a student of the University as long as I live.

## ON IMPARTING ELECTRIC CHARGES BY FRICTION.*

BY ED. RIECKE.

Some experiments on the electrification imparted by rubbing were published by Riess in the year 1876. The author has attempted to extend the results then obtained.

The rubbing bodies were generally rectangular or square plates, provided in the middle with vulcanite handles. The substances rubbed were principally flannel and silk, in the form of strips 83 cm. long and 11 c.m. (33½in. × 4½in.) wide, stretched in several layers on glass plates. The electroscope was a simple gold leaf electroscope placed in a metal box provided with two openings through which a lamp and lens served to project an image of the gold leaves in order to determine their divergence. This was then reduced to absolute electrostatic units.

Experiments with vulcanite plates and flannel showed that with strokes repeated in exactly the same way a weak charge at first appeared, which soon increased and finally reached a constant value. With regard to the dimensions of the rubber, it appears that the maximum density of electrification produced by rubbing is smaller the larger is the surface of the rubbing body. Whether the rubbing is done longitudinally or laterally is of little importance.

The maximum electric density $\epsilon$ for a surface of five square centimetres is given in the following table:—

| Plates. | Rubbed on Wool. | Rubbed on Silk. |
|---|---|---|
| Sealing wax | $\epsilon = 5{\cdot}70$ | $\epsilon = 5{\cdot}40$ |
| Shellac | 5·57 | 5·12 |
| Sulphur | 5·48 | 5·39 |
| Vulcanite I. to III. | 4·82 | 4·43 |
| Amber I. and II. | 4·60 | 4·40 |
| „ III. and IV. | 4·18 | 4·11 |
| Vulcanite IV. to VI. | 3·90 | 3·80 |
| Glass I. and II. | ... | 3·18 |
| „ III. and IV. | 2·65 | 2·90 |

From this we see that all bodies which, when rubbed on wool and silk, become negatively electrified, give with wool a greater electric density than with silk. Glass, which under the same conditions becomes positively electrified, gives with silk a greater density. If the rubbing bodies are arranged in order of the densities excited, the order is the same both for wool and silk (shellac and sulphur only changing places). The maximum density for most of the bodies was obtained by rubbing nearly the same length, but in the case of glass a length four times as great was required, and a 2·5 per cent. gradient has been mounted without difficulty.

# LEGAL INTELLIGENCE.

## The Kensington and Knightsbridge Electric Lighting Company (Limited) v. The Lane Fox Electrical Company (Limited).

This was a motion before Mr. Justice Sterling on Friday last, by the plaintiff Company asking for an injunction to restrain the defendant Company from threatening the plaintiffs, their customers, or any other person or persons with legal proceedings, or liability in respect of any alleged infringement of certain letters patent claimed by the defendants to have been assigned to them. The letters patent related to an invention of which Mr. St. George Lane Fox, an electrical engineer, was the author. He was the registered owner of the patent, but he had by an agreement, dated July 31, 1890, agreed to assign it to the defendant Company, of which he was the Managing Director and a large shareholder. On November 15, 1890, he had commenced an action against the plaintiff Company to restain them from infringing his patent, but the plaintiff Company had not yet put in their defence. On February 21, 1891, the defendant Company sent the following letter to Messrs. John Barker and Co., of Kensington :—

"We understand that your house is being supplied with electric light by the Kensington and Knightsbridge Electric Supply Company, which Company, as you are doubtless aware, is now being sued for damages for infringement of our patented system of electric distribution. We have been advised that you, as one of the users of the said system, are liable for the infringement. We beg, therefore, to caution you of the fact, and to offer you an indemnity upon the terms contained in the enclosed circular. These terms, however, are to be considered as withdrawn if not accepted by the 28th inst."

The circular referred to in this letter was to the effect that the Lane Fox Electrical Company (Limited), by whom all Mr. Lane Fox's patents for this system of electric light distribution were stated to be held, were prepared to grant licences for the use of the system on certain terms therein set out. A similar communication had been sent by the defendant Company to numerous other customers of the plaintiff Company, and it was against this course of action that the present motion was directed. It was said, on behalf of the defendant Company, that it had been decided that where an action had been commenced before the threats were made, an injunction to restrain the threats would not be granted ; and here such an action had been brought. It was necessary to bring the action in Mr. Lane Fox's name, the patent being vested in him, but the defendants were the real owners in equity. The question turned upon the construction of section 32 of the Patents, &c., Act, 1888, which provides that :—

"Where any person, claiming to be the patentee of an invention, by circulars, advertisement, or otherwise, threatens any other person with any legal proceedings or liability in respect of any alleged manufacture, use, sale, or purchase of the invention, any person or persons aggrieved thereby may bring an action against him, and may obtain an injunction against the continuance of such threats, and may recover such damage (if any) as may have been sustained thereby, if the alleged manufacture, use, sale, or purchase to which the threats related was not in fact an infringement of any legal rights of the person making such threats. Provided that this section shall not apply if the person making such threats with due diligence commences and prosecutes an action for infringement of his patent."

Mr. Graham Hastings, Q.C., and Mr. Wallace were for the plaintiff Company ; and Mr. J. C. Graham for the defendants.

Mr. JUSTICE STIRLING said, that no doubt the letter complained of contained a threat. The defendant Company claimed by the circular to have acquired the rights of the patentee of the invention, and were therefore within the definition of the Act. By the Act any person aggrieved might bring an action against any one uttering threats. The plaintiff Company were undoubtedly persons aggrieved, and might bring an action against any person whose "legal rights" were alleged to be infringed. But here the defendant Company had no legal rights, for Mr. Lane Fox had only agreed to assign his rights to them. Therefore the defendant Company, the persons making the threats, were simply entitled in equity to an assignment of the patent upon certain terms not disclosed. That the defendant Company were not entitled to sue was clearly shown by the fact that Mr. Lane Fox had brought an action in his own name. The constitution of the Company was somewhat remarkable. The capital consisted of 100 £1 shares, which were deemed to have been fully paid up, and Mr. Lane Fox might have good reason for not wishing to clothe them with the legal title so as to enable them to sue in respect of an infringement. There was only an equity here, to enforce which the Company would have to bring an action against Mr. Lane Fox. Then did the proviso apply ? The action was not brought by the persons making the threats, but by the legal owner of the patent, Mr. Lane Fox, and damages for the threats could only be recovered from this Company with a nominal capital of £100. Consequently an order must be made for an injunction to restrain the continuance of such threats.

## Latimer Clark, Muirhead, and Co. v. Westminster Electric Supply Corporation.

In the Queen's Bench Division, on Monday, the case of Latimer Clark, Muirhead, and Co. (Limited) *v.* Westminster Electric Supply Corporation (Limited) came before Mr. Justice Hawkins and a special jury. This was an action brought by the plaintiff Company against the defendant Company to obtain specific performance of a contract and damages for an alleged breach, and an injunction restraining the defendant Company from having the work performed by other contractors. The defendant Company denied that they made the contract. They further said that the alleged agreement was delivered by them to their solicitors as an escrow only upon the terms that it should not take effect or be operative or enforceable until the fulfilment of the following condition—namely, that the plaintiff Company, or one or more of the Directors thereof, forthwith subscribed for 3,333 shares of £5 each in the defendant Company, and that neither the plaintiff Company nor any Directors thereof had ever subscribed for the shares.

Sir C. Russell, Q.C., and Mr. Pollard appeared for the plaintiff Company, while the Attorney-General, Mr. Moulton, Q.C., and Mr. Shaw represented the defendant Company.

Sir C. RUSSELL, in opening the case for the plaintiff Company, said his clients were a limited company, carrying on the business of electrical engineers, and that the principal shareholders in the Company had previously carried on a similar business as a private partnership for a considerable number of years. The defendant Company was originally a small concern with a small capital, and in 1889 they were ambitious enough to desire to apply to Parliament for power to supply with electricity important districts in the city of Westminster, including Mayfair, Belgravia, and Pimlico. Being a small company it was necessary that they should go before the authorities in a position to effectively carry out the powers they were seeking, and, accordingly, two gentlemen—Mr. Brown Martin and Mr. Wallace—applied to the Directors of the plaintiff Company for their assistance in two directions. In the first place, they asked that the plaintiff Company should place at their disposal such technical assistance as might be required for the preliminary inquiry which took place before a Provisional Order was granted ; and secondly, they inquired whether the plaintiff Company would construct the necessary works in the event of their obtaining the Provisional Order. The plaintiff Company agreed to give the defendant Company the necessary assistance, and the defendant Company entered into a contract to give the plaintiff Company work to the extent of £100,000. That contract was deposited with the defendant Company's solicitors, Messrs. Fowler, upon the one condition that the Directors of the defendant Company went to allotment in reference to the new capital they were seeking to raise for the purpose of carrying out the works. The plaintiff Company rendered all the necessary assistance, and the defendant Company went to allotment. Now the defendant Company were seeking to import a new condition into the contract with the view of shuffling out of the bargain. Under the contract the plaintiff Company were to supply all the necessary machinery for the proposed central station at Westminster, to design and arrange the details of a complete system of distribution to suit the requirements of the district, to execute all the engineering works of the Company until the installation was at work, to prepare a preliminary estimate of the whole cost of the work, and to supply and work all the engines, machinery, mains, and appliances at a fair market value. The defendant Company now desired to say that the contract was conditional on the plaintiff Company subscribing for 3,333 £5 shares, and that, as they did not do so, they (the defendant Company) were entitled to cancel the contract. He (the learned counsel) submitted that if any of the Directors of the plaintiff Company agreed to subscribe capital in a certain event it was a separate and independent agreement, and had nothing whatever to do with the contract now sued upon, and that this was practically an undefended action.

Mr. WM. MURDOCK, secretary of the plaintiff Company, then gave evidence.

Mr. JOHN MUIRHEAD, a Director of the plaintiff Company, stated that his Company agreed to assist the defendant Company, and did so. The contract was entered into and sealed on December 5, 1889. When the contract was handed to Messrs. Fowler there was no such condition as that alleged by the defendant Company, namely, that the plaintiff Company or that individual Directors were to subscribe for 3,333 shares of £5 each in the defendant Company. In cross examination, witness said he accompanied Mr. Latimer Clark to the offices of the defendant Company on December 2, 1889. He never heard of any proposal that the plaintiff Company should subscribe. On December 2nd Mr Stratton asked Mr. Latimer Clark if he were ready with a subscription of £16,000, and Mr. Latimer Clark replied in the affirmative. Mr. Stratton then said, "Very well ; I will put you down for £16,000 in case of need." He was not told as early as November, 1889, that if a contract was given to the plaintiff Company they would have to subscribe £25,000. He could not remember having heard anything said about the plaintiff Company subscribing for shares in the defendant Company until December 2nd. It was arranged that £20,000 should be paid to him out of the first moneys coming from the contract, in order that he might meet any claims in connection with the subscription to the defendant Company. That £20,000 was for the purpose of bringing out the Company in a perfectly different way.

Mr. LATIMER CLARK gave corroborative evidence. In cross-examination, witness said he believed the defendant Company were attempting to get out of the bargain. On December 2, 1889, he was informed that the defendant Company had arranged with Messrs. Crompton to take shares to the extent of about £8,000. He was not present at the offices of the defendant Company on December 5th. He had no recollection of Mr. Wallace informing him on that date that the plaintiff Company would have to subscribe £16,000. He did not remember Mr. Wallace saying that the Directors of the defendant Company would seal the contract subject to the subscription for the shares, or that the contract would be left with Mr. Fowler until the plaintiff Company had subscribed £16,000.

Mr. F. MUIRHEAD having also given corroborative evidence,

The further hearing of the case was adjourned till Tuesday.

TUESDAY, APRIL 28TH.

On the hearing of the case being resumed on Tuesday morning,

The ATTORNEY-GENERAL said he should have to submit at the end of the case that his lordship was bound to direct judgment for the defendants. In all probability his lordship would think it more convenient that the whole of the evidence should be taken before he dealt with the point of law.

Digitized by Google

On the suggestion of Mr. Justice Hawkins, the parties and their respective counsel had a conversation, and in the result

The ATTORNEY-GENERAL said he was glad to be able to inform his lordship that an amicable settlement had been arrived at. It had been arranged that the defendant Company should pay to the plaintiff Company the sum of £4,000, to include everything.

Judgment for the plaintiff Company for £4,000 was entered accordingly.

## AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *April* 20, 1891.

**The Telephone in Mexico.**—At the annual meeting of the Mexican Telephone Company, held this week, it was reported that there are at the present time in the City of Mexico 759 subscribers that use this Company's system, and elsewhere, in its territory 364 subscribers, making in all 1,123. The monthly rental is from $5.00 to $6.00. The gross receipts for the past year were $76,000; the net receipts being over $26,000. This Company has applied for a renewal of its charter, and promises, should this be granted, to substitute iron poles and 1½in. cables in the streets in place of the present wires and wooden poles; and, also, to pay 50 cents per month per pole, and to give the municipality free fire-alarm wires on the same poles. In four years there has been an increase of 214 subscribers.

**Municipal Lighting in Massachusetts.**—The committee on manufactures of the Massachusetts Legislature, this week reported five Bills giving the right to five separate cities in that Commonwealth to establish and maintain electric light plants to do city lighting. A petition of the Mayor and Common Council of Boston for the same privilege was reported upon adversely by the committee.

**A Dynamo Telegraph Plant.**—At the new quarters of the Western Union Telegraph Company, in St. Louis, Mo., an extensive plant of small dynamos for furnishing current for electric circuits is now being installed. Three Rice automatic engines of 15 H.P. each are used for driving the generators, of which there are 15. Each engine drives a line shaft to which five dynamos are connected. Eleven of the generators are wound for 70 volts pressure at a speed of 1,250 revolutions. Two are wound for 30 volts, and two for five volts each. The generators, which are built by the "C. and C." Motor Company, are to be run in series of five each, two series to be run at a time, and three to be held in reserve. The field magnets of each series are energised by a shunt from the brushes of the last machine in the series. By tapping each series at points between the machines five different potentials varying from 70 to 350 volts can be supplied. The 30-volt and 5-volt machines supply the local currents. The exact potential required for any line is obtained by inserting in the circuit the necessary resistances, which consist of incandescent lamps placed in series.

**Thomson-Houston Annual Report.**—The annual meeting of the stockholders of the Thomson-Houston Electric Company was held in Middleton, Conn., on Monday of this week. The report made to the stockholders shows that the growth in the company's business, from the time of its organisation in 1883, has been as follows:—

| | | | |
|---|---|---|---|
| 1883 | $426,987.97 | 1887 | $2,335,594.80 |
| 1884 | 700,470.46 | 1888 | 4,435,902.23 |
| 1885 | 983,996.05 | 1889 | 8,222,789.12 |
| 1886 | 1,405,041.74 | 1890 | 10,617,661.67 |

On January 1, 1891, there were in the United States alone nearly 1,000 substantial companies using the system of the Thomson-Houston Electric Company. According to carefully prepared tables, this is about three times the number of local companies using the system of the next largest company engaged in the manufacture of electrical apparatus. If to the above are added the lighting and power stations of the companies working in alliance with the Thomson-Houston Electric Company, the number reaches 1,500, or more than double the aggregate of those using the apparatus of all other systems in the country. The total common stock of the Company already authorised and issued is $6,000,000, and of Preferred stock $4,000,000. The Company has branch offices in eleven different cities in the United States, through which the business of the different sections of the country is transacted. There is at present no section of the country that is not under the immediate and careful supervision of some one of these offices. The balance-sheet shows that the profits for the year have been upwards of $3,000,000. A statement is given showing the number and capacity of the local companies using the Thomson-Houston electric lighting system in the United States, which is as follows:—

| | No. of Companies. | No. of Arc Lamps. |
|---|---|---|
| January 1, 1883 | 5 | 365 |
| ,, 1884 | 31 | 2,478 |
| ,, 1885 | 59 | 5,867 |
| ,, 1886 | 100 | 13,227 |
| ,, 1887 | 171 | 21,840 |
| ,, 1888 | 303 | 36,936 |
| ,, 1889 | 419 | 51,621 |
| ,, 1890 | 587 | 68,203 |
| ,, 1891 | 755 | 87,131 |

Of these about 500 companies are operating both arc and incandescent plants, and employ between 600,000 and 700,000 incandescent lights of the Thomson-Houston manufacture. More than 150 lines of electric railways are in operation or under contract, aggregating over 2,000 cars, as a result of less than three years' operation of this department. The following named gentlemen were elected Directors of the Company for the ensuing year:—Henry A. Pevear, Chas. A. Coffin, Jos. N. Smith, Benj. F. Spinney, Chas. B. Newhall, Jefferson Coolige, S. Endicott Peabody, Elihu Thomson, and Fred. P. Fish.

## CORRESPONDENCE.

### TWISTED TELEPHONE LINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: From some of the conclusions of your article of April 17th on this subject I must strongly dissent.

The author, founding, apparently, on some Midland Railway experiments, pronounces against the efficiency of the "cross" as compared with the "twist." He also states that the French section of the London-Paris telephone line, although not silent, is far superior to the majority, indeed, to almost all of the telephone lines in this country, other than those erected by the Post Office.

These statements show that the author, whoever he may be, is by no means conversant with what has been done in Great Britain—I won't say England—in the matter of telephone trunk lines. The first assertion may form a subject for controversy; the second is simply untrue.

In December, 1887, I contributed to one of your contemporaries* an article which dealt somewhat exhaustively with the merits of the "cross" versus the "twist," the data being furnished by an experience then about three years old. The lapse of nearly four more years enables me to emphatically confirm the conclusions then arrived at. In one particular only has it been found desirable to modify the plan then illustrated and recommended. In lieu of the crossings being gutta-percha covered wires, arranged so as not to touch the poles or arms, these have for some years been bridges made up of several strands of uncovered hard copper wire, one bridge straight, the other arched either under or over the straight one, both being too stiff to admit of accidental disarrangement. As stated in the article, silence with loops crossed as recommended, is perfect, however great the disturbance. The 19-mile loop, with crossings every 12 spans, referred to as having been erected in 1884, and which was the first copper trunk line erected by a telephone company, still continues to work well. It runs from Dundee to Arbroath, parallel with, and in some cases almost touching, the poles of the Dundee-Arbroath Joint Railway, which carry the London-Aberdeen Wheatstone Automatic and other heavy circuits, the induction from which is so heavy that conversation

* Metallic Circuits for Telephone Lines. *Electrical Review*, December 2, 1887.

Digitized by Google

between Dundee and Arbroath on a single wire can only be carried on during lulls in the telegraphing. Since 1887 many much longer and perfectly silent crossed lines have been erected. In fact, I, who can claim to have had at least, as much experience with telephone trunk lines as any other engineer, have never put up a twisted line, nor can I conceive under what circumstances it would be necessary or desirable to do so. The constant twist, like the crossing at every pole mentioned as having been carried out on the Midland Railway, is a superfluity—an excess of precaution only comparable to the perpetual carrying of an open umbrella to guard against an occasional shower of rain. Everybody knows that two or more single wires may be run side by side on the same arm for about a mile without overhearing becoming perceptible. An uncrossed loop can be run for a much greater distance than this, probably ten or twelve miles, alongside a single wire, because overhearing in the loop results from the differential action of the single on the two wires of the loop, and it takes a long run to raise this difference to an equality with the direct action between two adjacent singles a mile long. Crossings every ten miles will kill all overhearing, and will generally be sufficient to neutralise telegraphic induction also. But the crossing must be properly done. I am aware that the Northern District Telephone Company in Northumberland, and the National Telephone Company in Lancashire, tried crossing with unsatisfactory results, but it was because the conditions necessary to observe were either not understood or were disregarded. Similarly, twisted loops that are not silent in respect to each other, and on which telegraphic induction is always present, have been erected in different parts of the country. But this is not the fault of the "twist" any more than the other was the fault of the "cross." Both are thoroughly efficient when properly done.

The drawbacks of the "twist" are chiefly (1) greater first cost; (2) unsightliness; (3) greater liability to faults; (4) greater difficulty in finding faults; (5) the re-arrangement of routes of twisted loops is a complicated operation which cannot economically be carried out without interrupting communication. These objections have been amply confirmed by observations extending over a series of years; especially have the greater liability to faults—about 6 to 1—and the difficulty of finding and removing them been demonstrated.—Yours, &c.,

A. R. BENNETT.

[We have invited Mr. Bennett to support the assertions made in his letter by some description of the faults to which he alludes, but he only informs us that contacts, according to his experience, are the great bugbears of the twist system.—ED. *E.*]

## THE LANE-FOX PATENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I shall be much obliged if you will allow me, through your columns, to offer a few observations for the purpose of explaining the report of the action of the Kensington and Knightsbridge Electric Light Company *v.* the Lane-Fox Electrical Company, which appeared in *The Times* of last Saturday. This report, although accurate as far as it goes, is calculated to convey, to anyone unacquainted with the history of the matter, a very misleading conception of the actual state of the case.

Briefly stated, the facts are as follows:—The patent in dispute covers the method of electric light distribution now very generally in use, and which is known as the "direct supply system." This patent was, until quite recently, held by the Brush Electric Light Company, and was the subject of litigation between that Company and the Edison-Swan Electric Light Company. Before, however, the case came into court a settlement was arrived at between the two Companies, whereby the Edison-Swan Company acknowledged the validity of the patent, and accepted a licence from the Brush Company. What the precise terms of this licence may be I have not been able to ascertain.

Suffice it to say, that inasmuch as it raised questions between the Brush Company and myself, a new agreement was entered into between us, by which the patent was made over to me subject to this Edison-Swan licence (the benefit of which was retained by the Brush Company), and also to a licence to the Brush Company itself. In this way I became entitled to royalties accruing from the use of the patent by the trade generally, with the above exceptions. I not unnaturally concluded that the patent, having been acknowledged by two such important firms as the Edison-Swan Company and the Brush Company, and that having the strong support of by far the most eminent scientific and legal authorities of the day (including Sir William Thomson, President of the Royal Society, Dr. Silvanus Thompson, Prof. Perry, Mr. W. H. Preece, Mr. Latimer Clark, Sir Richard Webster, Mr. Fletcher Moulton, and many others), it would be generally acknowledged by the various infringers, without any further dispute. Accordingly a limited company was formed, with the nominal capital of £100, for the purpose of holding the patent, and of apportioning certain interests therein. Instead, however, of honourably accepting the position, a movement was started in the trade, at the instigation of the Kensington and Knightsbridge Company, for organising an opposition to the patent. After all our conciliatory overtures with this trade combination had failed, an action was started against the Kensington and Knightsbridge Company, in the joint names of myself and my Company, and for this action we retained the services of the Attorney-General and Mr. Moulton, Q.C., from both of whom I had a general retainer of long standing. Now the Kensington and Knightsbridge Company holding also a general retainer (though of long subsequent date to my own) for these same counsel, claimed their services against us, because, according to the rules which govern these matters, my prior retainer was invalidated by the fact of my Company being made party to the suit. The consequence was that, in order that we might continue to have the services of these counsel, the original action had to be withdrawn, and a new one instituted in my own name alone. These facts will explain how it came about that we were placed in the rather curious position indicated in the report of the proceedings before Mr. Justice Sterling.—Yours, &c.,

ST. G. LANE-FOX.

66, Victoria-street, S.W., April 28, 1891.

## TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

"THE ELECTRICIAN"

**ELECTRICAL TRADES' DIRECTORY & HANDBOOK for 1891.**

The 1891 edition of our well-known Directory and Handbook is ready, price 5s., postage extra. The book consists of over 900 pages, and has entailed this year a heavy amount of work. The HANDBOOK DIVISION contains a mass of most useful information. The DIRECTORY DIVISION consists of 430 pages, and contains a very carefully compiled Alphabetical and Classified List of Firms and Persons engaged in the Electrical and Allied Trades in all parts of the world. This Division has been corrected up to date, and the book is thoroughly reliable, the very numerous changes which take place at the beginning of the year being incorporated. By the aid of this Directory, makers of Electrical Machinery, Apparatus, Instruments, Fittings, Sundries, Novelties, and other goods, may safely communicate direct with probable customers without the annoyance and great expense consequent upon using books which are mere lists of Members of Scientific Societies repeated again and again. The Colonial and Foreign Division of this Directory will be found extensive and reliable. *Orders should be forwarded at once.*

In the course of a few weeks "The Electrician" Company will publish "THE ELECTRICIAN" PRIMERS in two volumes, price per volume 2s. paper covers, 2s. 6d. cloth.

CUTTRISS, WALLIS, AND CO. (LIMITED).—As we notified in our last issue, the business of Messrs. Cuttriss and Co., Elmwood Electrical Works, Leeds, has, in conjunction with that of Mr. E. C. Wallis, of Bond-place, Leeds, been transferred to a limited liability company, under the above title, and in a circular issued by the new Company it is notified that the amalgamation is in consequence of a large increase of business in both firms. The circular adds that the new Company will largely increase their manufactures, and that they are in a position to undertake all classes of installation work, &c.

Digitized by Google

LYON'S LIQUID RESISTANCE.—The General Electric Co. inform us that they have been appointed sole licensees and manufacturers of the liquid resistance described in our last issue.

ANOTHER EXHIBITION.—Yet another exhibition purporting to represent the electrical, engineering, ironmongery, and other trades, is being held at the Agricultural Hall this week.

SCIENTIFIC APPLIANCE MANUFACTURING COMPANY (LIMITED), (IN LIQUIDATION).—A meeting is to be held at 26, Ludgate-hill, London, E.C., on May 25th, at six p.m., for an account of the winding up.

FIRE AT MESSRS. FOWLER, LANCASTER AND CO.'S.— A fire occurred on Wednesday at this Company's show rooms, which resulted in considerable damage to a number of electroliers and brackets, and a large stock of switches, &c., were destroyed. We regret to learn that only part of the damage is covered by insurance. We are pleased, however, to find that this will not in any way interfere with Messrs. Fowler, Lancaster and Co.'s business, and that they are in a position to execute orders with their usual promptitude.

ELECTRICAL ENGINEERING CORPORATION (LIMITED).—At a meeting held on the 23rd ult. resolutions were passed winding up this Company voluntarily, and appointing Mr. F. W. Pixley, 24, Moorgate-street, London, E.C., the liquidator.

CROSSLEY'S "OTTO" GAS ENGINES.—We have received from Messrs. Crossley Bros. some printed particulars of the latest type of their well-known gas engines, from which we learn that 15,000 of these engines are in use in Great Britain and Ireland for driving all kinds of machinery, &c. The machinery at Messrs. Crossley's large works, at Openshaw, is driven by their gas engines, indicating about 300 H.P.

ELECTRO-METALLURGICAL COMPANY (LIMITED). — Resolutions have been passed that this Company be voluntarily wound up, and that Mr. J. J. B. Arter, 26, Waterloo-street, Birmingham, C.A., be the liquidator.

# PATENT RECORD.

## APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

April 13, 1891.

6,276. G. W. BLANCHARD. London. Electric locking devices for the gear wheels of motors of electric cars (or carriages).

6,292. H. W. MILLER. London. An improved form of insulator for use with electrical current.

6,298. J. WODICKA. Crouch Hill. Improvements of armatures of dynamo-electric machines and motors.

6,318. N. MITCHELL. London. An improvement relating to medico-electric batteries.

April 14, 1891.

6,347. G. T. TUGWELL and E. A. MITCHELL. Brighton. Improvements in alternating current transformers.

6,372. R. VARLEY, jun. London. Improvements in electric time calls.

6,378. C. J. VAN DEPOELE. London. Improvements in and relating to electric motors.

6,397. C. LANGDON-DAVIES. London. Improvements in phonophoric telegraphy.

6,402. A. T. COLLIER. London. Improvements in microphonic or telephonic transmitters.

April 15, 1891.

6,474. W. GRITTEN and J. LANG. London. Improvements in materials or compounds to be used as substitutes for wood, vulcanite, ebonite, and the like, in the manufacture of articles such as electrical insulators, cells for electrical accumulators, boxes, door handles, toys, and other articles of the like kind.

6,485. A. T. GRAVIER. London. Improvements in dynamo-electric and electro-dynamic machines.

6,489. W. R. PRYKE. London. A combined ceiling switch, cut-out, and ceiling rose for electric incandescent lamps.

6,492. C. BARTER. London. An improved holder and shade for electric glow lamps.

6,502. J. VON DER POPPENBURG. Berlin, Germany. Improvements in galvanic batteries.

April 16, 1891.

6,517. C. M. DORMAN and R. A. SMITH. Manchester. Improvements in electric light switches.

6,559. J. M. NICOL. London. Improved electric bell push.

April 17, 1891.

6,614. H. M. TAYLOR. Edinburgh. Taylor's patent automatic electric bell signals for the prevention of collisions and accidents in foggy weather, or through engine drivers running past danger signals.

6,633. F. TEAGUE. Improvements in or relating to electric meters

6,655. J. C. FULLER and G. FULLER. London. Improvements in supports for telegraph insulators.

6,660. S. Z. DE FERRANTI. London. Improvements in the method of distribution of electrical energy, and in apparatus incidental thereto.

April 18, 1891.

6,677. D. T. PIOT. London. Improvements in the construction of magneto-electro medical.

6,730. W. M. MORDEY. London. Improvements in dynamo-electric machines.

## SPECIFICATIONS PUBLISHED.

1890.

4,791. DOUGLAS. Measuring electrical currents. (Price 8d.)

5,540. HIGGINS. Electrical measures. (Price 8d.)

# COMPANIES' MEETINGS & REPORTS.

## The Indo-European Telegraph Company (Limited).

The twenty-fourth ordinary general meeting of the members of this Company was held at Winchester House, 50, Old Broad-street, on Tuesday last, under the presidency of Mr. J. Herbert Tritton.

The MANAGING DIRECTOR (Mr. W. Andrews) read the notice convening the meeting, and the Company's seal was affixed to the register of shareholders.

The report and accounts were taken as read.

The CHAIRMAN: Gentlemen, you will observe that the receipts of the Company show an augmentation, omitting shillings and pence, of £5,518 over those of 1889, the gross take for the year 1890 being £113,807. The gross expenses are £57,901, being a decrease of £1,338 on those of 1889. As regards maintenance expenses there is an increased payment of interest upon £2,000 owing to the appreciation in the value of the rouble. The Company's payments have all along been made upon the basis of roubles, and of late the Company has had to pay more per rouble than before, the value being higher per £ sterling; but for this the reduction in the maintenance expenses would have been larger by this £2,000. There is also a loss on commercial account of £428, arising from the same increased value of the rouble. Notwithstanding this adverse circumstance, the outcome compares favourably with last year. We place £10,000 to the reserve, recommend the payment of a dividend which makes up 10 per cent. for the year, and carry forward £4,168, as against £2,039 for 1889. The Company has again expended considerable sums in the improvement and strengthening of the line, and in removing a considerable length from the highroad to the railway, where it is more protected from disturbance. The Indian traffic of this Company, and the Eastern Company, has shown more elasticity during 1890, there being an increase, as compared with 1889, in the gross of £9,904, and in the Company's total of £2,739. It is, however, still to be remarked that the income from this source has not yet reached the amount of receipts in 1885, the year preceding the reduction of the tariff, the gross being less by £55,876, and this Company's total by £13,494 than in that year. Taking the year 1886, in which year the reduction came into force on the 1st July, the gross receipts from Indian traffic are less by £35,727, and this Company's, again, less by £7,982. However, the traffic appears to have now taken a turn, and may, therefore, again work up to something like the old figure. It depends pretty much upon the activity of those classes of trade and business which give rise to the exchange of telegrams. The service has been such as to give the greatest encouragement to the development of the traffic, because the working of the lines of the Indian Government, and over their wires on the Indo-European system, as well as over the Company's wires, has been most excellent. Distinguished

Digitized by Google

services have, indeed, been rendered to Indian communications by the complete efficiency of the lines from end to end of the systems of the Government and of the Company. You will have gathered from the newspapers that the perseverance and energy of Sir John Pender have succeeded in bringing about an arrangement with the colonies of Australia for the introduction of a low rate for messages exchanged between Europe and Australia under the principle of a guarantee. As you are no doubt aware the basis of the arrangement is that any loss occasioned is to be borne one-half by the Australian Colonies, and the other by the Government lines and Companies' lines in proportion to their interests in the present revenues. Of course, this large measure has been a work requiring conciliatory views and careful consideration on the part of several important interests. For instance, our own Company had to obtain the consent of Germany and Russia. His Excellency the Post-master-General of Germany, Dr. von Stephan, has been long recognised as a leader in all postal and telegraph reforms, and responded to the exigencies of the position at once on behalf of Germany; the Russian Director-General of Posts and Telegraphs, His Excellency General von Besak, likewise liberally conceded the assent of Russia. The Indian Government, through Sir Juland Danvers; this Company, through the Managing Director, and the Eastern and Eastern Extension Companies, through Sir John Pender and the Managing Director, always subject to the respective Boards, together with the Colonial representatives, were all engaged in the work, and in the end all difficulties, and they were many, were surmounted, and the reduced tariff will be applied on and from the 1st of May next. Of course you will say that the results of lowering the Indian tariff are not an encouraging introduction to the reduced Australian rates, but then the circumstances are not the same. The Australian communities are growing, and are enterprising and active to an extraordinary degree; and it can only be said that if low rates to these progressive countries are not a success the experiment of low rates will at least have been tried under the most favourable conditions. The message traffic with Australia has always been an increasing quantity year after year without reference to tariff, and has always shown a decided tendency to rapid development. Some increment is pretty certain from the operation of this natural increase. We must hope for the best, and that a commensurate increase will be obtained on account of the low charges over and above the natural increase. The experiment of these reduced rates is to be confined to the period of one year. To myself, and I think you will agree with me, this seems insufficient to fully test the question, and I should not be surprised if an extended period were to become necessary. In any case, I may say that the Company's participation in the measure, whatever may be the result, will not affect the dividend. There is nothing more to be added, except that on the conclusion of the ordinary business a resolution will be proposed to which I venture to anticipate your unanimous support will be given; our Managing Director has hitherto had only a consultative voice at the Board, and no vote; it is now proposed that as regards responsibility as a Director he should be placed upon the same footing as the other members of the Board, and shall be on the same footing as to the action of the Board. He concluded by moving the adoption of the report and accounts, and the declaration of the dividend recommended.

Mr. H. WEAVER seconded the motion.

Mr. JACKSON wished it to be known that some of the shareholders did not think the reduction of tariff to Australia was anything extraordinary. He believed that the business public could now send a telegram at the rate of 1s. 7d. per word 7,000 miles across the Atlantic and the United States to the Pacific Coast. They ought to bear in mind the fact that the Indians were as much subjects of the Queen as the colonists, and if they desired to encourage and develop traffic he trusted that the 4s. rate would never be receded from. If it did diminish their dividend, it could do so only in a minute degree. He was glad to see that Sir John Pender had wakened up to the fact that monopoly would not do in these days, and that Eastern telegraphs might meet with a competitor as Western ones had done, and, therefore, it was necessary to be abreast of the times in such enterprises. The reduction of the tariff was a most important question, and even if, at the end of the year, it was found that it did not pay, he trusted that they would not revert to the old rates. He wished to say that their line was only about half the length of that to San Francisco—that was to say, 3,600 miles.

The CHAIRMAN pointed out that a comparison of lines between Australia and San Francisco would be very misleading, for they had to bear in mind the comparative length of land lines and cables involved. He need not say that the initial cost of deep-sea cables was very much heavier than that of land lines. He did not think that the reductions of tariff were likely to affect their dividends.

The resolution was carried unanimously.

Mr. C. W. EARLE proposed, and Mr. C. HOLLAND seconded, the reelection as Directors of Mr. J. Herbert Tritton and Major-General Tremenheere, R.E.

The motion was agreed to *nem. con.*

Mr. WELLS proposed, and Mr. WOODWORTH seconded, the reappointment of the auditors, Messrs. C. F. Kemp, Ford, and Co., which was carried unanimously.

The CHAIRMAN: Now, gentlemen, we come to the last resolution of which notice has been given:—

"*That in addition to the regulations of the Company, as contained in the Articles of Association, the following new regulation (to be numbered 116A) be adopted, that is to say—*

"*That the present Managing Director of the Company shall be a member of the Board, having all the privileges and being subject to all the obligations of an ordinary Director, except that he shall not receive extra remuneration as a Director, nor shall he retire from office by rotation. If the Directors think fit, this provision shall apply to any future Managing Director whom they may appoint.*

"*The other regulations of the Company shall be treated as qualified so as to give full effect to this new regulation.*"

It gives me a considerable amount of satisfaction to be the medium of moving this resolution. There are few men in the business world who have done more for the companies which they represent than Mr. Andrews has done for the Indo-European Telegraph Company. His qualifications are known throughout the world, I may say, as a highly efficient telegraph official. It is only giving to him a portion which is his due that we ask him to be made a member of the Board like ourselves.

Mr. WEAVER seconded the motion.

Mr. JACKSON thought that it was due for the shareholders to state that Mr. Andrews' 21 years management of the Company had placed them in a very exceptional position as a telegraph company. Unfortunately for him (the speaker) he had been largely interested, for his small means, in telegraphs, a large portion of his income being dependent on telegraph securities, and he must say that the position of this Company was a most gratifying exception in point of the returns yielded on his investments. He thought that Mr. Andrews' 21 years' experience entitled him to the confidence of the Board, and certainly more than entitled him to the confidence of the shareholders—even their gratitude; and he thought it was a very good principle indeed that an expert should be on the Board. In Mr. Andrews they had a thoroughly qualified man who understood his business. There was one thing he would like to ask Mr. Andrews, however, at which he hoped that gentleman would not take offence. Mr. Andrews was Chairman of two companies, and a Director of two others. He (Mr. Jackson) did not object to that, for the reason that Mr. Andrews' knowledge and experience qualified him for the work; but he wished to ask whether, in carrying out the views of the Directors, there would be any embarrassment on Mr. Andrews' part, having regard to his many other duties?

The resolution was carried unanimously.

Mr. ANDREWS said he was quite sure that if any inducement were needed in the case of any individual, whoever he might be, for the due performance of his duty, nothing would tend more to the continued exertions of such a person than the proceedings which had just taken place. He felt, and he desired to express, his grateful appreciation of what had been done and of the way in which it had been done. In reference to the very proper question of Mr. Jackson—referring to the fact that one's offices might be unduly multiplied, he might say that in his particular case the work he did was of a similar kind to that which he did in this Company. It added, if anything, to his experience, and the man who extended the area of his survey—so long as that survey was confined to a particular direction—was sure to become more efficient in his service. He begged to inform Mr. Jackson that in no way would he allow other engagements at any time to interfere with the performance of the obligations which he owed to this concern, and which for a period of 21 years had been performed with satisfaction to them.

A vote of thanks to the Chairman and Directors terminated the proceedings.

## Metropolitan Electric Supply Company (Limited).

Sir John Pender, K.C.M.G., presided over the fourth ordinary general meeting of this Company, which was held at Winchester House, Old Broad-street, on April 29, 1891.

The SECRETARY (Mr. E. Cunliffe-Owen) read the notice convening the meeting, and the report of the Directors was taken as read.

The CHAIRMAN: As this is an important meeting, at which it is desirable that the shareholders should clearly understand the position of the Company, dealing as it does with the finances of the Company for 15 months, I propose to put before you a statement which will be available in the future as a record of the past. One of the first points which will occur to you in connection with the report is the form in which, for the first time, the accounts are presented, a form which, as you will have learned from the report, is in accordance with the requirements of the Board of Trade, who, under the provisions of the Electric Lighting Act, have power to prescribe in what manner the accounts of all electric light undertakings are to be furnished to them for public information. The balance-sheet which accompanied the report to September 30, 1889, dealt with a period which ended only a few weeks after the granting of the orders under which we were then working, and covered the expenditure attendant upon the starting of the Company's operations, and the commencement of its working, which at that time only included a few customers. Although it was known that the Board of Trade possessed the powers to which I have referred, the Company were at that time without information as to what would be required. Acting under the advice of the Company's auditors, the accounts were prepared and laid before you in the ordinary form of a company's balance-sheet. Since then, however, the Board of Trade have prescribed a form of account, which, although not yet finally settled, being still under discussion in some minor particulars, is sufficiently comprehensive for the purpose required, and has been followed as closely as possible in the accounts now before you. I may say that we were given to understand by the Board that they would be content with a detailed account for the period commencing with the date of the last balance-sheet, dealing with the expenditure prior to that date as a lump sum, but on carefully going into the matter, we found that such a mode of dealing with the figures could not be a satisfactory one, and the whole of the accounts from the commencement of the Company have therefore been reconstructed in order that the present and future balance-sheets might give a clear record of what the Company has done and is doing. The accounts speak for themselves, and you will, from them, be able to form a fair idea of the amount of work which has had to be carried out, and the time and care, as well as money which has had to be expended, to bring the Company's various undertakings to their present condition of practically complete working. There is one item of detail to

Digitized by Google

which I ought to refer: I allude to the apportionment of management and general expenditure between capital and revenue. During the fifteen months over which the accounts extend, the direct capital xpenditure amounted to £195,000, while the total turnover revenue which has been handled was only £27,000, from which it will be evident that the time and attention of the Board and staff, with the exception of the actual station staffs, which, of course, are wholly paid for out of revenue, have been mainly occupied with capital details. In view of this fact, the Board have considered that the proportion of management and general xpenditure shown in the accounts as chargeable to revenue is a liberal one, and it is satisfactory to find that with this charge, the revenue which has been mainly earned during the latter portion of the period shows a profit, though, of course, only small. The Board are fully alive to the fact that as capital expenditure decreases, the proportion of charge to revenue must very largely increase, until in a little while the whole load of management has to be borne by revenue, but making all allowances for this increase of charge, the revenue is now growing so satisfactorily that future success seems assured. With regard to the interim dividend of 2s. per share for the three months ending March 31st last, I am glad to be able to tell you that the income for that period shows an actual increase on that for the December quarter, although we have, of course, had to deal with brighter weather and individually smaller requirements than in October, November, and December. Our expenditure has not proportionately increased, and, making a full allowance for management expenses, we have no hesitation in saying that the profits for the quarter amply justify the interim distribution which we have had the pleasure to announce, and which is a tangible proof that the anticipations which we have held out at previous meetings are in a fair way of being fulfilled. The remarks which I made when I last had the pleasure of meeting you in November will, I think, be sufficiently fresh in your minds to obviate the necessity of my dealing at any great length with the period which the report embraces. It may, however, be interesting for you to realise the difference of our position at the commencement and the close of this period, and for this purpose I would remind you that in October, 1889, we had just opened the first portion of our Sardinia-street station, and had run temporarily a few overhead lines to connect up our first customers. Our Rathbone-place station was also supplying a few customers by means of overhead wires, and the small plant which we had then lately purchased with the building from Messrs. Pritchett. The erection of the Manchester-square station had not even been commenced. Our Whitehall station was then, as it is now, doing good and steady work. The total number of lamp-connections was, on October 1, 1889, 6,111; it is to-day 60,000. Our customers then numbered 37, and now amount to 480, and as our report informs you our revenue, which for the quarter ending December 31, 1889, was £2,866. 15s. 7d., amounted for the corresponding period of 1890 to £10,726. 19s., an increase of 275 per cent. During this period the plant at Sardinia-street has been duplicated, the new plant at Rathbone-place has been installed, the Manchester-square station has been erected and fully equipped, and an elaborate network of underground mains, about which I will speak to you later on, has been laid down. With the growth of our capabilities of supply has also grown our business. And with the growth of our business we are pleased to say that the demand for the light also appears steadily to grow, so that I fully believe that at our next year's meeting we shall be able to report to you a lamp connection of well over 100,000. And you must remember that this, and an even greater, increase in our business can be amply dealt with by our existing machinery, and, as I endeavoured to explain to you at our last meeting, the greater our production the less in proportion will be our expense of production. Therefore, if we can show a profit when supplying 50,000 lights, we can proportionately show a much larger profit when supplying 100,000 lights. I have had a diagram prepared for you which will show you at a glance the present position of our business. On this diagram each black mark represents a consumer's house, and you will at once realise that we are still only on the threshold of our work and that, even when our present output is doubled, much, very much, remains to be done. Looked at from this point of view a map of London forcibly reminds me of a map of Africa; and we, like my friend Mr. Stanley and so many others, are engaged in filling up the blank spaces, and in illuminating the darkness which is still but too apparent. Our work is still essentially a pioneering one, and if we can make a pioneering business pay it augurs well for our profits hereafter. And here I would like to make a few remarks as to the choice we have made of the system for supplying electricity to the public. The system we have mainly adopted is that known as the alternate-current transformer, which we work at the extremely moderate pressure of one thousand volts. We elected to adopt it under the very best practical and scientific advice, as being the system best fitted for pioneering work. We have every reason to be satisfied with our choice, for it has enabled us to cover our large areas at infinitely less cost than any other known system would have done. The advocates of other systems have been lately doing their best to disparage the merits of the alternating current, and have endeavoured to make a strong point out of the loss of energy, which, to a certain extent, undoubtedly occurs in connection with the transforming apparatus, but allow me to remind them that this loss is insignificant when compared with the heavy initial outlay which the use of the continuous current necessitates. And I would, moreover, point out that any loss which we have to bear will be reduced to a minimum so soon as the increasing density of our lighting warrants the establishment of transformer sub-stations. This question of transformer sub-stations, or, as the Americans say, of banking transformers, has for a long while been receiving our careful attention, and we have all along had in view their ultimate adoption as soon as our business is sufficiently developed to ensure their being worked economically. Another great advantage of our system over all others adopted in London is that each of our alternate-current stations can assist or be assisted by any other—indeed, it is our usual practice at present to shut down one of our stations entirely during the hours when the load is lig[illegible], and during the summer it is quite possible that we shall fin[illegible]e station adequate to deal with the requirements of the whole [illegible] our areas during the hours of minimum demand, thus gaining considerable economy in working. In speaking to you of our systems of supply, I dare say you all have in your minds that adopted by another great London supply company. We must all admire the indomitable pluck with which the difficulties inseparable from the achievement of such a scheme have been faced; we must all admit the genius of the engineer who is responsible for such a gigantic design, and most heartily do I wish him success, and we must acknowledge the accustomed skill displayed by my friend the chairman of that company, in his recent review of their position and prospects. We sincerely trust that not only for their own sake, but for the sake of the cause of electric lighting generally, their success is now assured, and we are glad to think that we were able to be of some assistance to them in their hour of need. But as the Chairman could not avoid attempting to make a point at our expense in dealing with their anticipated immunity from vibration difficulties, so I venture to repeat the friendly warnings which I have often uttered before, namely, that it is dangerous to put all your eggs in one basket. One of the principal arguments brought by the London Corporation in establishing one large central station outside London was based on the fact that the Gas Light and Coke Company had done the same at Beckton, and, what the Gas Company did after fifty years and more working on a more modest scale, our friends have done after three or four years of purely pioneering work. Of the two examples we prefer to follow that of the former, and to walk before we run. When our figures can show something like the returns of the Gas Light and Coke Company with its 200,000 customers and its million tons of coal, which is, I believe, yearly required to meet the demands upon them, then will be the time for us to consider whether economy and efficiency will best be served by the erection of a great outlying generating station, or whether our present policy of smaller plants which can render one another mutual assistance, thus reducing the risk of failure of supply to a minimum, will even then be the soundest one. With regard to this vibration question to which Mr. Forbes refers, it is of course inevitable that the erection of large machinery works in the midst of a great town like this should give rise to complaints. We have of course had to deal with grievances respecting ancient lights, alleged noise, and what not, about which I would say more but for the fact that we have at present two cases *sub judice*. I may, however, say this, that every precaution has been taken to prevent the possibility of any noise or vibration occurring, and as a practical proof that such precautions can be taken with success I would inform you that you are now sitting within a very few yards of a powerful plant which is working at this very moment, and which supplies the electricity and other requirements for the whole of this vast building. There is one other point in Mr. Forbes' remarks to which I would like to allude. In answer to a question respecting the amount receivable per lamp per annum he is reported to have replied that £1 per light "is not enough, and that his Corporation would now refuse to take a contract at such a rate." If this applies to their customers as a whole I must congratulate the London Corporation on their experience, which is quite at variance with that of ourselves or, I believe I may safely add, of any other London Supply Company. We can fully admit that there are classes of customers with whom a contract on such terms would be out of the question, whose consumption would need a far larger contract price than 20s. But against these classes have to be set what we may style the private customers, whose demands on our supply are comparatively small, and from whom it would be impossible and indeed unfair to obtain so high a price per light. I am speaking now of our experience as gained by our supply of current by meter, for I may inform you that the larger proportion of our customers are now charged by this means. Our experience of the average revenue obtained for each 8 c.p. lamp connection per annum places it at about 12s., and I believe that even this figure is a better one than is obtainable by companies whose area of supply is of a more purely residential character than ours. In making these remarks I do not wish you to think that we are losers by this experience. If you will reflect a moment you will readily understand that the less each lamp in our system is used the greater may be the number of lamp connections our plant can safely deal with. We are therefore in a position to supply a far larger number of lights than we originally believed our plant was capable of meeting, and hence our operations are considerably widened, and we shall gain by number what we have lost by rate. Our policy is to give the light at the lowest price consistent with a fair dividend. as this policy will more quickly develop the use of the light, and while we must always bear in mind that we have a formidable competitor in gas; still, looking to the advantages which the electric light has over that illuminant, I feel that with anything like a price approaching that of gas, our light must eventually take the lead. Our stations have, as is stated in the report, worked very satisfactorily, and this is the more gratifying as they commenced to supply current before all the fittings and accessories were completed. With regard to our system of underground mains, I may state that the length of conduits at present laid amounts to 40 miles. The whole of this work has been executed under the immediate supervision of our own staff, and by our own workmen, a more efficient and economical plan than that of employing a contractor. Into these conduits we have drawn 90 miles of mains, and it is a matter of deep satisfaction for me to inform you that not one single fault or leakage has yet occurred in any one of our circuits. Anyone who realises what this means will readily agree as to the excellence of the cable employed and to the skill and care with which our staff has manipulated it. It also tends to strengthen our conviction that the system we have adopted for our mains is the proper one. I must not omit to testify to the Board's appreciation of the loyalty and energy which has been displayed by our engineering staff, and to the skill with which they have

Digitized by Google

overcome the many difficulties which have of necessity arisen in working new plants under trying conditions. I should also like to remind you that we have always made it a practice ' e a constant supply by night and by day, and although at any rate at firs l during the small hours of the night the demand has scarcely justified us in doing this from an economical point of view, we have, nevertheless, always believed it to be our first duty to honourably carry out the responsibilities which have been imposed upon us by our Parliamentary obligations, and to prove to our customers that electric lighting is no less than gas, reliable whenever wanted. We have had from some of our leading customers very satisfactory and encouraging letters. I may read one as a fair illustration of many others:—"Dear Sir,—It gives me very great pleasure to be able to testify to the admirable way in which I have been supplied up to this time with the electric light by the Metropolitan Supply Company. I have indeed nothing but praise for it. From the opening of this theatre, two years ago, not a hitch has occurred, and the light has been pure and steady throughout." That is from Mr. John Hare, of the Garrick Theatre. You cannot have anything more satisfactory than that. It is very good evidence of what we have done. I am reminded that we have had letters of a similar kind from Mr. Henry Irving, Mr. George Edwards, Mr. Augustus Harris and Mr. Sedger. All this is most encouraging, because to these gentlemen a few moments' darkness would be something terrible. It is most satisfactory to us, and is also a compliment to our staff; but, after all, an efficient staff is what makes an efficient system. With regard to our Paddington concession, which, you will remember, was granted to us last August, we are already making great progress in this district with our mains, and are already supplying upwards of 2,000 lights from our Manchester-square station. Indeed, had it not been for the exceptionally severe winter, which stopped our works for at least two months, our progress would have been still more marked. The large demand for light in this important parish renders it necessary for us to proceed at once with the erection of a station on the wharfside premises which we have acquired, and as the bulk of the machinery is already completed and the building works to be commenced in a few days' time, we have every reason to believe that the station will be completed in time for next winter's lighting. You will observe from the report that, as far as we can at present estimate, the erection of this station with the supply mains and the completion of the present system of mains in our other districts will, as nearly as possible, absorb our present issue of capital. We shall, therefore, soon issue notices for the payment of the final call of £1 per share, and I think that we shall be meeting the wishes of shareholders in this respect, as there will then be no further liability on the shares, which will therefore improve their already favourable position on the Market, and will tend to add to their attractiveness as a sound investment. Now, gentlemen, as I told you at the beginning of these remarks, we have given you a report of the past. We have fulfilled to the letter the promise that we made, namely, that we were not going to adopt a speculative system, but one which had been proved successfully in America. We are adopting a system which will be extended by fresh installations, but we shall still be working all our installations singly or as a whole. We told you in the prospectus that we took up this question because we thought the time had come when electric lighting should be taken in hand by practical people. A very large amount of money had been spent previously on speculative paper installations. I believe that every shilling of our money has been well spent, and we have established what I believe will be in the future a thoroughly sound investment. If our future grows as the past has done, success will come at a very early day indeed. I am pleased with the result so far, because, when I was examined before the Commissioner on Electric Lighting, I made this statement—I believe I have made it before in this room, and I shall repeat it to-day—that, looking from the standpoint of the present moment, judging from what we have seen in the past, I believe that, before we have done, we shall have installations which will cost us over £2,000,000. So satisfied am I of the progress of the light—and I believe the experienced gentlemen sitting by me think the same—that we look forward to developing this industry into something far larger than I dare venture to prophesy to-day. As I stated in my previous remarks, we are declaring our dividend now simply upon three months' earnings, and with 50,000 lights; but before I meet you again we shall have at least 100,000 lights, and probably considerably more. I believe our installations are capable of giving us a very much larger amount, but we want to be prudent and to err on the safe side. When you are getting a respectable dividend, and we find that the way is clear, and the demand continues to grow, we shall not be backward in meeting that demand, and I do believe that we shall not have the slightest difficulty in getting any money that may be required for our extensions. Until, however, we have proved that what we have done at present is not only sound in principle, economical in working, and profitable to our shareholders, we shall make no step in that direction. I went round the stations yesterday, and I wish that some of the shareholders would spend an afternoon in visiting them. I think they would be pleased with what they would see. The stations are compact and thoroughly efficient. They are everything which a man who takes an interest in a progressive thing is pleased at. I was thoroughly pleased, and I believe that we have not only good installations, but that we have also very good men to work them. I believe that no money in any concern of this kind has been more carefully or better expended than yours has been during the last 18 months. My friend, the Chairman of the London Company, paid a very high compliment to the Board of Trade; and I wish to repeat pretty much the words he used. Of course, that Department has to be guided, more or less, by the Acts of Parliament, and we find in these Acts that provisions exist which we may call obstructive, but as long as there is a desire on the part of the Board of Trade to remove difficulties we can only say that they are so far doing as much as they possibly can to help us. For this I feel personally obliged to them. I cannot but venture to add a hope that one of these days they may find it possible to recommend improvements being made in the Electric Lighting Acts. Now, gentlemen, I have only a few more words to say. We have a broad field to supply, and as you see by this map behind me, our space is a very large one, and as this great City of London is growing and extending hand over hand, I think the field before us is not only a wide one, but one which is also very encouraging indeed. In these times if there is anything new—anything that will enable a trader to display his goods to greater advantage, or to prevent injury to his stock—depend upon it the traders will adopt it. When I drove along Oxford-street yesterday I asked as we went along how many of the Oxford-street shops were supplied, and I was astonished to find that the number was perfectly insignificant. All these tradesmen will, however, be obliged eventually to use the light, and as our system is equal to very large expansion, I look forward to a very rapid development of it in that quarter. A great deal has been said about gas and the electric light. I believe that there are some people who are using the electric light for a price even less than that of gas; but I do believe this, that even if the cost is a little more, the electric light must take its place in all homes and in all places of business where comfort, cleanliness, and economy are desired. I may add that Mr. Gordon, who has been a Director of the Company from the beginning, now retires from the Board. He has had a great deal to do as our electrical engineer during the time we have been building the works to carry out our system. Mr. Gordon finds that the demands now made upon his time owing to the growth of his business are such that he can no longer serve us as a Director, and therefore he does not offer himself for re-election. He has done good work for us. He will continue with us as a consulting engineer, and I wish him good speed in the more extensive sphere into which he is now entering. With these remarks I beg to move:

"*That the report of the Directors and the accounts for the period commencing December* 1, 1889, *and ending December* 31, 1890, *submitted to this meeting, be and the same are hereby approved and adopted.*"

Sir GEORGE ELLIOT, Bart., M.P.: Gentlemen, I have great pleasure in seconding the motion for the adoption of the report and accounts.

The CHAIRMAN then expressed his readiness to answer any questions, but no shareholder rising to address the meeting he put the resolution in the usual way and declared it carried unanimously. On the motion of the Chairman, seconded by Sir James Anderson, the retiring Directors, Sir R. N. Fowler, Bart., M.P., and Mr. J. C. Parkinson were re-elected, and subsequently Messrs. Deloitte, Dever, Griffiths and Co. were re appointed auditors to the Company. A cordial vote of thanks was then passed to the Chairman and Directors for their successful administration of the affairs of the Company.

The CHAIRMAN, in reply, observed that since they first met the shareholders a rather anxious time had been experienced by the Board, and a great amount of work had been done. He thought they could all be congratulated, and that he might take credit for the Board and the staff that the work which had been done had been done well. The dividend now declared was small but it was only on three months' earnings, and every additional 1,000 lights—and their number ought to increase daily—would add to their exchequer. He thought the shareholders could now sit down quietly and watch the progress of this business.

The meeting then separated.

## Reuter's Telegram Company, Limited.

The ordinary general meeting of the shareholders of this Company was held on Wednesday at the offices, 24, Old Jewry, under the presidency of the Right Hon. Sir John C. D. Hay, Bart., K.C.B.

The SECRETARY (Mr. Bradshaw) read the notice convening the meeting and the Report of the Directors.

The CHAIRMAN: Gentlemen, I have now to move the adoption of the Report. In doing so, I think I have reason to congratulate you on the results shown in the balance sheet. Our revenue, when compared with the preceding years, shows a substantial increase. The expenditure, you will also observe, has, at the same time, been considerably augmented. We have reason to believe that our efforts to maintain our service in the highest efficiency are being appreciated generally by the press. We certainly shall not suffer in the long run from any exceptional or temporary sacrifice that we may make to attain that efficiency and accuracy which distinguish our agencies. Roughly speaking, our telegraphic outlay has been £5,000 in excess of 1889, which alone is sufficient to account for the slightly diminished dividend. In these times 5 per cent. may be considered a fair return for capital invested, and as we carry forward nearly £1,000, I trust the shareholders will feel that they have reason to be satisfied. As the High Court has sanctioned the modification in the Memorandum of Association, which was unanimously approved at the Extraordinary General Meetings in December, we have now been able to commence our advertisement business, which we anticipate will eventually yield highly profitable results. We have opened a separate office for this purpose in the immediate vicinity. I must, however, again warn shareholders that large profits cannot be expected at once. But no great pecuniary risk is involved, and if we do not at once realise large profits, we have not to fear losses. The extra current and preliminary expenses incidental to starting our new business will be the only fresh outlay for which we have to provide. I am happy to inform the shareholders that Mr. George de Reuter and Mr. Frederick J. Griffiths have joined the Board as Directors. In Mr. George de Reuter we have an associate, who, in addition to his hereditary claims to our respect and confidence, has shown, not only at the Bar, but as Director of the Bank of Persia, business-like ability of no ordinary character. Mr. Griffiths by his indefatigable zeal in your service, as secretary for more than a quarter of a century, has made himself master of the details of our business, and though

Digitized by Google

after his long service as secretary he had a perfect right to devolve his arduous duties upon his worthy successor, Mr. Bradshaw, we consider ourselves most fortunate in securing Mr. Griffiths' knowledge and services to the Company as our associate in the direction.

Baron DE REUTER seconded the resolution, which was carried unanimously.

On the motion of the Hon. MARK NAPIER, seconded by Mr. FREDERICK J. GRIFFITHS, the retiring Director, Baron de Reuter was unanimously re-elected.

Baron DE REUTER having briefly acknowledged his re-appointment,

The Auditors, Messrs. Welton, Jones and Company, were re-elected, and a vote of thanks accorded to the Chairman and Directors.

## Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited).

An extraordinary general meeting of this Company was held at the registered office, 64, Cannon-street, on Monday, Mr. F. L. Rawson in the chair, when the subjoined resolution, which was passed by the Company in general meeting on the 6th ult., was submitted for confirmation as a special resolution.

Resolved: That the Articles of Association be altered in manner following:—

(a) *Article 109 shall be cancelled.*

(b) *In place thereof the following Article shall be substituted, namely, "(109) All dividends shall be payable out of profits only; but such dividends may be declared and paid either in cash or by the distribution of specific assets taken at their par value, and in particular of shares, debentures, or other securities of any other company, or partly in one way and partly in the other."*

(c) *Article 110 shall be altered by inserting after the words "until they have received a return" the words following (namely) "in cash;" and by inserting after the words "and in addition 100 per cent. premium" the words following (namely) "also in cash;" and by substituting the word "Founders" for the word "Reversion."*

The SECRETARY (Mr. J. Shurmer) read the notice convening the meeting, in full.

The CHAIRMAN then said: Gentlemen, it will be unnecessary for me to say more than that these resolutions are the same that were actually passed on the 6th inst., and that the effect of these resolutions is this—that after the priority shareholders have received a second £5 per share, making an amount of £10 per share in cash, the Directors will have the power of distributing the assets of the Company at par value, giving the proportionate amount to the priority shares and the founders' shares. He then moved the confirmation of the first resolution.

Mr. J. J. ATKINSON seconded the motion, which was carried unanimously; as were the other resolutions.

The proceedings then terminated.

## Brazilian Submarine Telegraph Company (Limited).

The following is the report of the Directors for the half-year ended December 31, 1890, to be submitted to the thirty-fifth ordinary general meeting of the Company, to be held on Wednesday, the 6th inst., at Winchester House, Old Broad-street, E.C., at 12 o'clock:—

The revenue for this period amounted to £143,363. 13s. 1d., and the working expenses to £18,106. 2s. 9d. After providing £12,880 for debenture interest and sinking funds, and £1,960. 11s. for income tax, there remains a balance of £110,416. 19s. 4d.; to this is added £2,416. 18s. 1d. brought forward from 30th June last, making a total of £112,833. 17s. 5d. First and second interim dividends amounting to £39,000 have been paid, and £50,000 transferred to the Reserve Fund, leaving the sum of £23,833 17s. 5d. to be carried to the next account. Of this amount the Directors intend distributing £13,000, or 2s. per share to the shareholders, in addition to the usual quarterly dividend of 3s. per share, payable on June 24th next.

The receipts for the half-year include the sum of £1,500 dividend to June 30, 1890, on the Company's shares in the African Direct Telegraph Company (Limited).

The Directors deeply regret that the Right Hon. Viscount Monck, who has occupied the position of Chairman of the Company since its formation in 1873, and Sir Thomas Fairbairn, Bart, who has been a Director since 1874, desiring to reduce their engagements, have resigned their seats on the Board of the Company.

The Board have elected Sir James Anderson Chairman of the Company.

The vacancies on the direction created by the retirement of Viscount Monck and Sir Thomas Bairbairn, Bart., have been filled by the Board, by the appointment of Lord Sackville Arthur Cecil and Mr. John Denison Pender.

A serious fault appeared in the 1874 cable, about two miles off Lisbon, on December 18, 1890, which was repaired by the Telegraph Construction and Maintenance Company's s.s. "Britannia." The same cable was reported interrupted about 18 miles from Madeira on January 7, 1891. Arrangements were immediately made for the despatch of the Telegraph Construction and Maintenance Company's s.s. "Scotia," and the necessary repair was accomplished after laying in 25 knots of new cable. The cost of effecting these repairs will appear in the accounts for the current half-year. The shore end of the Lisbon-Madeira 1882 cable broke on March 8, 1891, close to Madeira. The Directors have much pleasure in stating that this cable was effectively repaired by the Company's Madeira staff. Neither of the foregoing operations caused any interruption to the transmission of messages, the traffic having been carried by the duplicate cable.

In accordance with the provisions for repayment of the First Issue of Debentures, dated July 31st, 1884, 160 Bonds, representing £16,000, were drawn on the 24th instant, for payment at par on July 31st next. This, with the previous drawings, will make a total repayment of £96,800, leaving £53,200 of the first issue of debentures outstanding.

The various sections of the Company's line are in good working order.

## The Kensington and Knightsbridge Electric Lighting Company (Limited).

The following is the Report of the Directors of this Company to the end of the year 1890:—

The whole of the compulsory area has had its streets, with the exception of about three-quarters of a mile, supplied with mains, and in 2½ miles of streets, external to this area, mains have also been provided, making the total length of streets down which mains have been placed, 10 miles, about 4 miles of which have been executed in the year 1890. It is computed that there are about 1,300 houses fronting on these mains, and on the 31st December last only 291 were taking current. During the year the number of houses and shops connected with the system has increased from 147 on December 31, 1889, to 291 on December 31, 1890; while the number of lamps calculated on the usual basis of eight candle-power has increased from 11,794 to 25,535.

The battery station in Queen's Terrace-mews, which was in the course of construction at the time of the last Report, has now been completed and at work for some months with most satisfactory results. The plant at both Kensington-court and Chapel-place stations has been increased, not only to meet the extra lighting obtained during the year, but also to provide power for a large increase of demand. It may be found, however, that the demand will increase with sufficient rapidity to necessitate the execution during the current year of larger extensions than the Company's present funds would enable them to provide. To guard against such a contingency the Directors think it would be well that they should be in a position to issue some further Preference shares, those of the first issue having been already taken up, with the exception of about £2,000. They will therefore submit to the shareholders the requisite resolution for creating further Preference shares, the date and conditions of their issue being left to be determined by the Directors when the money is wanted.

The dividend on the Six per Cent. Preference shares was duly paid to June 30, 1890, and out of the balance standing to the credit of the net revenue account on December 31, 1890,—£1,804. 2s. 2d.—the sum of £922. 18s. 3d. has been appropriated for the payment of the Preference dividend to that date, leaving £881. 3s. 11d. available for the next account.

Sir Charles Grant retired from the Directorship during the year, and Mr. George H. Hopkinson was appointed by the Directors to fill the vacancy. In accordance with the articles of association, Mr. Granville R. Ryder and Mr. R. W. Wallace retire from the Directorship, and, being eligible, offer themselves for re-election. The auditors, Messrs. Lovelock, H. W. Whiffen, and Dickenson, offer themselves for re-election.

## Submarine Cables Trust.

The following is the report of the Trustees to the twentieth ordinary annual meeting of the certificate holders, to be held at the offices of the Trust, Winchester House, Old Broad-street, E.C., on the 5th inst., at 2 o'clock:—

The revenue for this period, including the balance of £431. 8s. 11d. brought from the previous accounts, amounted to £24,098. 3s. 3d. The coupons due on April 15, 1890, were paid on October 15, 1890, and the coupons due on October 15, 1890, were paid on April 15, 1891. The expenses of the Trust amounted to £1,175. 7s. 6d., and the payments on account of the coupons to £20,286, together £21,461. 7s. 6d., leaving a balance of £2,636. 15s. 9d. to be carried forward. This balance, which is equivalent to 15s. 7d. per cent. on the value of the outstanding certificates, the trustees propose to distribute to the certificate holders on the 15th proximo, together with a small amount to be taken from the current year's revenue, so as to admit of the payment of £1 on account of the coupon due on 15th instant.

The meeting will have to elect two auditors for the current year; Mr. John G. Griffiths and Mr. John Gane offer themselves for re-election.

A table showing the original and present investments of the Trust is appended to the trustee's report.

## NEW COMPANIES REGISTERED.

**CORIFACT SYNDICATE (LIMITED).**—Registered with a capital of £15,000 in £1 shares. Object, to carry on business as manufacturers of artificial leather, leather board, electrical apparatus, &c.

**CUTTRISS, WALLIS, AND CO. (LIMITED).**—Registered by Vincent and Vincent, 20, Budge-row, E.C., with a capital of £10,000 in £5 shares. Object, to acquire the Elmwood Electrical Works, Camp-road, Leeds, and also the business of E. C. Wallis, of 1, Bond-place, Leeds, in accordance with an agreement made between Thomas Cuttriss and St. Wells Cuttriss of the first part, Edwin Cooper Wallis of the second part; and Richard Wilkinson Graham, on behalf of the Company, of the third part, and to carry on, under the style of Cuttriss, Wallis, and Co. (Limited), the business of electrical apparatus manufacturers. There shall not be less than three nor more than five Directors. The first are Thomas Cuttriss, St. Wells Cuttriss, Edwin C. Wallis, and John William Bannister, all of Leeds. Qualification, £150. Remuneration, £50, divisible.

**LONDON ELECTRICAL TRAMWAYS COMPANY (LIMITED).**—Registered by Hurrell and Mayo, 165, Queen Victoria-street, E.C., with a capital of £150,000 in £1 shares. Object: to acquire the tramway system of the

Digitized by Google

North London Tramways Company, and to carry on and develop and extend the same. The first subscribers are :—C. J. Westwood, 3, Adelaide-place, E.C. ; F. C. Winby, 3, Adelaide-place, E.C. ; C. Docwra, 3, Adelaide-place, E.C. ; B. Laucler, Chigwell, Essex ; E. J. Relf, 12, Humber-terrace, Westcombe-park, S.E. ; R. Krugh, Hermon-Hill, Wanstead ; A. W. Hurrell, 165, Queen Victoria-street, E.C. There shall not be less than three nor more than seven Directors ; the first are the signatories to the Memorandum of Association. Qualification, £100. Remuneration to be determined in general meeting.

## CITY NOTES, &c.

**BRAZILIAN SUBMARINE TELEGRAPH COMPANY.**—Our advertisement columns contain a list of the numbers of the Five per Cent. Debentures (1884 issue) which were drawn on April 24th, and will be paid off at par on July 31st next. The receipts of this Company for the past week amounted to £5,998.

**CITY AND SOUTH LONDON RAILWAY COMPANY.**—The traffic receipts of this Company for the week ended April 26th amounted to £784.

**COWLES SYNDICATE.**—The members of this syndicate held a private meeting at Winchester House, Old Broad-street, E.C., on Wednesday.

**ELECTRIC TRACTION IN PARIS.**—At the fourth ordinary general meeting of the Continental Metropolitan Tramways Company (Limited), held yesterday under the presidency of Mr. B. H. Van Tromp, who stated that: —"It was with feelings of the ve y greatest disappointment that he had to come before them that day without being able to announce that they had any system of electrical traction upon their tramway lines in Paris ; but with all the tramways companies in England, none of them showing courage enough to go for an electrical system, he thought that the shareholders must not be surprised that they had not a scheme in view for Paris. He might, however, state that they had been in negotiation in regard to this matter, and at the present moment they had under consideration a proposal made to them by the Lineff Company, whose system could be seen at work at Chiswick. He had seen it at work there, and, as far as he could judge from a non-scientific point of view it was simplicity itself, but it was a question whether a system that worked well in a yard or a siding of 90, 100, or 150 feet would be equally satisfactory when in practical working on an ordinary road and where the conditions would not be quite so favourable. That was a matter that had yet to be decided, but he might tell them that they had had certain proposals made to them, and he had just had placed in his hands a telegram from the Chairman of the syndicate to which he had referred the willingness to lay down in Paris on a part to be decided between them, an experimental line of one, two, or three miles in length as might be arranged, and to incur every expense which might be necessary for such an undertaking at a price of so much per mile, run with a guarantee of a certain mileage per day. Of course they must guarantee such a minimum mileage giving a certain fixed income or otherwise it would not be worth while for an electric traction company to undertake the work. They had given the most serious consideration to some half a-dozen systems, and he might say that their line in Paris was at the present time being inspected with a view to electrical traction, but he wanted to point out that in adopting any system it would be only adopted on the grounds that this Company would undertake no expense in the matter, and that they would undertake no risk, but all must devolve upon the Electric Company, who must be willing to guarantee this Company against all claims that might be made either by the city authorities or by other people. He repeated that they would only undertake an experimental working of electricity upon their system upon a basis of arrangement freeing them from all expense and from all risk or loss."

**ELMORE COPPER.—A CHALLENGE.**—Considerable correspondence has appeared in some of our financial contemporaries regarding the Elmore process of copper deposition. The correspondence itself has not been of a particularly edifying character, consisting chiefly of *tu quoque* arguments, but we think the challenge contained in Mr. William Elmore's letter in the *Financial Times* of Wednesday may probably clear the atmosphere. After referring to the letter of Mr. Alexander Watt in our contemporary, in which the Elmore process is stated to be at least unreliable and incapable of standing a severe test, Mr. Elmore proceeds :—"I am willing to deposit with any approved bank or person the sum of £500 provided Mr. Watt or any champion of his does the same, and I will undertake to make an Elmore tube under the supervision of any well-known expert ; and I will forfeit this sum to Mr. Watt, or to a recognised charity, if this tube shows any sign of foliation or lamination even when subjected not only to a 'moderate heat,' but to a temperature up to the point of fusion—Mr. Watt to likewise forfeit the same sum in the event of his contention being proved wrong. As a matter of fact, by the Elmore burnishing process the copper is made perfectly homogeneous, but, by a modification of conditions, the copper may be deposited in superposed layers upon one mandrel, and it may be laminated to any extent at will. We take advantage of this latter fact in our patented process for the manufacture of copper sheets."

**THE FRENCH SUBMARINE TELEGRAPH COMPANY.**—Continental papers contain the prospectus of an issue of 7,100,000fr., in 14,200 bonds of 500fr. each (say, £284,000), of the French Submarine Telegraph Company (Société Francaise des Télégraphes Sous-Marins). The capital of this Company is 11,000,000fr. (say, £440,000). The present issue of bonds, which bear 5 per cent. interest, is made by the principal French banks at the price of 97½ per cent., and subscriptions are invited for Saturday, May 9th next. The prospectus states that this new issue of bonds is for the purpose of finishing the last section of the system of 6,754 kilometres, for which the Company are the concessionaires. The completion of the system is to be carried on by the Société Générale des Téléphones.

**ORIENTAL TELEPHONE COMPANY (LIMITED).**—Under the heading "A Nice Point in Company Law," *The Statist* of Saturday last contained an interesting article on the case recently before Mr. Justice Kekewich, a report of which appeared in our last issue.

**STOCK EXCHANGE.**—The Committee have appointed Tuesday, May 5th, a special settling day in the National Telephone Company (Limited), provisional certificates for £350,000 Four and a-Half per Cent. Debenture Stock ; and have ordered these securities, and Six per Cent. Preference Shares, Nos. 63,417 to 69,995, and Ordinary Shares, Nos. 63,417 to 77,978, of the Brush Electrical Engineering Company (Limited), to be quoted in the official list.

**SUBMARINE CABLES TRUST.**—Notice is given that on and after May 15th a payment of £1 will be made on account of the coupon due on the 15th inst. by Messrs. Glyn, Mills and Co., of Lombard-street, between the hours of 10 a.m. and 2 p.m. The coupons should be left with the bankers for examination four clear days before payment. They will be stamped with the words "£1 paid," and returned to the holders. Due notice will be given when the trustees have sufficient money in hand to pay the balance of £2 per coupon.

**SWAN UNITED ELECTRIC LIGHT COMPANY.**—The Directors of this Company have resolved to pay an ad-interim dividend at the rate of 6 per cent. per annum for the half-year ended March 31, 1891, to be distributed in accordance with the articles of association. The dividend will be paid upon the register as it stood on April 28th, and the dividend warrants will be issued on May 21st.

**WESTERN AND BRAZILIAN TELEGRAPH COMPANY.**—The traffic receipts of this Company for the week ended April 24, 1891, after deducting 17 per cent. of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited), were £4,726.

# THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

## VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

**MOSSES & MITCHELL.** 70, Chiswell-st., London. E.C.
